(54) Titre : METHODE DE PROCESSUS DE RECEPTION ET APPARAILLAGE DE RECEPTION DANS UN SYSTEME DE COMMUNICATION DU SERVICE MOBILE

(54) Title: RECEIVING PROCESS METHOD AND RECEIVING APPARATUS IN MOBILE COMMUNICATION SYSTEM

(57) Abrégé/Abstract:

A receiving process method of a receiving apparatus used in a mobile communication system is provided in which a sending apparatus sends a plurality of code channels as code channel groups to which spreading codes are assigned to a receiving apparatus, and the receiving apparatus receives the code channels, the receiving process method comprising the steps of: when spreading codes used for the code channel groups are orthogonal code sequences, generating received spreading signal sequences of the code channel groups according to the number of received paths; and removing received spreading signal sequences of a received path of own code channel group of the receiving apparatus which should be removed from received signals.

ABSTRACT OF THE DISCLOSURE

A receiving process method of a receiving apparatus used in a mobile communication system is provided in which a sending apparatus sends a
5 plurality of code channels as code channel groups to which spreading codes are assigned to a receiving apparatus, and the receiving apparatus receives the code channels, the receiving process method comprising the steps of: when spreading codes used
10 for the code channel groups are orthogonal code sequences, generating received spreading signal sequences of the code channel groups according to the number of received paths; and removing received spreading signal sequences of a received path of own
15 code channel group of the receiving apparatus which should be removed from received signals.

-1-

TITLE OF THE INVENTION

RECEIVING PROCESS METHOD AND RECEIVING
APPARATUS IN MOBILE COMMUNICATION SYSTEM

5 BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a mobile communication system adopting CDMA (DS-CDMA) for performing spread spectrum multiple access. More particularly, the present invention relates to a
10 receiving process method for canceling interference due to multipath when high speed data transmission is performed for down-link transmission from a base station in cellular communication using DS-CDMA.

15 In addition, the present invention relates to a receiving apparatus which can remove multipath interference according to the receiving process method.

2. Description of the Related Art

20 Wide band DS-CDMA (W-CDMA) has been adopted as a wireless access method in the next generation mobile communication method IMT-2000 (International Mobile Telecommunication 2000). The maximum information transmission speed in IMT-
25 2000 is 144kbps in a mobile environment, 384kbps in a walking environment and 2Mbps in a quasi-still environment. Thus, it is predicted that multimedia services in addition to voice services will be provided in the next generation mobile communication
30 system. On the other hand, when considering rapid popularization of the Internet, multiplicity of information, enlarging capacity and developments of the next generation internet in recent years, it becomes necessary to develop a wireless access
35 method for realizing information transmission speed exceeding 2Mbps in mobile communication. Especially in down-link transmission from the base station, it

-2-

is considered that high-speed and large capacity traffic due to download of images, files, video and the like from databases and web sites will increase. Therefore, a high speed packet transmission

5 technology suitable for such data traffic becomes necessary. Against this backdrop, ultrahigh-speed packet transmission by extending the W-CDMA wireless interface is being studied for realizing high-speed packet transmission exceeding 2Mbps. For example,

10 application of adaptive modulation/demodulation and error correction (channel coding) and ARQ (Automatic Repeat reQuest) based on adaptive wireless link control (link adaptation) is studied. The adaptive modulation/demodulation and error correction based

15 on the link adaptation are methods for switching modulation level (number of bits in one symbol), SF (spreading factor), multi-code multiplexing number, and coding ratio of error correction according to propagation environment of each user in order to

20 perform high speed data transmission effectively. For example, as the propagation environment for a user becomes better, maximum throughput of the mobile communication system can be increased by switching modulation methods of W-CDMA from QPSK to

25 more effective multilevel modulation, that is, 8PSK, 16QAM, 64QAM modulation. For example, when SF=4, multi-code number is 3, error correction coding ratio is 1/2, and 64QAM is used for data modulation, 8.5Mbps ultrahigh-speed data transmission is

30 theoretically possible by using a W-CDMA wireless interface of chip rate 3.84Mcps.

As mentioned above, 8.5Mbps ultrahigh-speed data transmission is theoretically possible by increasing the modulation level, decreasing SF

35 (increasing multi-code number), and increasing coding ratio of error correction. However, increasing the modulation level leads to increasing

-3-

required desired wave signal power to interference power ratio (SIR) which is necessary for satisfying the same receiving quality (bit error rate).

5 In addition, when applying the adaptive modulation/demodulation and error correction to an actual mobile communication environment, tolerance to multipath fading (frequency selective fading) becomes important. For example, orthogonalization between users (between code channels) is possible in
10 the same transmission path in a down-link in the W-CDMA. However, degradation of transmission quality occurs due to interference between multipaths under multipath environment.

Generally in DS-CDMA, this multipath
15 interference can be suppressed to $1/SF$ of received signal power on average for each code channel like general multi-user interference. However, for performing ultrahigh-speed data transmission of 8.5Mbps by using W-CDMA wireless interface having
20 chip rate 3.84Mcps, it is necessary to decrease SF near to 1 and increase the multi-code number for increasing data rate. In this case, degradation of received SIR due to multipath interference becomes very large. As a result, even when other user does
25 not exist and even when background noise such as thermal noise is small, an area for realizing high-speed packet transmission of multilevel modulation, low SF and high coding ratio is limited to an area very close to a base station where there is no
30 multipath interference so that average throughput of the system deteriorates.

SUMMARY OF THE INVENTION

A first object of the present invention is
35 to provide a receiving process method for avoiding degradation of receiving characteristics due to multipath interference which is a problem for

27879-167

-4-

performing high-speed transmission such as down-link high-speed packet transmission using DS-CDMA in a mobile communication system.

A second object of the present invention is to
5 provide a receiving apparatus for removing multipath interference according to the receiving process method.

A broad aspect of the invention provides a receiving method of a receiving apparatus used in a mobile communication system in which a sending apparatus sends a
10 plurality of code channels as code channel groups to which spreading codes are assigned to a receiving apparatus, and said receiving apparatus receives said code channel groups, said receiving method comprising the steps of: when spreading codes used for said code channel groups are
15 orthogonal code sequences, generating received spreading signal sequences of said code channel groups according to the number of received paths; and removing a received spreading signal sequence, from received signals, that is a replica of a signal of an own code channel group of said
20 receiving apparatus transmitted via a path that is different from another path via which said signal of said own code channel group is transmitted.

According to the receiving process method, received spreading signal sequences (= multipath
25 interference replicas) used for canceling interference of code channel groups of received paths which become interference under multipath environment are generated. In the receiving apparatus, interference path occurring between own code channel group due to multipath is removed by using
30 the multipath interference replicas.

27879-167

-4a-

According to the receiving process method of the present invention, interference path due to multipath is canceled, received SIR (Signal-to-interference power ratio) in the receiving apparatus

-5-

can be improved even under multipath environment. That is, even when high speed data transmission is performed by multiplexing a plurality of code channels under multipath environment, degradation of mean throughput of information transmission speed can be avoided since receiving quality improves. As a result, an area where a base station can provide high speed data transmission in required quality can be enlarged.

10 From the viewpoint of canceling multipath interference of other code channel group (orthogonal channel) of the sending apparatus to which the receiving apparatus is connected, the receiving process method may includes the steps of:

15 when spreading codes of other code channels used for control or used for other channels in the code channel group are orthogonal code sequences,

 generating received spreading signal sequences of the code channel groups according to the number of received paths; and

 removing received spreading signal sequences of received paths of other code channels which should be removed from received signals.

25 According to the receiving process, multipath interference occurring between multipaths of other code channel groups sent from the sending apparatus to which own code channels are connected can be canceled. Therefore, received SIR of the receiving apparatus can be further improved.

30 From the viewpoint of canceling multipath interference of other code channel group (non-orthogonal channel) of the sending apparatus to which the receiving apparatus is connected in multipath environment, the receiving process method may includes the steps of:

 when all or a part of the spreading codes

27879-167

-6-

used for the code channel groups are non-orthogonal code sequences,

generating received spreading signal sequences of the code channel groups according to the number of received paths; and

removing received spreading signal sequences of other code channels which are non-orthogonal in the same received path from received signals.

According to the receiving process method, it becomes possible to cancel multipath interference occurring between multipaths of other code channel groups (non-orthogonal channel) sent from the sending apparatus to which own code channels are connected and multipath interference occurring in the same path. Therefore, received SIR of the receiving apparatus can be further improved.

From the viewpoint of canceling interference due to received code channel group from an adjacent sending apparatus, the receiving process method may includes the steps of:

when the receiving apparatus receives a code channel group from another sending apparatus which is not connected to the receiving apparatus,

generating received spreading signal sequences of the code channel group from another sending apparatus according to the number of received paths; and

removing received spreading signal sequences of the code channel group from received signals.

In this case, multipath routes are different between the code channel group sent from the other sending apparatus to which the receiving apparatuses is not connected and other code channel groups (non-orthogonal channel) sent from the sending apparatus to which the own code channel

-7-

group is connected. Thus, every channel become interference.

Therefore, according to the receiving process method mentioned above, since all receiving
5 spreading signal sequences generated for non-orthogonal channels and channels of the other sending apparatus are subtracted, received SIR of the receiving apparatus can be further improved.

In the receiving process method, the
10 receiving spreading code sequence may be generated on the basis of an estimated value of channel variations and an estimated value of data modulation obtained for each code channel.

In addition, The receiving process method
15 may include the steps of:

the sending apparatus sending pilot signals of which the receiving apparatus knows sending phase and sending amplitude to the receiving apparatus periodically; and

20 the receiving apparatus measuring received phase and received amplitude of the pilot signals, and obtaining the estimated value of the channel variations by comparing the sending phase and sending amplitude with received phase and received
25 amplitude.

The receiving process method may include the steps of:

the receiving apparatus obtaining the estimated value of channel variations by averaging
30 the estimated value of channel variations obtained by using the pilot signals and an estimated value of channel variations obtained by comparing decision results of data modulation with receiving phase and amplitude for data signals.

35 From the viewpoint of improving generation accuracy of the multipath interference replica by updating estimated value of the channel variations,

-8-

the receiving process method may include the steps of:

obtaining the estimated value of channel variations on the basis of the pilot signals, the data signals and the decision results of the data modulation;

updating data modulation decision results by using the estimated value of channel variations; and

10 updating the estimated value of channel variations on the basis of the updated data modulation decision results.

In the receiving process method, the same estimated value may be used as the estimated value of channel variations for code channels sent from the same sending apparatus.

As for estimation of data modulation used for generating the multipath interference replicas, the receiving process method may include the steps of:

20 performing coherent detection by using the estimated value of channel variations for received despread signals of data signals obtained by despread receiving signals from which the received spreading signal sequences have been subtracted;

wherein, when the receiving apparatus receives signals by path diversity or by antenna diversity, the receiving apparatus estimates data modulation by performing hard decision for signals on which antenna diversity has been performed.

30 The receiving process method may include the steps of:

when the sending apparatus performs data modulation for sending original information data sequences which have been error correction coded beforehand,

the receiving apparatus performing

-9-

coherent detection by using the estimated value of channel variations for received despread signal of data signals obtained by despreading received signals from which the received spreading signal sequences have been subtracted, performing error correction decoding on signals after performed antenna diversity combining when signals were received by path diversity or antenna diversity so that original information data sequences are estimated;

the receiving apparatus performing error correction coding on the original information data sequences which is estimated; and

the receiving apparatus performing data modulation by using data sequences which are obtained by performing error correction coding on the original information data sequences so that data modulation is estimated.

From the viewpoint of improving receiving quality of signals to be demodulated by using received spreading signal sequences (multipath interference replicas) having high generation accuracy, the receiving process method may include the steps of:

updating the received spreading signal sequences on the basis of updated estimated values of channel variations; and

demodulating code channels to be demodulated by using signals obtained by subtracting the updated received spreading signal sequences from received signals.

The above object is also achieved by a receiving apparatus which receives code channel groups each including code channels from sending apparatuses, the receiving apparatus including an interference canceler which comprises a plurality of stages,

-10-

- a first stage of the stages comprising:
a data modulation estimation part and a
channel estimation part for estimating data
modulation and channel variations for each received
code channel which is a subject for interference
canceling;
- a multiplier for multiplying an estimated
data modulation signal by an estimated value of
channel variations; and
- a received spreading signal sequence
generation part for obtaining a received spreading
signal sequence for each multipath by performing
spreading a received signal by using a corresponding
spreading code;
- a stage after the first stage in the
stages comprising:
an other channel multipath interference
canceling part for subtracting received spreading
code sequences of other code channels obtained in
the previous stage from received signals for each
received code channel which is a subject for
interference canceling;
- an own channel multipath interference
canceling part for subtracting received spreading
signal sequences of own code channels obtained in
the previous stage corresponding to a path which is
a subject for demodulation;
- a part for preparing signals corresponding
to the number of multipaths obtained by subtracting
received spreading signal sequences from received
signals by the other channel multipath interference
canceling part and by the own channel multipath
interference canceling part, and updating estimated
values of data modulation and channel variations by
using the prepared signals;
- a received spreading signal sequence
updating part for updating received spreading signal

-11-

sequences on the basis of updated estimated values of data modulation and channel variations;

5 a last stage in the stages comprising a data demodulation part for demodulating data by using signals obtained by subtracting received spreading code sequences obtained in the previous stage from received signals for code channels to be demodulated.

10 The receiving apparatus may include:
a data modulation estimation adaptive switching part for switching between a first data modulation estimation part and a second data modulation estimation part for performing estimation of data modulation in each stage of the interference
15 canceler;

the first data modulation estimation part estimating data modulation by performing hard decision for signals on which antenna diversity has been performed, when the receiving apparatus
20 receives signals by path diversity or by antenna diversity;

the second data modulation estimation part performing error correction coding on the original information data sequences which were estimated, and
25 performing data modulation by using data sequences which are obtained by performing error correction coding on the original information data sequences so that data modulation is estimated.

30 In addition, the receiving apparatus may include:

a subtracting part for subtracting received spreading signal sequences from received signals after multiplying the received spreading signal sequences by predetermined interference
35 removing weight coefficients.

BRIEF DESCRIPTION OF THE DRAWINGS

-12-

Other objects, features and advantages of the present invention will become more apparent from the following detailed description when read in conjunction with the accompanying drawings, in

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

10 In the following, embodiments of the present invention will be described with reference to figures.

Fig.1 shows a configuration of a mobile communication system in which a multipath interference canceling method is applied according to an embodiment of the present invention.

In Fig.1, the mobile communication system adopts, for example, CDMA for wireless access. The mobile communication system includes a receiving apparatus 10 (which will be called a mobile station hereinafter), a sending apparatus₁ 20 (which will be called a base station₁ hereinafter), a sending apparatus₂ 21 (which will be called a base station₂ hereinafter), and an upper station (example : wireless circuit control apparatus). Each base station 20, 21 sends a plurality of code channels. A part of code channels sent from the same base station are orthogonalized by using orthogonal spreading code and other code channels are not orthogonalized. In a commercial system of W-CDMA and IS-95, all code channels of down-link are basically orthogonalized. However, since special spreading code is used in synchronization channels of W-CDMA, a few number of channels which are not orthogonal to other channels exist. In addition, since the number of spreading codes for orthogonalization is limited, non-orthogonal code channel transmission by using the non-orthogonal

-14-

spreading codes is performed when code channels the number of which exceeds the limited number are necessary.

As shown in Fig.1, other code channel groups (②, ③) sent from the base station₂₀ can be considered to be common channels such as common control channels or communication channels to other carrier. Code channels of other base station (base station₂₁ in this case) can be orthogonalized in the same path. However, the code channel from the base station₂₁ can not be orthogonalized to the code channel sent from the base station₂₀ since they are received by the mobile station 10 asynchronously. In addition, in this example, the base station₂₀ and the base station₂₁ send spreading code information to the mobile station 10 as down-link control information for the mobile station 10 to obtain spreading code information of each code channel other than its own channel.

Fig.2 shows the same configuration as Fig.1 in which the mobile station 10 obtains the spreading code information of each code channel other than the own channel by using a way different from the way shown in Fig.1. In the example of Fig.2, the base station₂₁ sends its own spreading code information to the base station₂₀ via an upper station, and the base station₂₀ sends spreading code information of the both base stations (base station₂₀ and base station₂₁) to the mobile station 10 as down-link control information.

As mentioned above, although methods in which the base station₂₀ sends the spreading code information to the mobile station 10 as the control information have been described, there is a method in which the mobile station 10 recognizes spreading codes without information from the base station₂₀. For example, the mobile station 10 prepares

-15-

estimated spreading code candidate beforehand,
obtains correlation between received signal and the
spreading code candidate. As a result, the mobile
station 10 can recognize spreading code used in
5 other base station by obtaining spreading code
having large correlation.

A sending format of packet data sent from
the base station, 20 is as shown in Figs.3A and 3B,
wherein packet data is a sending unit of data, and
10 is obtained by dividing sending data into each
constant amount of data.

Fig.3A shows a sending format example in a
case in which a pilot channel is code-multiplexed.
In this case, one packet includes N_s slots, and the
15 pilot signals for estimating channels are code-
multiplexed to data channels as a code channel which
is spread by a spreading code (①). On the other
hand, Fig.3B shows a sending format example in a
case in which the pilot channel is time-multiplexed.
20 In this case, the pilot signals are inserted into
data signals periodically (for each slot) (②). In
addition, one packet ($=N_s$ slot) includes K code
channels (#1~#K) in both cases.

In the following, the first case in which
25 the pilot signal is code-multiplexed will be taken
for explaining embodiments of the present invention.
The pilot channel will be called a common pilot
channel (CPICH) since the pilot channel can be also
used for channel estimation of other transmission
30 data channels.

A receiving apparatus (which will be
called an interference canceler hereinafter) to
which the receiving process method of the present
invention is applied is configured as shown in Fig.4
35 for example. In this example, it is assumed that
the interference canceler is used for a down-link by
which the base station sends data and the mobile

-16-

station receives the data.

In Fig.4, the interference canceler (first configuration example) includes a plurality of stages of interference estimators 100 and 110, delay lines 121-124, subtractors 150-153, multipliers 140, 141, and interference estimator signal output parts 130, 160. In this example, $I_{b,l}^{(p-1)}$ represents a received spreading signal sequence of l th path ($1 < l < L$) of b th antenna branch ($1 < b < B$) in p th stage ($1 < p < P$) of the interference estimator. The received spreading signal sequence will be called a multipath interference replica hereinafter. In the first stage interference estimator 100, signals received by the receiving antennas #1 and #2 are directly input. In and after the second stage interference estimator 110, received signals from which all other multipath interference replicas $I_{b,l}^{(p-1)}$ generated in the previous stage have been subtracted are input. The interference estimators 100, 110 estimate channels (channel estimation). The channel estimation value is updated for each stage (for each interference estimator stage) by using common pilot channel, or, in addition to this, by using decision data modulation and data symbol. Decision of data modulation by using this is also updated. The multipath interference replica is updated by using the channel estimation value for each stage. Therefore, as channel estimation accuracy and data decision accuracy improve, generation accuracy of the multipath interference replica improves.

Next, the configuration and the operation of the interference estimator 100, 110 will be described with reference to Fig.5. In the following, the first stage interference estimator 100 will be described as an example.

-17-

This interference estimator 100 includes Rake/antenna diversity combining parts 200, 210, a parallel/serial converter (=P/S converter), an error correction decoder 230, hard decision parts 240, 241, an error correction coder 250, a data modulator 260, a serial/parallel converter (=S/P converter) 270, channel estimators 300, 310, multipath interference replica generators 320, 330, spreading parts 340, 341, computing units 350-353, 360-363, an antenna signal input part 400, and a multipath interference replica signal output part 410. In addition, a multiplier 280 which performs complex conjugate operation between signals of the Rake/antenna diversity combining parts 200, 210 and signals from the data modulator 260 is provided in the interference estimator. In addition, the Rake/antenna diversity combining part 200 includes despreading parts 201, 202, multipliers 203, 204 and an adder 205. The channel estimator 300 includes despreading parts 301, 302, and channel estimators 303, 304. The multipath interference replica generator 320 includes spreading parts 321, 322, and multipliers 323, 324.

Canceling of multipath interference due to multipath between the own channel code groups is performed in the following way in the above-mentioned configuration.

An input signal to the despreading part which performs despreading of the l th path of the b th antenna in the p th stage in the interference estimator in the multipath interference canceler is a signal in which all other multipath interference replicas are subtracted from the received signal.

A narrow band modulation signal wave form $d_k(t)$ and spreading signal modulation wave form $c_k(t)$ of k th code channel is represented by the following equations 1 and 2.

-18-

$$d_k(t) = \sum_{i=-\infty}^{\infty} g_k(i) \cdot \exp[j\phi_k(i)] \cdot u_d(t - iT_d) \quad (1)$$

$$c_k(t) = \sum_{i=-\infty}^{\infty} \exp[j\phi_k(i)] \cdot u_c(t - iT_c) \quad (2)$$

5 In the equations (1) and (2), T_d indicates a symbol interval, an T_c indicates a chip interval. In addition, $U_d(t)=1(0)$ for $0 < t < T_d$ (otherwise) and $U_c(t)=1(0)$ for $0 < t < T_c$ (otherwise), and $N=T_d/T_c$ is SF.

$\phi_k(i) \in \{q\pi/2 + \pi/4; q=0,1,2,3\}$ indicates QPSK spreading

10 modulation by spreading codes in which code channels are orthogonalized by using orthogonal spreading codes. $g_k(i)$ and $\phi_k(i)$ indicate data modulation amplitude and phase respectively. $g_k(i)$ and $\phi_k(i)$ are represented by the following equations
15 respectively according to the data modulation method.

1. OPSK modulation

$$g_k(i) = \sqrt{2} \quad (3)$$

$$\phi_k(i) \in \{q\pi/2 + \pi/4; q=0,1,2,3\} \quad (4)$$

2. 8PSK modulation

20 $g_k(i) = \sqrt{3} \quad (5)$

$$\phi_k(i) \in \{q\pi/4; q=0,1,\dots,7\} \quad (6)$$

3. 16QAM modulation

$$g_k(i) = \sqrt{x_k^2 + y_k^2} \quad (9)$$

$$\phi_k(i) = \tan^{-1} \frac{y_k}{x_k} \quad (10)$$

25 wherein

$$x_k \in \left\{ (2q_x + 1) \sqrt{\frac{1}{2.5}}; q_x = -2, -1, 0, 1 \right\} \quad (7)$$

-19-

$$y_k \in \left\{ (2q_y + 1) \sqrt{\frac{1}{2.5}}; q_y = -2, -1, 0, 1 \right\} \quad (8)$$

4. 64QAM modulation

$$g_k(i) = \sqrt{x_k^2 + y_k^2} \quad (13)$$

$$\phi_k(i) = \tan^{-1} \frac{y_k}{x_k} \quad (14)$$

5 wherein

$$x_k \in \left\{ (2q_x + 1) \sqrt{\frac{1}{7}}; q_x = -4, -3, \dots, 3 \right\} \quad (11)$$

$$y_k \in \left\{ (2q_y + 1) \sqrt{\frac{1}{7}}; q_y = -4, -3, \dots, 3 \right\} \quad (12)$$

10 In the same way, a narrow band modulation signal wave form $d_{cpich}(t)$ and a spreading modulation signal wave form $c_{cpich}(t)$ of the common pilot channel can be represented as follows.

$$d_{cpich}(t) = \sum_{i=-\infty}^{\infty} \exp[j\pi/4] u_{cpich}(t - iT_{cpich}) \quad (15)$$

$$c_{cpich}(t) = \sum_{i=-\infty}^{\infty} \exp[j\phi_{cpich}(i)] u_c(t - iT_c) \quad (16)$$

15 wherein T_{cpich} indicates a symbol interval, and $u_{cpich}(t) = 1(0)$ for $0 < t < T_{cpich}$ (otherwise). Since spreading by orthogonal spreading code is performed also for the common pilot channel, code channels in the same path are orthogonalized. The sending signals are transmitted in L multipath channels and
20 are received by B receiving antennas. A received signal $r_b(t)$ at the b th antenna can be represented by

$$r_b(t) = \sum_{l=1}^L \xi_{b,l}(t) \left(\sum_{k=1}^K d_k(t - \tau_l) \cdot c_k(t - \tau_l) + d_{cpich}(t - \tau_l) \cdot c_{cpich}(t - \tau_l) \right) + n(t)$$

(17), wherein $\xi_{b,l}$ indicates complex fading envelope
25 of the l th path of the b th antenna, τ_l indicates

-20-

propagation delay of the l th path. $n(t)$ indicates additive Gaussian noise component of one-sided power spectrum density $N_0/2$. A despreading part output of the interference estimator corresponding to the m th
 5 symbol of the n th slot for the the l th path of the b th antenna of the k th code channel in the l th stage is indicated by the following equation.

$$z_{k,b,l}^{(1)}(n,m) = \frac{1}{T_d} \int_{nT_{slot}+mT_d+\tau_l}^{nT_{slot}+(m+1)T_d+\tau_l} r_b(t) \cdot c_k^*(t-\hat{\tau}_l) dt \quad (18)$$

In the same way, despreading output of the common
 10 pilot channel is represented by the following equation.

$$z_{cpich,b,l}^{(1)}(n,m) = \frac{1}{T_{cpich}} \int_{nT_{slot}+mT_{cpich}+\tau_l}^{nT_{slot}+(m+1)T_{cpich}+\tau_l} r_b(t) \cdot c_{cpich}^*(t-\hat{\tau}_l) dt \quad (19)$$

wherein T_{slot} indicates a slot interval. A channel estimation value used for Rake combining in r th time
 15 of repeated channel estimation ($1 < r < R$) of the p th stage ($1 < p < P$) is represented by $\hat{\xi}_{b,l}^{(p,r)}(n)$. A first stage channel estimation value $\hat{\xi}_{b,l}^{(1,1)}(n)$ is obtained by the following equation by using the common pilot channel.

$$20 \quad \hat{\xi}_{b,l}^{(1,1)}(n) = \frac{1}{N_{cpich}} \sum_{i=1}^{N_{cpich}} z_{cpich,b,l}^{(1)}(n,m) \cdot d_{cpich}^*(n,m) \quad (20)$$

wherein N_{cpich} is a symbol number of the common pilot channel included in one slot. That is, by multiplying the received complex signal by complex conjugate of sending complex signal, complex envelop
 25 change of channel is obtained. By using the channel estimation value and by multiplying BL multipath components by complex conjugate of $\hat{\xi}_{b,l}^{(1,1)}(n)$, coherent Rake combining output $\hat{d}_k^{(p=1,r=1)}(n,m)$ in the m th symbol of

-21-

the n th slot of the k th code channel is obtained by the following equation.

$$\hat{d}_k^{(1,1)}(n,m) = \sum_{b=1}^B \sum_{l=1}^L z_{k,b,l}^{(1)}(n,m) \cdot \hat{\xi}_{b,l}^{(1,1)*}(n) \quad (21)$$

When tentative data decision is performed after Rake combining is performed, hard decision for data sequence $\hat{d}_k^{(1,1)}(n,m)$ is performed, and tentative decision data symbol sequence

$$\tilde{d}_k^{(1,1)}(n,m) = g_k^{(p=1,r=1)}(n,m) \cdot \exp \left[j\phi_k^{(p=1,r=1)}(n,m) \right] \quad (22) \quad \text{is}$$

reproduced. On the other hand, the tentative data decision is performed after error correction

decoding, branch metric is calculated for $\hat{d}_k^{(1,1)}(n,m)$, the branch metric of K code channels is parallel/serial-converted, error correction decoding is performed, so that binary information data

sequence $b^{(p=1,r=1)}(i)$ is obtained. Other methods can be used for error correction decoding. Error correction coding is performed for the decoded information data sequence, and the decoded information data sequence is assigned to K code channels by serial/parallel conversion. After that, data modulation is performed so that tentative decision data symbol sequence

$$\tilde{d}_k^{(1,1)}(n,m) = g_k^{(1,1)}(n,m) \cdot \exp \left[j\phi_k^{(1,1)}(n,m) \right] \quad (23) \quad \text{is reproduced.}$$

Then, by multiplying data symbol $z_{k,b,l}^{(1)}(n,m)$ of the despreading part output by complex conjugate of $\tilde{d}_k^{(1,1)}(n,m)$ (reverse modulation) so that data modulation

-22-

component is removed, the data symbol can be used as pseudo-pilot symbol. Thus, channel estimation is performed again by using the KNd pseudo-pilot symbols in addition to the common pilot channel,

5 Rake combining is performed and the tentative data decision value is updated. The channel estimation

value $\hat{\xi}_{b,l}^{(1,r+1)}(n)$ obtained after repeating this process r times is represented by

$$\hat{\xi}_{b,l}^{(1,r+1)}(n) = \frac{1}{1+w} \hat{\xi}_{b,l}^{(1,r+1)}(n) + \frac{1}{1+w} \frac{1}{\sum_{k=1}^K \sum_{m=1}^{N_d} g_k^{(1,r)}(n,m)^2} \sum_{k=1}^K \sum_{m=1}^{N_d} z_{k,b,l}^{(1)}(n,m) \cdot d_k^{(1,r)*}(n,m)$$

10 (24).

In the above description, although channel estimation using the common pilot channel is performed by averaging pilot channels of one slot interval, this can be also done by other methods which are generally known. For example, the first term of the equation (24) indicates a channel estimation value using the common pilot channel, the second term indicates a channel estimation value in which decision feedback data symbol is regarded as the pseudo-pilot symbol. The channel estimation value by decision feedback data is obtained by using weighted mean value according to amplitude. In addition, w in the equation (24) is a weight coefficient in averaging the channel estimation value by the common pilot channel and the channel estimation value by the decision feedback data symbol. Optimal estimation accuracy can be obtained by using a small value for w when data decision error is large and by using a large value when data decision error is small. $w=0$ indicates a case where the data symbol is not used for channel estimation. Since the symbol number used for channel estimation increases by adding channel estimation by the

-23-

decision feedback data, effects of averaging noise and interference increase. Therefore, channel estimation accuracy improves. (However, since decision error is included in the decision feedback data symbol, the decision error may affect the channel estimation accuracy.) In the interference estimator, by using thus obtained channel estimation

value $\hat{\xi}_{b,l}^{(1,R+1)}(n)$ and the tentative decision data symbol sequence $\hat{d}_k^{(1,R)}(n,m)$, the multipath interference replica of the l th path of the b th antenna can be obtained by a following equation.

$$\hat{I}_{b,l}^{(1)}(t-\hat{\tau}_l) = \sum_{l=1}^L \hat{\xi}_{b,l}^{(1,R+1)}(t) \left(\sum_{k=1}^K \hat{d}_k^{(1,R)}(t-\hat{\tau}_l) \cdot c_k(t-\hat{\tau}_l) + d_{cpich}(t-\hat{\tau}_l) \cdot c_{cpich}(t-\hat{\tau}_l) \right) \quad (25)$$

By using the multipath interference replica, a despreading part input signal of the interference estimator of the l th path of the b th antenna in the second stage can be represented by the following equation.

$$r_{b,l}^{(2)}(t) = r_b(t) - \alpha \sum_{\substack{j=1 \\ j \neq l}}^L \hat{I}_{b,j}^{(1)}(t-\hat{\tau}_j) \quad (26)$$

wherein α is an interference canceling weight coefficient and $0 < \alpha$. When error included the generated interference replica is large, this effect can be alleviated by using a small α . However, since too small α decreases the effect of removing interference, the effect of multipath interference removal can be increased by setting optimal α according to generation accuracy of the interference replica. For example, when there are many multipaths, since accuracy of channel estimation degrades, there is a case in which using smaller α is more effective. In addition, as the number of

-24-

stages becomes large, since the accuracy of the multipath interference replica improves, receiving characteristics can be improved by using larger α .

In the same way, a despreading input
 5 signal of the interference estimator of the p th stage ($p > 2$) can be obtained by the following equation by using the multipath interference replicas generated in previous stage.

$$r_{b,l}^{(p)}(t) = r_b(t) - \alpha \sum_{\substack{j=1 \\ j \neq l}}^L \hat{I}_{b,j}^{(p-1)}(t - \tau_j) \quad (27)$$

10 In each stage, for a signal in which the multipath interference replicas are subtracted, channel estimation, tentative decision of data modulation are performed like in the first stage so that the multipath interference replica is updated. Then, in
 15 the final stage ($p=P$), data sequence after Rake

combining $\hat{d}_k^{(P,R)}(n,m)$ is error-correction-decoded (when error correction coding was performed), and binary
 information data sequence $\hat{b}^{(P)}(i)$ is demodulated.

As mentioned, since a signal in which all
 20 other multipath interference replicas $\hat{I}_{b,l}^{(p-1)}$ generated in previous stage have been subtracted from the received signal is input into each interference estimator in and after second stage, the multipath interference replica is updated for each stage.
 25 Therefore, the multipath interference replica having high accuracy can be used for removing multipath interference of the own channel. Thus, interference canceling of high receiving quality can be realized.

In the above embodiment, although a case
 30 in which the common pilot channel is code-multiplexed has been described, the interference canceler of the present invention can be easily

-25-

applied to a sending format shown in Fig.3B (a case where common pilot channels are time-multiplexed).

Next, an example for removing multipath interference due to code channel group other than the own channel code group with reference to figures.

Compared with the multipath interference canceler shown in Fig.4, the multipath interference canceler shown in Fig.6 includes interference estimators 510, 540 of other orthogonal code channel, and interference estimators 520, 550 of other non-orthogonal code channel. In this embodiment, although the multipath interference canceler includes the interference estimators 520, 550 of other non-orthogonal code channel, it is possible to use processing parts of other sending apparatus instead of the interference estimators 520, 550 of other non-orthogonal code channel.

In the same way as the above-mentioned interference estimator, each interference estimator performs channel estimation and decision of data modulation so that the multipath interference replica is output. In Fig.6, the multipath interference replica of the own channel is indicated

by $I_{b,l}^{(p)}$, the multipath interference replica of other

orthogonal channel is indicated by $O_{b,l}^{(p)}$, and the multipath interference replica of the other non-

orthogonal channel is indicated by $U_{b,l}^{(p)}$. In the multipath interference canceling method shown in Fig.6, estimation of the multipath interference replica for each code channel group is performed in parallel for each stage. That is, in the first stage, the multipath interference replica is generated by using the received signal itself. In the second stage, the multipath interference replica

27879-167

-26-

is estimated more accurately on the basis of a signal in which the multipath interference replica estimation value of the first stage is subtracted from the received signal.

5 Since code channels sent from the same sending station are received by the mobile station
10 after receiving the same channel variation, accuracy of channel estimation can be improved and receiving processing amount can be decreased by
10 performing the above-mentioned channel estimation by providing commonality of channel estimator and by using more common pilot channels and data signals.

 In the second configuration example of the interference canceler shown in Fig.6, the
15 interference estimator in and after the second stage receives a signal obtained by subtracting all other multipath interference replicas generated by the previous stage from the received signal. In this embodiment, as for interference replicas of code
20 channels which are non-orthogonal, multipath interference replica of the same path is also subtracted from the received signal so that receiving quality improves.

 On the other hand, in the configuration
25 example 3 of the interference canceler shown in Fig.7, estimation of the multipath interference replica for each code channel group is performed in series. The configuration of this interference canceler is the same as that of Fig.6. Interference
30 estimators 700, 730 of the own code channel, interference estimators 710, 740 of other orthogonal code channel, and interference estimators 720, 750 of other non-orthogonal code channel are added. In this embodiment, although the multipath interference
35 canceler includes the interference estimators 720, 750 of other non-orthogonal code channel, it is possible to use parts of other sending

-27-

apparatus instead of the interference estimators 720, 750 of other non-orthogonal code channel.

In the example of Fig.7, processes are performed in the order of interference estimation of own channel, interference estimation of other orthogonal code channel and interference estimation of other non-orthogonal code channel. Therefore, in the first stage, interference estimation can be performed for succeeding channel by a signal obtained by subtracting interference replica of processed channel from the received signal. Thus, the performance is better than that of the configuration example 2 shown in Fig.6. After the second stage, as for an interference estimator, multipath interference replicas for channels which was processed earlier are subtracted from the received signal, in addition, multipath interference replicas obtained in the previous stage for the own channel and channels which will be processes after the own channel are subtracted from the received signal. It can be expected that receiving quality of the configuration example 3 of Fig.7 is better than the configuration example 2. However, since it can be considered that process delay for signal processing generally becomes large for the example 3, the configuration example 2 or the configuration example 3 is selected according to the circumstances. In addition, it is possible to adopt a combined configuration, for example, a configuration including the configuration example 3 for the first stage and the configuration example 2 in and after the second stage.

Next, multipath interference decreasing effect when the interference canceler (Figs.4, 6, 7) of the present invention is applied, and improvement effect of receiving quality obtained by interference decreasing effect will be described with reference

-28-

to Figs.8 and 9.

Fig.8 indicates a case where code channel signals sent from the base stations (base station₁, 20 and base station₂, 21) are received by the mobile station 10 by using two paths on the basis of Figs.1 and 2, in which the received paths from the base station₁, 20 are indicated as path 1 and path 2 and the received paths from the base station₂, 21 are indicated as path 3 and path 4. Therefore, received signal at the mobile station 10 is one in which following code channels are multiplexed.

① received signal of path 1 of the own code channel group (orthogonal channels) to be demodulated

② received signal of path 2 of the own code channel group (orthogonal channels) to be demodulated

③ received signal of path 1 of other code channel group (orthogonal channels) of the base station₁, 20 (own cell)

④ received signal of path 2 of other code channel group (orthogonal channels) of the base station₁, 20 (own cell)

⑤ received signal of path 1 of other code channel group (non-orthogonal channels) of the base station₁, 20 (own cell)

⑥ received signal of path 2 of other code channel group (non-orthogonal channels) of the base station₁, 20 (own cell)

⑦ received signal of path 3 of code channel group of the base station₂, 21 (other cell)

⑧ received signal of path 4 of code channel group of the base station₂, 21 (other cell)

Accordingly, the mobile station 10 receives the signals of ①-⑧ in the same bandwidth as received spread signals corresponding to the examples of Figs.1 and 2. The mobile station 10

-29-

performs despread by using spreading code of code channel desired to be demodulated so that only the code channel is converted into narrow band signal and is demodulated. Figs.9A shows a case where the interference canceling method of the present invention is not applied. In this case, since the path 1 of the own code channel to be demodulated is converted into a narrow band signal and is demodulated, signal component of the same path (① in Fig.8) of the other orthogonal code channels of the base station 1 does not remain in the despread signal, however, other received signals (②-⑧) remain as interference. Therefore, the receiving quality becomes one according to SIR shown in Fig.9A.

When the interference canceler shown in Fig.4 is applied for performing interference canceling, interference of other multipath (② of Fig.8) of the own code channel is removed as shown in Fig.9B. Thus, the SIR of despread signal becomes larger than that of Fig.9A in which the interference canceling is not performed so that the receiving quality improves. In addition, when interference canceling is performed on the basis of the interference canceler shown Fig.5 or Fig.6, interference estimation is performed for the other orthogonal channels and the other non-orthogonal channels other than the own code channels. Therefore, the effect of interference decreasing becomes as shown in Figs.9C-9E. That is, Fig.9C shows a case where interference canceling is performed for the own code channel and the other code channel group (orthogonal channel) of the base station, 20. In this case, interference signals of ③ and ④ of Fig.8 are removed. In addition, Fig.9D shows a case where interference canceling is performed for the own code channel + other code channel group (orthogonal channel) of the base

-30-

station₁, 20 + other code channel group (non-orthogonal channel) of the base station₁, 20. In this case, the interference signals of ⑤ and ⑥ shown in Fig.8 are removed. In addition, Fig.9E shows a case
 5 where interference canceling is performed for the own code channel + other code channel group (orthogonal channel) of the base station₁, 20 + other code channel group (non-orthogonal channel) of the base station₁, 20 + code channel group of the base
 10 station₂, 21. In this case, the interference signals from two paths of the code channel of the base station₂, 21 are removed, further improvement of the received quality becomes possible as shown in Fig.9E.

Accordingly, by applying the interference
 15 canceler of Fig.5 or Fig.6 to mobile communication in which multipath fading occurs, received quality is improved further compared with interference canceler of Fig.4 since SIR of despreaded signal becomes large.

20 Next, a result of computer simulation showing effects of this interference canceling method will be described. Fig.10 shows the throughput characteristics, and Fig.11 shows data used for the computer simulation.

25 As shown in Fig.11, the data for the computer simulation is as follows.

Chip rate (1) : 3.84Mcps, Symbol rate : 240ksps,
 Information bit rate : 8.42Mbps, spreading ratio :
 16, number of multicode : 12, spreading code :
 30 orthogonal code sequences, Gold sequences,
 Modulation method : 4QAM for data modulation, QPSK
 for first spreading, Channel coding/decoding :
 convolutional coding (rate=1/2, constraint length=9)
 / soft decision, Viterbi decoding, Antenna
 35 diversity : 2branch, Channel model : L-path Rayleigh,
 Doppler frequency $f_d=80\text{Hz}$.

As shown in Fig.11, the information bit

-31-

rate 8.42Mbps is realized by using 64QAM data modulation in 3.84Mcps chip rate, spreading ratio 16, 12 multICODES, convolutional coding ratio 1/2.

Fig.10 shows the result of the computer simulation performed by using the data shown in Fig.11.

In Fig.10, the vertical axis indicates throughput (bits/sec), the lateral axis indicates average receiving E_b/N_0 (dB) in which E_b/N_0 is signal power to noise power density ratio per 1 information bit.

In this computer simulation, propagation models of $L=1 - 4$ paths were evaluated in which interference removing weight coefficients for $L=2, 3, 4$ are 0.9, 0.7, 0.7 respectively. In addition, the number P of stages of the interference canceler is 4 and repeated number R of channel estimation is 1. In addition, throughput characteristics in which the multipath interference canceler is not applied are evaluated for checking effects of the case in which the multipath interference canceler is applied. In the figure, the cases in which the multipath interference canceler is applied are indicated by $\times$ ($L=1$), $\circ$ ($L=2$), $\square$ ($L=3$), $\triangle$ ($L=4$), and the cases in which the multipath interference canceler is not applied are indicated by $\bullet$ ($L=2$), $\blacksquare$ ($L=3$), $\blacktriangle$ ($L=4$).

As shown in the result of computer simulation, high throughput of 8.4Mbps is achieved in a high E_b/N_0 area in $L=1$ path environment ($\times$ in Fig.10). However, the throughput deteriorates below 2Mbps without the multipath interference canceler in $L=2$ path environment ($\bullet$ in Fig.10). On the other hand, by applying the interference canceler (4 stages) of the present invention, high throughput of 8Mbps can be obtained even in the $L=2$ path environment ($\circ$ in Fig.10). It is understood that the throughput in the multipath environment can be

-32-

largely improved according to the present invention.

As described above, according to the present invention, the multipath interference replicas are generated on the basis of accurate
5 channel estimation values using decision feedback data after or before error correction (channel coding) decoding of common pilot channels and communication channels in code channels which are spread by orthogonal code sequence and non-
10 orthogonal code sequence, and the multipath interference replicas are removed from the revived signals (multipath interference cancel). Thus, it becomes possible to largely improve received quality (bit error rate, throughput and the like) in
15 multipath environment. As a result, since received signal power required for the same received quality can be largely decreased, an area where high speed data transmission is available covered by a base station can be enlarged compared with a conventional
20 technology in which high speed data transmission is limited to an area very close to the base station where there is no multipath interference.

The channel estimation can be performed without the decision feedback data.

25 In the above-mentioned examples, the function of the interference canceler corresponds to the other channel multipath interference canceling part, the own channel multipath interference canceling part and the subtracting part. The
30 function of the interference estimator in the interference canceler corresponds to the data modulation estimation part, the channel estimation part, multiplier, received spreading signal sequence generation part, the data modulation estimation
35 updating part, channel estimation updating part, the received spreading code sequence updating part and the data demodulation part.

-33-

In addition, the function of interference estimator of the interference canceler corresponds to the first to third channel variation estimation part, the data modulation decision updating part, the channel variation estimation updating part, the same estimation value application part, the coherent detection part, the first and second data modulation estimation part, the original information data sequence estimation part and data modulation estimation adaptive switching part.

As mentioned above, according to the present invention, in cellular communication using DS-CDMA, especially when ultrahigh-speed data communication equal to or higher than the chip rate is performed, received quality can be largely improved in multipath environment by generating multipath interference which largely degrade received quality and by subtracting the multipath interference from the received signals.

In addition, according to the present invention, a receiving apparatus which can cancel multipath interference even when performing ultrahigh-speed data transmission in multipath environment can be provided.

The present invention is not limited to the specifically disclosed embodiments, and variations and modifications may be made without departing from the scope of the invention.

27879-167

-34-

CLAIMS:

1. A receiving method of a receiving apparatus used in a mobile communication system in which a sending apparatus sends a plurality of code channels as code channel groups to which spreading codes are assigned to a receiving apparatus, and said receiving apparatus receives said code channel groups, said receiving method comprising the steps of:

when spreading codes used for said code channel groups are orthogonal code sequences,

generating received spreading signal sequences of said code channel groups according to the number of received paths; and

removing a received spreading signal sequence, from received signals, that is a replica of a signal of an own code channel group of said receiving apparatus transmitted via a path that is different from another path via which said signal of said own code channel group is transmitted .

2. The receiving method as claimed in claim 1, comprising the steps of:

if spreading codes of other code channels used for control or used for other channels in said code channel group are orthogonal code sequences,

generating received spreading signal sequences of said code channel groups according to the number of received paths; and

removing received spreading signal sequences of received paths of other code channels.

27879-167

-35-

3. The receiving method as claimed in claim 1,
comprising the steps of:

if a part of said spreading codes used for said
code channel groups are non-orthogonal code sequences,

5 generating received spreading signal sequences of
said code channel groups according to the number of received
paths; and

removing received spreading signal sequences of
other code channels which are non-orthogonal in the same
10 received path from received signals.

4. The receiving method as claimed in claim 1,
comprising the steps of:

if said receiving apparatus receives a code
channel group from another sending apparatus which is not
15 connected to said receiving apparatus,

generating received spreading signal sequences of
said code channel group from another sending apparatus
according to the number of received paths; and

removing received spreading signal sequences of
20 said code channel group from received signals.

5. The receiving method as claimed in claim 1,
wherein said receiving spreading code sequence is generated
on the basis of an estimated value of channel variations and
an estimated value of data modulation obtained for each code
25 channel.

6. The receiving method as claimed in claim 5,
comprising the steps of:

27879-167

-36-

said sending apparatus sending pilot signals of which said receiving apparatus knows sending phase and sending amplitude to said receiving apparatus periodically; and

5 said receiving apparatus measuring received phase and received amplitude of said pilot signals, and obtaining said estimated value of said channel variations by comparing said sending phase and sending amplitude with received phase and received amplitude.

10 7. The receiving method as claimed in claim 6, comprising the steps of:

 said receiving apparatus obtaining said estimated value of channel variations by averaging said estimated value of channel variations obtained by using said pilot
15 signals and an estimated value of channel variations obtained by comparing decision results of data modulation with receiving phase and amplitude for data signals.

8. The receiving method as claimed in claim 7, comprising the steps of:

20 obtaining said estimated value of channel variations on the basis of said pilot signals, said data signals and said decision results of said data modulation;

 updating data modulation decision results by using said estimated value of channel variations; and

25 updating said estimated value of channel variations on the basis of said updated data modulation decision results.

9. The receiving method as claimed in claim 5, wherein a same estimated value is used as said estimated

27879-167

-37-

value of channel variations for code channels sent from the same sending apparatus.

10. The receiving method as claimed in claim 5, comprising the steps of:

5 performing coherent detection by using said estimated value of channel variations for received despread signals of data signals obtained by despreading received signals from which said received spreading signal sequences have been subtracted;

10 wherein, when said receiving apparatus receives signals by path diversity or by antenna diversity, said receiving apparatus estimates data modulation by performing hard decision for signals on which antenna diversity has been performed.

15 11. The receiving method as claimed in claim 5, wherein when said sending apparatus performs data modulation for sending original information data sequences which have been error correction coded beforehand, the receiving method further comprising the steps of:

20 said receiving apparatus performing coherent detection by using said estimated value of channel variations for received despread signal of data signals obtained by despreading received signals from which said received spreading signal sequences have been subtracted,
25 performing error correction decoding on signals after performed antenna diversity combining when signals were received by path diversity or antenna diversity so that original information data sequences are estimated;

27879-167

-38-

said receiving apparatus performing error correction coding on said original information data sequences which are estimated; and

said receiving apparatus performing data modulation by using data sequences which are obtained by performing error correction coding on said original information data sequences so that data modulation is estimated.

12. The receiving method as claimed in claim 8,
10 comprising the steps of:

updating said received spreading signal sequences on the basis of updated estimated values of channel variations; and

demodulating code channels to be demodulated by
15 using signals obtained by subtracting said updated received spreading signal sequences from received signals.
