PROCESS FOR CARRYING OUT ENDOTHERMIC REACTIONS AT HIGH TEMPERATURES

Erich Schallus and Armin Götz, Knapsack near Köln, Germany, assignors to Knapsack-Griesheim Aktiengesellschaft, Knapsack near Köln, Germany

Application January 10, 1956, Serial No. 558,357

Claims priority, application Germany January 15, 1955

1 Claim. (Cl. 260—679)

The present invention relates to a process for carrying out endothermic reactions at high temperatures, wherein energy is transferred by a gaseous medium in a manner such that by energy supplied the molecules of the gaseous medium are split into atoms and the energy set free upon recombination of said atoms to molecules is used to effect the endothermic reactions.

There exist, for example, three versions of supplying energy in endothermic reactions at high temperatures, namely:

(a) Transfer of heat from a solid to a gaseous medium, for example, by means of a Cowper stove, a pebble heater, or a coke shaft;

(b) Transfer of heat from a gaseous medium to a gaseous medium, for example, by flame reaction;

(c) Supply of energy by an electric current, for example, with the use of the electric arc method.

Although there are a plurality of processes which have become known for each of these three versions, in some of the typical high temperature reactions only an unsatisfactory energetic effect is attained, and this becomes evident, for example, in the production of acetylene. Some of these processes, for example the production of acetylene from carbon and hydrogen, could not at all be conducted in an economical manner. Thus, for example, reference is made to the process according to Wulff as a version of (a) above. This process involves the drawback of necessitating large storage facilities for pebble heaters, although the hydrocarbons used are only partially converted to acetylene. Besides, a rather great amount of olefins is obtained and, finally, this process is restricted to the use of hydrocarbons containing 1 to 4 carbon atoms.

Processes according to version (b) have also been disclosed in the literature which, however, have the following disadvantages:

The starting material used is only partially reacted; a great amount of olefins is always obtained. Furthermore, practically pure oxygen is necessary to produce the gaseous heating medium, since when using air only insufficiently high temperatures are attained, or a too diluted acetylene gas is formed. Still further, the yield is reduced by secondary reactions of the combustion products which react, among others, with the starting material and the resultant acetylene and form carbon monoxide and hydrogen.

Version (c) is used, for example, in electric arc methods conducted on an industrial scale. If, however, such method is applied to hydrocarbons, their conversion is only about 50 percent. Besides, the separation of the non-reacted hydrocarbon from the hydrogen and the repeated expenditure of energy for once more heating up said non-reacted hydrocarbon involve further expenses. Furthermore, diacetylene and soot are formed and, finally, these processes are restricted to the use of hydrocarbons with a small number of carbon atoms.

Summing up, in the processes mentioned above the reactions must be fairly adapted in each particular case

2

to the mode of execution. Furthermore, many of these processes could not at all be carried out in an economical manner, for example the reaction of hydrocarbons with nitrogen to obtain hydrogen cyanide, or the formation of acetylene from carbon and hydrogen.

The present invention is based on the observation that the disadvantages involved in the processes known for carrying out endothermic reactions can be prevented by using a process wherein, for the transfer of energy, at least one gas, such as hydrogen and/or nitrogen, is caused to participate in the reaction by heating it so that part or all its molecules are thermally split into atoms, the gas so formed—containing free atoms—is caused to act outside the heating zone upon the other reactant or reactants, and the reacted mixture is chilled. According to the process of this invention the energy set free upon recombination of the atoms to molecules is used to carry out the endothermic reactions. The term "recombination" as used herein means the re-formation of neutral molecules from atoms.

For the reaction according to this invention, it is not necessary that the consumption of the gas split into atoms be visible, though this is often the case. In many cases it suffices to use a gaseous medium which shifts the equilibrium of the endothermic reactions in the direction of the reaction course desired, without the participation of this medium in the reaction being detectable in the composition of the individual reaction products formed. Thus, for example, in the manufacture of acetylene from hydrocarbons, it is particularly advantageous to use a gaseous medium which favorably influences the formation of acetylene and hinders the formation of soot. Due to the presence of the hydrogen required for the supply of energy, it is even possible to prevent the formation of soot practically completely.

According to this invention endothermic reactions can be conducted with particular advantage using hydrogen and/or nitrogen as gases which transfer the energy. Such reactions are, for example, the preparation of unsaturated organic compounds which, on the one hand, contain at least one triple bond and at most 2 carbon atoms and, on the other hand, contain at most two atoms of at least one element selected from the group consisting of hydrogen and nitrogen, such as acetylene ($\text{HC}\equiv\text{CH}$), hydrogen cyanide ($\text{H}-\text{C}\equiv\text{N}$), and dicyane ($\text{C}\equiv\text{N}$)₂. It is also possible to a small extent to produce ethylene. For the production of the aforesaid unsaturated organic compounds from hydrocarbons or carbon, on the one hand, and hydrogen and/or nitrogen, on the other hand, generally about 0.05 to about 2 mols of hydrogen and/or nitrogen are used per 1 gram atom of carbon contained in the starting material. If hydrocarbons are used as starting material for the manufacture of products containing hydrogen, it is preferable to use about 0.1 to about 1 mol of hydrogen or nitrogen per 1 gram atom of carbon contained in the hydrocarbon. If a pulverized carbon-containing material, for example coal or coke is used as starting material, it is advisable to use greater amounts of the gas, i.e. between 0.2 and 2 mols of hydrogen and/or 0.2 to 2 mols of nitrogen per 1 gram atom of carbon contained in the starting material used. Such carbon-content is about equal to the weight of the residue which is obtained after the carbon-containing starting material has been degassed. To this end, it is possible to use both degassed or undergassed coal. It is, however, advisable to use a coal which has almost been freed from humidity by drying it, for example, at a temperature of 110 to 130° C.

It is particularly advantageous to use equi-atomic quantities, i.e. to use 1 gram atom of hydrogen and/or 1 gram atom of nitrogen per 1 gram atom of carbon.

As starting materials containing carbon there can be

used, for instance, saturated or unsaturated hydrocarbons containing up to 30 or more carbon atoms or pulverized carbon. The term "carbon" as used herein means all kinds of carbon or coal such as lignite, coal, coke obtained from coal or lignite, or charcoal. It is particularly advantageous to use saturated hydrocarbons, such as methane, ethane, propane, butane, pentane, heptane, octane, decane or dodecane, especially in the form of the usual liquid technical or commercial mixtures, for example in the form of hydrocarbon oils. If high-boiling oils or hydrocarbons containing, for instance, up to 30 carbon atoms are used, the hydrogen and/or nitrogen can be caused to act upon the liquid oils or liquid hydrocarbons, especially when these liquid compounds participate in the reaction in a finely divided form, for example as a spray. To this end, it is advisable to admix the finely dispersed liquid substances to the current of the totally or partially dissociated gas. Generally, it is, however, more suitable to vaporize the hydrocarbons prior to the reaction.

Instead of aliphatic saturated hydrocarbons containing between 1 to about 30 carbon atoms or more, there can also be used unsaturated and/or branched hydrocarbons. As branched hydrocarbons there come into consideration, for example, isobutane, isooctane, isoheptane etc. As unsaturated hydrocarbons there can be used with advantage, for example, ethylene, propylene, butylene and isobutylene. It is, however, also possible to use natural mixtures of hydrocarbons of natural origin or those obtained in industry; for example topped Kuwait oil may be used.

In the process of this invention hydrogen and/or nitrogen is used for the transfer of energy in a manner such that, by the supply of energy, the molecules of these gases are split into atoms and the energy set free upon the recombination of the atoms is used, outside the heating zone, to effect and to feed the endothermic reaction, i.e. for endothermically splitting the hydrocarbons or carbon bonds into carbon and for the formation of acetylene and/or hydrogen cyanide. In many cases, the aforesaid gases participate in the reaction.

The process according to this invention is particularly suitable for use in the production of acetylene. In this case the reaction proceeds as follows: hot hydrogen the molecules of which are partially or totally dissociated into atoms is caused to act upon carbon or, advantageously hydrocarbons, for instance, such as have been mentioned above. Contrary thereto, when solid carbon is reacted with nitrogen, dicyane can be obtained. If, however, solid carbon is treated with a mixture of partially or totally dissociated hydrogen and nitrogen, or—more advantageously—hydrocarbons, for instance those mentioned above, are treated with hot nitrogen which has at least partially been split into atoms, it is possible to produce hydrogen cyanide. In the production of hydrogen cyanide from nitrogen and aliphatic saturated hydrocarbons, it is possible to use, as hydrocarbon, for example, propane, for example 0.1 to 1 mol, especially 0.7 to 0.6 mol of propane, per 1 mol of nitrogen.

Instead of hydrocarbons or carbon there may be used as carbon-containing starting materials for the process according to the invention aliphatic amines such as methyl amine, ethyl amine, propyl amine, butyl amine, lauryl amine, oleyl amine, ethylene-diamine, trimethylamine, dimethylamine, tetramethylendiamine, hexamethylendiamin etc. When using these substances as carbon-containing starting material, the same amounts of hydrogen and/or nitrogen as stated above may be used, and hydrogen cyanide or mixtures thereof with acetylene may be obtained.

The chilling of the reaction mixture, generally, is performed in a manner such that a liquid which practically does not react with the reacting or reacted components

is injected into the reacted mixture. Water can, for example, be used as such liquid.

According to the process of this invention the heat necessary to perform endothermic reactions is produced by the energy set free upon recombination of the gas atoms to molecules. For instance, use is made of the heat of reaction of the following reactions:

or

for carrying out endothermic chemical high-temperature processes. To attain a high concentration of energy in the reaction zone, the molecules are previously dissociated into atoms and recombined in the reaction chamber.

An apparatus suitable for use in carrying out the process of this invention is illustrated diagrammatically in the accompanying drawing.

It should be noted that the whole apparatus as well as the feed pipes are made of or lined with refractory material, for example carbon, chamotte tiles, dynamidon tiles, chalk-dinas tiles or magnesium silicate tiles.

In the drawing the numerals designate the following parts: Through pipe 1 the gas to be activated which advantageously has been preheated to a temperature of about 1000° C. enters the chamber 2 in which an angular momentum is imparted to the gas to be dissociated and then passes through a nozzle like aperture 3 into an electric arc 4 formed between two carbon or metal electrodes or into another source of energy, for example a high frequency discharge, a glow discharge, or a quiet electric discharge, where the gas is split into atoms. Since the lifetime of these atoms is only within the order of about 0.1 to 1 second, which depends on the fact that the re-unification of the atoms to the molecule can only be performed by a triple collision, the gas passing through the source of energy is required to have a high rate of speed.

It is, therefore, advisable that the minimum velocity rate of the gas be above 400 meters per second, preferably more than 1000 meters per second. The electrodes consist, for example, of tungsten or carbon and the electric arc is for instance charged with about 35 kw. After the atomic gas has left the source of energy 4 it passes through a further contracted aperture 5 where it contacts the substance to be reacted with the atomic gas. It is advisable to preheat this substance, preferably to a temperature of about 1000° C., it is then passed through conduit 6 to point 5. In the reaction chamber 7 which is somewhat conically enlarged in downward direction the reaction between the two components sets in after the most favorable temperature for the optimum conversion has been adjusted by the temperature of the preheated gases and a suitable choice of the corresponding current intensity and tension of the electric arc. At the same time, a chilling agent, for example water, is sprayed through the nozzle-like distributor 8, so that the reacted mixture which escapes at 9 is fairly rapidly cooled, for instance, to a temperature of about 100° C. If it is desired to react solid substances with the atomic gases, these substances are blown in finely divided form, for instance as dust, into the reaction chamber through conduit 6 by means of a current of preferably non-atomic gases of equal kind.

Having regard to the medium lifetime of the atoms and the high velocity of the gas, it is evident that several meters behind the electric arc recombination of the atoms to molecules has not yet taken place. This zone which contains the free atoms and which is outside the electric arc is suitable for carrying out endothermic reactions. If, for example, hydrocarbons regardless of the size of the molecules are introduced into this zone the following takes place:

The recombination of the hydrogen atoms to molecules takes place directly at the place the hydrocarbons

5

are introduced. Therefore, the energy is set free in the midst of the reaction agglomerate and directly at a part of the hydrocarbon molecule. The molecule of the hydrocarbon is split into small particles which form acetylene due to the presence of hydrogen, without soot or higher acetylenes such as diacetylene being formed. A further advantage of the process according to this invention resides in the fact that it is not necessary to put up with an incomplete conversion of the hydrocarbon in favor of the yield of acetylene.

As compared with the known processes, the process of this invention provides a better utilization of the hydrocarbon used as starting material and is not dependent on the use of hydrocarbons having a certain size of the molecules; furthermore, much lower costs are involved in concentrating the acetylene due to the absence of soot and diacetylene; no separation of methane from hydrogen and less expenditure of electric energy are necessary.

If the endothermic reactions are performed in an electric arc, these reactions do not show an optimum result since the electric arc consists of zones having different temperatures. The zones at the border are colder than the middle zones. Contrary thereto, according to this invention, the reaction is not achieved in the electric arc but only outside the heating zone, that is to say in an exactly delimited and specifically adjustable zone of temperature which allows of obtaining optimum conversions.

The normal electric arc methods practically must be considered to be endothermic reactions. This means that in the production of acetylene from hydrocarbons or in the production of hydrogen cyanide from hydrocarbons and nitrogen according to the known processes the electric energy is converted to heat energy in the presence of the hydrocarbon, or hydrocarbon and nitrogen, respectively. Prior to this invention it was impossible to convert electric energy to thermal energy and at the same time perform the endothermic reaction with the best possible effect. In the production of hydrogen cyanide it must also be observed that the temperatures required to sensitize nitrogen and hydrocarbons are far different.

By the process of this invention, all the disadvantages inherent to the known processes are avoided as disclosed above. For producing hydrogen cyanide from hydrocarbons, generally only nitrogen is passed through the electric arc. In the production of acetylene from the elements which hitherto has been impossible on an industrial scale since coal dust and hydrogen cannot be passed continuously through the electric arc, powdered carbon is reacted with atomic hydrogen.

The following examples illustrate the invention. The conversion is performed in an apparatus as described above in which carbon has been used as highly refractory material. For all the examples herein the same apparatus was used and unless otherwise stated the conversions were conducted under the same reaction conditions.

Example 1

Through the opening 1 of an arc furnace of 35 kw. 4 m.³ per hour of hydrogen, suitably preheated to 1000° C., are introduced in a tangential manner into chamber 2 in which an angular momentum is imparted to the hydrogen. From said chamber the hydrogen passes through the nozzle 3 and enters the electric arc burning between the electrodes 4. The nozzle is suitably measured so that the hydrogen enters the area of the electric arc at a rate of at least 400 m./sec., preferably about 1000 m./sec. After having left the electric arc, the now atomic hydrogen, at 5, strikes propane which is introduced at 6 at a rate of 4 m.³ per hour and has suitably been preheated to about 1000° C. In the reaction chamber 7 a temperature of 1200 to about 1600° C. prevails, which temperature is the most favorable one for the optimum conversion. The reaction products are

6

immediately cooled to about 100° C. by means of water introduced through nozzle-like distributor 8 at a rate of about 100 liters per hour. Of the carbon used in the form of propane there are obtained: 85 percent in the form of acetylene; 5.3 percent in the form of propylene; 8 percent in the form of ethylene; 1.7 percent in the form of methane. No formation of higher acetylenes or soot takes place.

Example 2

The process is carried out in the apparatus and under the conditions described in Example 1 with the exception, however, that, instead of propane, there are introduced, per hour, about 5 kilograms of a topped oil of Kuwait origin (boiling at a temperature between 160 and 340° C.) in the form of vapor and having a temperature of about 500° C.

Of the carbon used there are obtained: 78 percent in the form of acetylene; 5.1 percent in the form of propylene; 13.3 percent in the form of ethylene; 3.2 percent in the form of methane. In this case also no soot is formed.

Example 3

The process is carried out in the apparatus and under the same conditions as described in Example 1, with the exception, however, that instead of propane there are introduced, per hour, 4 kilograms of dodecane in the form of vapor and having a temperature of about 500° C. There are obtained in the form of acetylene about 80 percent of the carbon contained in the dodecane.

Example 4

The process is carried out in the same apparatus and under the same conditions as described in Example 1 with the exception, however, that instead of propane, there are introduced, per hour and behind the electric arc, 1.5 kilograms of most finely pulverized lignite suspended in hydrogen which is blown in in an amount of about 2 cubic meters per hour and which has been preheated to a temperature of about 1000° C. The hydrogen freed from the unreacted lignite dust contains up to about 18 percent by volume of acetylene.

Example 5

The process is carried out under the same conditions as described in Example 1 with the exception, however, that instead of hydrogen, there are passed through the electric arc per hour 5 cubic meters of nitrogen preheated to a temperature of 1000° C. and split in the electric arc into atoms. The propane introduced at 5 is used in a quantity of 3 cubic meters per hour. There are obtained in the form of hydrogen cyanide about 60 percent of the carbon used in the form of propane and 15 percent of the carbon used are obtained in the form of acetylene. The remainder consists almost completely of methane.

We claim:

The process of preparing extremely high yields of an unsaturated organic compound containing at least one triple bond and at most two carbon atoms and consisting of carbon and at most two atoms of at least one element selected from the group consisting of hydrogen and nitrogen, said process comprising the steps of thermally dissociating the molecules of a gas selected from the group consisting of hydrogen, nitrogen, and mixtures thereof into atoms by passage in direct contact with an electric arc, admixing thermally dissociated gas with a carbon-containing substance selected from the group consisting of finely divided carbon, aliphatic amines and hydrocarbons within a time of from about 0.1 to about 1.0 second from the time of dissociation and in a zone removed from said electric arc, the ratio of thermally dissociated gas to selected substance being from about

0.2 to about 2.0 mols of dissociated gas per gram atom of carbon in said selected substance, the flow rate of thermally dissociated gas from the electric arc to the zone removed from the electric arc being at least about 400 meters per second, the heat liberated by reassociation of said thermally dissociated atoms causing an endothermic reaction and forming said unsaturated organic compound, and immediately thereafter rapidly cooling the resulting reaction mixture.
