ABSTRACT OF THE DISCLOSURE

A compressor motor time-delay circuit for protecting a refrigerant compressor against rapid cycling which includes time-delay means for maintaining a specified predetermined minimum time period between starts of the compressor motor.

This invention relates to automatic control apparatus and more particularly, to a refrigerant compressor motor time delay circuit.

In operation of a refrigeration system utilizing a refrigerant compressor, it is desirable to prevent short cycling of the compressor motor upon intermittent opening and closing of the controls for the compressor. Many hermetic refrigerant compressors utilize a low starting torque compressor motor. If an attempt is made to restart the compressor shortly after the previous shut-off, system pressure will not be equalized and the motor will be inadequate to operate the compression mechanism. Without the time delay provided by the present invention, the compressor motor locked rotor protection means could be called upon to function too frequently. After several cycles, motor temperatures might increase to a level that prevents reset of the overload safety device for extended periods of time, limiting the ability of the system to operate as needed. Additionally, extremely rapid recycling of external control switches can occur, such as chattering of thermostat contacts caused by mounting on light walls subject to vibration. This type of operation can result in compressor motor and/or switching device failures because of extremely high transient currents. By preventing this, the present invention provides improved protection to the motor and switching devices.

It is recognized that there have been previous attempts to utilize timer means to prevent operation of the compressor in an on-off manner when switches in the control circuit are opened and closed rapidly. Thermal timers have heretofore been used and also mechanical switch timer means have been used. These systems, however, have not been altogether reliable and are generally more complex and expensive than the present construction.

An object of the present invention is to provide an improved compressor motor time delay arrangement.

Another object of this invention is to provide improved compressor motor time delay means for protecting a refrigerant compressor against rapid cycling that might be caused by chattering or rapid opening and closing of thermostat contacts, or by rapid voltage surges as a result of lightening. Other objects and advantages of the present invention will become apparent hereinafter.

The specific details of the invention and their mode of functioning will be made most manifest and particularly pointed out in clear and precise terms in conjunction with the accompanying drawing wherein:

The single figure illustrates schematically a refrigeration system and includes schematically a wiring diagram of a presently preferred form of compressor motor time delay circuit.

Referring now to the drawing, there is illustrated a refrigeration system 10 of conventional design that could

2

utilize the present invention. The refrigeration system 10 includes a refrigerant compressor 11 which might be of the hermetic type wherein the motor and compression mechanism are enclosed within a single hermetically sealed casing. The compressor in operation pumps high pressure vaporous refrigerant to the condenser 12 through discharge line 13. In the condenser 12, the vaporous refrigerant is converted to the liquid phase. The condenser may be air cooled or liquid cooled in a conventional manner. The liquid refrigerant then flows from the condenser through an expansion device indicated generally at 14. Examples of suitable expansion devices are capillary tubes or thermal expansion valves. Refrigerant passes from the expansion device 14 to the evaporator 16, where the refrigerant may evaporate and return to the vaporous phase. The refrigerant is returned to the compressor through a suction conduit 17 connecting the evaporator to the compressor.

In many applications the compressor motor is a low starting torque motor for purposes of economy. In the event that the high side and low side of the refrigeration system are not balanced after shut-off of the compressor, then the starting torque requirements will be excessive and the compressor motor may stall.

Consider now the electrical circuit of the present invention for preventing undesirable cycling of the compressor motor. The compressor motor 19 is supplied with power from a suitable source via lines T₁ and T₂. Contactor coil 21 controls energization of the compressor motor through opening and closing of contact 21a.

The contactor coil 21 is in a control circuit supplied with power through leads L₁ and L₂. The leads L₁ and L₂ may be at a higher or lower voltage than lines T₁ and T₂, for example, a transformer may be used to change the voltage at L₁ and L₂, although it may be taken directly from T₁ and T₂ if desired.

Provided in the circuit is a thermostat or control switch indicated generally at 20. The thermostat 20 closes in response to cooling demand and opens when the cooling demand is satisfied. In practice, a control relay actuated by a room thermostat provides the control switch contacts.

Provided in series with the thermostat 20 is a protection switch 22, which, for example, may be a high pressure cut-out switch suitably attached to the compressor or other part of the high pressure side of the refrigeration system which will open the electrical circuit if the compressor head pressure exceeds a predetermined maximum. It will be understood that other desirable safety switches may be used in addition to the illustrated protection switch 22.

The compressor motor time delay circuit includes timing motor means comprising a timing motor 24, a cam 26 rotated by the motor and a pair of timing motor switches or contacts 24a and 24b actuated by the cam 26.

Connected in circuit with the timing motor 24 are a pair of relays. The first relay is a single pole single throw type and includes a relay coil 28 and a contact 28a in series therewith. The contact 28a is normally open, and when closed is adapted to connect the relay coil 28 between lines L₁ and L₂ so as to hold the relay coil energized.

The second relay is a single pole double throw type and includes relay coil 30 and first and second contacts 30a and 30b. The contact 30a in line 32 is normally closed and the contact 30b in line 34 is normally open.

The contactor coil 21 is connected across lines 36 and 38. Contact 21a is adapted to open and close the circuit to the compressor motor 19, which is in a circuit across the lines T₁ and T₂, which are connected to a suitable source of power.

Considering now the electrical circuit at start-up, the thermostat 20 is normally open until there is a demand for cooling. The contacts 24a and 24b of the timing motor 24 are in the positions shown in dotted line. Upon closure of thermostat 20, a circuit is completed through thermostat 20, protection switch 22, relay coil 28, contact 24b and line 29 to line L₂. Upon energization of coil 28 normally open contact 28a will be closed and a holding circuit will be provided to maintain the coil 28 energized.

The timing motor 24 is energized since a circuit is completed from L₁ to L₂ through the thermostat 20, the protection device 22, timing motor 24, contact 24a and normally closed contact 30a to L₂. The circuits to the contactor coil 21 and relay coil 30 are open since the switch 24b is in the dotted line position and the contact 30b in line 34 is open.

After a short interval of operation of timing motor 24, on the order of 20 seconds, for example, cam 26 has rotated and switches 24a and 24b have been moved to the solid line position indicated. Switch 24a switches to the solid line position first, with switch 24b following by a short interval of time, on the order of two seconds. The timing motor now runs through switch 24a and line 31.

Relay coil 30 and the compressor contactor coil 21 now are energized through a circuit from lines L₁ to L₂ including contact 24b (which is in the solid line position) and contact 28a. The coils 21 and 30 are held energized through the contact 30b in line 34, which was closed upon energization of coil 30. Upon energization of the contactor coil 21, contactor coil contact 21a will close, thereby closing the circuit between lines T₁ and T₂ and permitting energization of the compressor motor 19.

Assuming that the demand for cooling has continued for a predetermined time period on the order of five minutes, thermostat 20 remains closed and the compressor motor 19 remains running. Relay contact 28a remains closed and contact 30b in line 34 remains closed. At the end of the predetermined time cycle, the timing motor 24 is stopped as the cam actuates switches 24a and 24b back to the dotted line position. The timing motor is stopped since the contact 30a in the line 32 has been opened. The circuit will remain in this condition until the cooling demand is satisfied and/or a protective device is opened.

Assume an operating condition wherein after two or three minutes of running time the thermostat 20 is opened. The relay coils 28 and 30 as well as the contactor coil 21 are deenergized. Accordingly the compressor motor 19 is stopped when contact 21a opens the circuit across lines T₁ and T₂. Also timing motor 24 will be stopped. In the event that the thermostat 20 recloses, the timing motor 24 will commence to run through contact 24a and line 31. However, the relay coils 28 and 30 and contactor coil 21 will remain deenergized.

Should the thermostat 20 immediately reclose, the timer motor 24 will be energized as indicated. However, the relays 28 and 30 and the contactor coil 21 will remain deenergized. Thus the remainder of the time in the predetermined time cycle will run out before the switches 24a and 24b can be shifted back to the dotted line position illustrated.

In the event of an over-anticipated or misapplied thermostat that would produce a cooling demand on-off cycle of less duration than the predetermined timing cycle, for example, a three minute on, three minute off cooling demand cycle, upon the first demand for cooling upon closure of thermostat 20, the timing motor 24 would be energized as indicated above. The contactor coil 21 would be energized after a delay of twenty seconds to energize the compressor motor for a period of two minutes and forty seconds in the illustrated embodiment of the invention. When the thermostat 20 opens at the end of three minutes, the compressor motor 19 would be deenergized and the timing motor 24 would be deenergized. Then when

the thermostat 20 closed again calling for cooling, there would be two minutes and twenty seconds of demand time left before switches 24a and 24b would be returned to the dotted line position by cam 26 actuated by timing motor 24. The compressor motor 19 would remain off another twenty seconds before it could be restarted. The total time from start to restart then might be on the order of eight minutes and twenty seconds in the given example.

The compressor motor time delay circuit of the present invention may be provided in a compact device that can be field wired to a refrigeration system with little difficulty. The relay 28 is a simple single pole double throw relay. The relay 30 is a simple single pole double throw relay.

The novel compressor motor time delay circuit of the present invention functions to provide a timed demand cycle. The circuit functions to prevent restart of the compressor motor for a minimum predetermined time, on the order of five minutes when the thermostat or safety protection switch is opened, so as to prevent undesirable rapid recycling of the compressor motor, and thus prevent damage to the compressor motor.

While I have described a presently preferred embodiment of the invention, it will be understood that the invention is not limited thereto, since it may be otherwise embodied within the scope of the following claims.

I claim:

1. In a time-delay circuit for controlling operation of a refrigerant compressor motor to permit equalization of pressures in the refrigeration system after shutdown and for minimizing undesirable rapid cycling of the compressor motor in operation, said compressor motor being adapted to be supplied from a source of electric power and power supply means for the time-delay circuit, the improvement comprising control switch means for interrupting the power supply means, contactor coil means for controlling energization and deenergization of the compressor motor time-delay means operative in response to closure of the control switch means for initiating a minimum predetermined time period to prevent reenergization of the compressor motor for at least said minimum predetermined time, said time-delay means including a first relay means, second relay means and timing motor means including first and second cam-actuated switches, the contactor coil means including a contactor coil, the first relay means including first and second cam-actuated switches, the first relay means including a first relay coil and a normally open contact in series therewith, and the second relay means including a second relay coil and a first normally closed contact and a second normally open contact, the second normally open contact being in series with the second relay coil, the second normally open contact being in circuit with the contactor coil, whereby closure of the control switch means will energize the second relay coil, closing the second normally open contact and completing a circuit through the contactor coil to energize same and to energize the compressor motor and at the same time, the timing motor means will be actuated to initiate the minimum predetermined time period, with subsequent opening of the control switch means deenergizing the contactor coil to deenergize the compressor motor, as well as the timing motor means, and with subsequent closing of the control switch means being ineffectual to energize the contactor coil and thereby energize the compressor motor until the minimum predetermined time period has elapsed.

2. A time delay circuit as in claim 1, wherein the timing motor means includes a timing motor and a cam operated from the timing motor for actuating each of said timing motor switches between a first position and a second position, the first normally closed contact of the second relay means being in series with the timing motor when the first timing motor switch is in the first position, the second normally open contact of the second relay means being parallel with the first relay coil and second

5

cam actuated switch when said second switch is in said first position.

3. A time delay circuit as in claim 2, wherein the timing motor is energized when the control switch means is closed and the first timing motor switch is in the first position and which timing motor is deenergized in the event that the control switch means is opened.

4. A time delay circuit as in claim 3 wherein the second cam actuated switch moves from the first position to the second position before the first cam-actuated switch and moves from the second position to the first position after the first cam-actuated switch.
