METHOD AND ARRANGEMENT FOR VIDEO CODING

TECHNICAL FIELD

[0001] The invention relates generally to a method and an arrangement for encoding and decoding of information related to video coding.

BACKGROUND

[0002] Video coding may be performed in intra mode and/ or inter mode. Intra mode exploits redundancies within a video frame, and inter mode exploits redundancies between video frames. In inter mode, pixel luma/ chroma predictions are obtained from already coded/ decoded pictures called reference pictures. Depending on the number of reference pictures used for prediction, inter mode is categorized into uni-prediction mode (or uni-directional mode), bi-prediction mode (B mode), and possibly tri-prediction mode, etc., where, respectively, 1, 2 and 3 reference pictures are used. Within this document, these different modes, i.e. uni-prediction, bi-prediction, etc., will be referred to as “reference modes”.

[0003] Advanced Video Coding (AVC), which is also known as H.264 and MPEG-4 Part 10, is the state of the art standard for 2D video coding from ITU-T (International Telecommunication Union - Telecommunication Standardization Sector) and MPEG (Moving Picture Experts Group). The AVC codec is a hybrid codec, which takes advantage of eliminating redundancies between frames and within a frame.

[0004] In AVC, two reference lists are defined, in which indicators of the relevant reference pictures are placed in a certain order. These indicators are denoted reference indices in AVC, and are numbered from 0 to N, such as e.g. (0,1,...,N). The first list, List 0 (L0), primarily manages the past reference pictures, i.e. reference pictures preceding a current picture in time, and the second list, List 1 (L1), typically manages the future reference pictures, i.e. reference pictures

subsequent to a current picture in time. For low delay video coding, L1 may also manage past reference pictures. Each list can hold indicators of up to 15 reference pictures, i.e. the number N of indices is $N=14$.

[0005] Further, in AVC, an indicator, or reference mode index, specifying the selection of one of the reference picture lists (e.g. for uni-prediction), or both reference picture lists (e.g. for bi-prediction), is coded together with a partition structure in Macro Block (MB) mode/ sub-MB mode, while the indicators, or reference picture indices, specifying the selected reference pictures in the respective lists, are coded as separate syntax elements. "Partition structure" refers to partitions, such as e.g. 16x16, 16x8 or 8x16, of a 16x16 MB. A partition, e.g. 16x16, is typically associated with one motion vector (MV) and one reference index when uni-prediction is used, and with two MVs and two reference indices when bi-prediction is used. An MV has a horizontal component MV_x and a vertical component MV_y that describes how pixels of the current partition are produced from the corresponding reference picture.

[0006] The number of reference pictures associated with a picture or partition depends on the reference mode associated with the same partition, i.e. whether it is uni-prediction or bi-prediction, etc. When decoding the reference information in a decoder, both the reference mode index and the one or more reference picture indices associated with a picture or partition must be correctly decoded, in order for the decoder to be able to decode the picture or partition correctly. Incorrect decoding of either of the reference mode index and the one or more reference picture indices may result in erroneous interpretation of the reference information.

[0007] The current methods of coding reference information, such as the method of AVC described above, require a relatively large number of bits in order to convey the reference information associated with each block. This is identified as inefficient in terms of coding efficiency.

SUMMARY

[0008] It would be desirable to enable an improved coding efficiency for reference information, i.e. the information identifying the one or more reference pictures used for prediction of a current frame. It is an object of the invention to enable an improved coding efficiency for reference information. Further, it is an object of the invention to provide a method and an arrangement for enabling an improved prediction of reference information. These objects may be met by a method and arrangement according to the attached independent claims. Optional embodiments are defined by the dependent claims. The prediction, encoding and decoding described below may be performed within the same entity or node, or in different entities or nodes.

[0009] According to a first aspect, a method is provided in a video decoding entity. The method comprises obtaining an encoded block B_e , and a set of neighbor blocks of the encoded block, B_e , each neighbor block being associated with one or more reference pictures. The method further comprises determining the frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighbor blocks. The method further comprises selecting a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, such as to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , to be used when decoding the encoded block B_e . The method further comprises obtaining an indication specifying whether the prediction, C_{pred} , corresponds to C . When the prediction, C_{pred} , is indicated to correspond to C , the encoded block, B_e , is decoded based on the prediction C_{pred} . Thus a decoded block, B , of pixels is obtained.

[00010] According to a second aspect, an arrangement is provided in a video decoding entity. The arrangement comprises a functional unit, which is adapted to obtain an encoded block, B_e , and a set of neighbor blocks of the encoded block, B_e , where each such neighbor block is associated with one or more reference pictures. The arrangement further comprises a functional unit, which is adapted to determine the frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighbor blocks. The arrangement further comprises a functional unit, which is adapted to select a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighbor blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , to be used when decoding the encoded block, B_e . The arrangement further comprises a functional unit, which is adapted to the obtaining unit (904) being further adapted to obtain an indication specifying whether the prediction, C_{pred} , corresponds to C . The arrangement further comprises a functional unit, which is adapted to decode the encoded block, B_e , based on the prediction C_{pred} , when the prediction, C_{pred} , is indicated to correspond to C , thus providing a decoded block, B , of pixels.

[00011] According to a third aspect, a method is provided in a video encoding entity. The method comprises determining the frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with a set of blocks, which are neighbors of a block B of pixels. The method further comprises selecting a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighbor blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , used when encoding the block, B . The method further comprises determining whether the

prediction, C_{pred} , corresponds to C , and providing an indication specifying the result of said determination to a decoder of the block.

[00012] According to a fourth aspect, an arrangement is provided in a video encoding entity. The arrangement comprises a functional unit, which is adapted to determine, for a block, B , having a set of encoded neighbor blocks, each being associated with one or more reference pictures used when encoding said neighbor block, the frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighbor blocks. The arrangement further comprises a functional unit, which is adapted to select a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighbor blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , used when encoding the block, B . The arrangement is further adapted to determine whether the prediction, C_{pred} , corresponds to C . The arrangement further comprises a functional unit, which is adapted to provide an indication specifying the result of said determination to a decoder of the block.

[00013] The above methods and arrangements may be used for improving coding efficiency. The coding efficiency may be improved, due to that the use of less bits in order to identify the one or more reference pictures used for prediction of a current frame is enabled. The above methods and arrangements may further enable an improved error resilience performance. Further, the above methods and arrangements allow reference picture index prediction to be carried out in a simple manner.

[00014] The above methods and arrangements may be implemented in different embodiments. In some embodiments the reference pictures associated with the neighbor blocks are identified by a combination of a reference mode parameter

and one or more reference picture parameters. In other embodiments, the reference pictures associated with the neighbor blocks are identified by a single syntax element. By bundling of reference mode and index to form a single syntax element, easy manipulation of reference index numbers becomes feasible.

[00015] In some embodiments, the frequency of occurrence of reference pictures and/ or combinations of reference pictures involves the counting of reference pictures and/ or combinations of reference pictures associated with the neighboring blocks. Different occurrences of reference pictures or combinations of pictures may be assigned different weights, based on different criteria, such as e.g. the number of transform coefficients associated with the neighboring block with which the occurrence in question is associated.

[00016] The indication of whether C_{pred} corresponds to C may be signaled as a syntax element in the bit stream, or implicitly. When C_{pred} is indicated not to correspond to C further information may be conveyed, which enables the determining of which reference picture(s) to use when decoding the encoded block, B_e .

[00017] The determined frequency of occurrence of the reference pictures and/ or combinations of reference pictures may be used for mapping indicators of the reference pictures or combinations of reference pictures to variable length code words. The indication of whether C_{pred} corresponds to C may be such a code word. The further information needed when C_{pred} is indicated not to correspond to C may also be signaled using such a code word. Thus, it may be assured that the shortest code words are used for the most probable alternatives.

[00018] Further, in some embodiments, one or more sub-regions of a block associated with multi-prediction may be identified, based on implicit information, in which sub-regions the respective corresponding regions of the multi-prediction reference blocks have a relatively low correlation between them. An alternative

prediction may be used for the identified sub-regions, instead of the multi-prediction. The alternative prediction may be a single-prediction or weighted multi-prediction. The alternative prediction would be a prediction using only one of the reference blocks associated with the multi-prediction.

[00019] The embodiments above have mainly been described in terms of a method. However, the description above is also intended to embrace embodiments of the arrangements, adapted to enable the performance of the above described features. The different features of the exemplary embodiments above may be combined in different ways according to need, requirements or preference.

[00020] According to yet another aspect, a computer program is provided, which comprises computer readable code means, which when executed in one or more processing units, causes any of the arrangements described above to perform the corresponding procedure according to one of the methods described above.

[00021] According to yet another aspect, a computer program product is provided, which comprises the computer program of above.

BRIEF DESCRIPTION OF THE DRAWINGS

[00022] The invention will now be described in more detail by means of exemplifying embodiments and with reference to the accompanying drawings, in which:

Figures 1 and 2 are schematic views illustrating the determining of the frequency of occurrence of different combinations of a reference mode and one or more reference pictures associated with neighboring blocks of a current block, according to exemplifying embodiments.

Figure 3 is a schematic view illustrating assignment of indicators (code words) to different index symbols, according to the prior art.

Figure 4 is a schematic view illustrating assignment of indicators (code words), according to an exemplifying embodiment.

Figure 5 is an illustration of assignment of code words to reference information, according to an exemplifying embodiment.

Figure 14 is a schematic view illustrating partitioning based on implicit information, according to an exemplifying embodiment.

DETAILED DESCRIPTION

[00023] It is realized that one problem with existing video coding technology is that no satisfying reference mode/ reference picture prediction scheme is defined or applied. It is realized that in, for example, a scene-cut/ fading/ flash scenario, it is quite common that the same e.g. combination of reference mode and reference pictures is used for the prediction of neighboring or adjacent MBs. Further, it is realized that the current coding methods do not take advantage of the correlation between the reference modes/ reference picture(s) used for neighboring MBs. In previous solutions, the separate components identifying the MB reference information are encoded independently and conveyed to a video decoder.

[00024] Within this document it will be assumed that the indicators of the reference mode and one or more reference pictures used when encoding a block of pixels are jointly encoded, and thus all reference information necessary for decoding an encoded block will be represented by a single syntax element, for example denoted “reference indicator”, “reference index”, “reference index symbol” or “RIS index”, where “RIS” stands for “Reference Index Signaling”, or “Reference information Indicator Signaling”, which will be described in more detail further below in this description. Such joint encoding provides a useful possibility to perform reference information prediction both for uni-prediction, using a single reference picture, and predictions using multiple reference pictures, such as e.g. bi-prediction, tri-prediction, and so forth. However, it should be noted that the procedure of reference information prediction described below could also be used

for state of the art reference information representations, such as e.g. the reference mode index and reference picture list indices used in AVC.

[00025] Within this document, the term “neighboring blocks of block X” is used as referring to blocks which are neighbors of block X, i.e. located adjacent to or in the vicinity of block X. Further, within this document, the term “block” is used as referring to a unit of pixels. The term “reference picture” or “reference block” is used as referring to a previously coded/ decoded picture, a block, a region or an area of a picture, which picture, block, region etc, is used as reference for prediction.

[00026] An exemplifying prediction scheme on MB level could be described as follows. The exemplifying prediction scheme applies to both encoder and decoder, and it could be applied for any block size.

[00027] In association with the encoding/ decoding of a current MB, the encoder/ decoder is arranged to analyze the reference indicators of the encoded MBs in the surrounding, also called “the context” of the MB. These surrounding blocks could also be denoted the “neighboring blocks” of the current block. The encoder/ decoder counts the number of times each one out of a set of candidate indicators or indices appears amongst the neighboring blocks, and selects one, e.g. according to a predefined scheme, with the highest count, as being a prediction or estimate. The selected reference indicator should be related to inter prediction. The selected reference indicator is set to be a prediction or estimate of which reference picture(s) (and reference mode) that may be suitable to use when encoding/ decoding the current MB. The prediction is derived through analysis of information related to the encoded/ decoded neighboring blocks of the MB, rather than through analysis of the current MB itself. In an encoder, the MB may either be coded or uncoded during this selection of a prediction, since in this example, the prediction is not to be used for the selecting of reference picture(s) (and reference

mode) to use when encoding the current MB. In a decoder, the current MB is in a coded state during the prediction.

[00028] An exemplifying neighboring block reference indicator analysis and selection of an estimate is illustrated in figure 1. In the example illustrated in figure 1, four neighboring blocks of a current block are considered. However, the method is applicable also for other sets or subsets of considered neighboring blocks. An example set of neighboring blocks could consist of, e.g., a left block, a top left block and an above block relative to the current block. Another example set could comprise only the left block and above block. In figure 1, the neighboring blocks of the current block are associated with the respective reference indicators, or indices: 1, 1, 2 and 0. Thus, the reference indicator "1" has the highest count, i.e. the highest frequency of occurrence, by appearing twice amongst the neighboring blocks. Thus, the reference indicator "1" is selected to represent the prediction or estimate of the reference picture(s) (and mode) used, or to be used, when encoding the current block, or, when the prediction takes place in a decoder, the prediction of the reference picture(s) (and mode) to be used when decoding the current block.

[00029] Figure 2 illustrates another exemplifying embodiment of determining the frequency of occurrence of certain reference indicators for a current block, by the counting of reference indicators associated with the neighboring blocks of the current block. Here, the current block is a large MB, and the neighboring blocks are smaller in size than the current block. In some cases it may be of interest to have the same number of neighboring blocks in the context independently of the block size of the blocks in question.

[00030] When counting the number of occurrences of a certain reference indicator amongst the neighboring blocks, more than one candidate may have the same highest counting number. This is illustrated in figure 2, where the reference

indicators “1” and “2” both appear four times. This could be solved, e.g., by selecting the reference indicators in accordance with a predefined ranking scheme. For example, when the reference indicators are represented by the numbers 0-2, as illustrated in figures 1 and 2, the reference indicator represented by the highest, or lowest, number could be selected as prediction.

[00031] The difference between a block of predicted pixel values and the original pixel values, i.e. the source before being encoded, is coded by transform coding, e.g. DCT (Discrete Cosine Transform). The output of the transform comprises transform coefficients, which are then quantized. The number of transform coefficients associated with a block reflects how good the match is between the predicted block and the original block, for the given quantization. Relatively few transform coefficients indicate that there is a good match. Consequently, reference indicators associated with neighboring blocks having few transform coefficients could be considered more reliable.

[00032] Thus, the counting of occurrences could also be weighted according to e.g. the coded transform coefficients associated with the reference blocks. As described above, a reference index associated with a neighboring block with few coded transform coefficients could be considered a more reliable prediction than a reference index associated with a neighboring block with many transform coefficients, and may thus be assigned a larger weight for the reference index prediction. In another example, blocks with coded coefficients may have larger weight than blocks without coded coefficients, i.e. skipped blocks. In another example, a reference index associated with a neighboring block that has a large MV partition, for example a large MB, could be considered more reliable than a neighboring block with a smaller MV partition, and would thus be assigned a larger weight for the reference index prediction. Using weights which are multiples of 2 is beneficial in view of complexity. The weighted counting could also be implemented by use of a lookup table.

[00033] Some reference indicators may be more related to each other than others. For example, when using jointly encoded reference information, the reference indicator representing bi-prediction using the reference frames ref0 and ref1 will be more related to the reference indicator representing uni-prediction using one of ref0 and ref1, than for example to a reference indicator representing uni-prediction using reference frame ref2. Thus, when counting a bi-prediction indicator, the corresponding indicators representing uni-prediction using the same reference frames could be updated with some minor count value, i.e. lower than the count value for a “full match”. Similarly, reference indicators representing uni-prediction using e.g. ref0 and ref1 are more related to the corresponding reference indicator representing bi-prediction using ref0 and ref1, than to other bi-prediction reference indicators. Thus, when counting a uni-directional reference indicator, the count of reference indicators corresponding to a multi-prediction where the reference frame in question is used can also be updated with some minor value.

[00034] One advantage of introducing reference indicator prediction, or reference index prediction, is to allow more efficient mapping of a VIC (Variable Length Coding) table. By considering prediction and the VIC table together, more compression can be obtained. For example, when assuming coding of 3 indices, e.g., (0,1,2), without the use of prediction, a fixed VIC table may be assigned, as the one illustrated in figure 3. Assuming that the index symbol “2” occurs most frequently, the table illustrated in figure 3 would have a sub-optimal design, since “2” is encoded using a codeword with two bits, i.e. “11”, while the less frequent “0” is encoded using one bit, i.e. “0”.

[00035] When prediction is added, a better VIC table design is enabled. An example of such an improved VIC table design is illustrated in figure 4. In such an improved VIC design, the bits spent for encoding a reference indicator or index symbol can be adapted based on the prediction and thus on the context of the current block. In the table illustrated in figure 4, the most frequently occurring

reference indicator in the context of the current block is encoded using a single bit code word, in this example “0”. The code words “10”, and “11”, comprising two bits, could be defined to identify e.g. the reference indicator having the second highest frequency of occurrence and the reference indicator having the third highest frequency of occurrence, respectively. Both the encoder and decoder of reference indicators should be aware of, and agree on, how to perform the prediction and how to interpret the code words.

[00036] The example described above is just a simple example, and it should be noted that the possible design is not limited to this. There are various ways to assign different VIC tables to reference indicators or index symbols, e.g. when more reference indicators or index symbols are involved. An example approach could be to vary the indexing with the probability of occurrence of the indices, such that a frequently occurring reference indicator is assigned a low index number, and vice versa, and that a low index number cost less bits to encode than a high index number. Context-Adaptive Binary Arithmetic Coding (CABAC) can be used to achieve varying bit cost for representing reference indicators or indices according to their probability. Some examples of different contexts are e.g. the reference indicators associated with the neighboring blocks, a counting number of reference indicators, or a weighted counting number of reference indicators, as described above.

[00037] Another approach is to employ so-called “bubble sorting” of the indices or numbers representing the reference indicators as they are occurring. In this example, a VIC bubble table is a fixed VIC table where the length of the code words increases with increasing VIC table index, such as in the AVC UVIC (Universal Variable Length Code) table, but where the mapping between the index symbols or numbers representing the reference indicators and the VIC table index is adaptive. The adaptation is done by the swapping of neighboring “mapping positions”, much like the mechanisms in bubble sorting. An example of such

swapping is illustrated in figure 5, where a symbol "A" is mapped to index 4 in the VIC table 504a and a symbol "B" is mapped to index 5 in the VIC table. Assume now that VIC index 5 (symbol B) is decoded. After decoding of symbol B, the index mapping of symbol A, which in table 502 was to VIC index 4, and symbol B swap positions, such that symbol A is mapped to VIC index 5 and symbol B is mapped to VIC index 4, as shown in table 506. With this strategy of neighbor index swapping, the VIC table becomes adapted such that the most probable symbols end up being mapped to low VIC indices and thus to short code words, giving improved compression efficiency.

[00038] An embodiment of the encoding part of the procedure of reference indicator prediction will now be described with reference to figure 6. The procedure could be performed in a video encoding entity, which could be a video encoder or an entity comprising further functional units in addition to a video decoder, such as e.g. a computer, a mobile terminal or a video-dedicated device.

[00039] The procedure will be described as performed for a block, B, of pixels having a set of encoded neighboring blocks, where each neighboring block is associated with one or more reference pictures used when encoding said neighboring block. The frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks is determined in an action 602.

[00040] Then, a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks is selected, in an action 604, to be a prediction, C_{pred}, of the reference picture or combination of reference pictures, C, used when encoding the block, B. The block B may have been encoded at this stage, or, it is still to be encoded.

[00041] When the block B has been encoded, e.g. in an action 606 which may or may not be considered a part of the described procedure, using the reference picture or combination of reference pictures C, it is determined in an action 608, whether the prediction, C_{pred} , corresponds to C, which was used when providing an encoded block B_e , by encoding of the block, B. The result of this determining action is provided to a decoder of the block, B_e , in an action 610 or 612. For example, when C_{pred} is determined to correspond to C, a predetermined bit in a bit stream could be set to "0", and when C_{pred} is determined not to correspond to C, the predetermined bit could be set to "1". Further, in the case when C_{pred} is determined not to correspond to C, further information identifying C could be provided to a decoder of B_e in an action 614.

[00042] Below, an example arrangement 700, adapted to enable the performance of the above described procedure of reference indicator prediction will be described with reference to figure 7. The arrangement is illustrated as being located in a video encoding entity, 701, which could be a video encoder or an entity comprising further functional units in addition to a video encoder, such as e.g. a computer, a mobile terminal or a video-dedicated device. The arrangement 700 is further illustrated to communicate with other entities via a communication unit 702 which may be considered to comprise conventional means for any type of wired or wireless communication. Uncoded video to be encoded is assumed to be obtained from the communication unit 702 or a memory by an obtaining unit 704, and blocks of video are assumed to be encoded in an encoding unit 712, where the functional unit 712 uses conventional methods.

[00043] The arrangement 700 comprises a determining unit 706, which is adapted to determine, for a block, B, received from the obtaining unit 704, the block B having a set of encoded neighboring blocks, each being associated with one or more reference pictures used when encoding said neighboring block, the

frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks. The arrangement 700 further comprises a selecting unit 708, which is adapted to select a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , used when providing an encoded block B_e by encoding the block, B .

[00044] The determining unit 706 is further adapted to determine whether the prediction, C_{pred} , corresponds to C . The arrangement 700 further comprises a providing unit 710, adapted to provide an indication specifying the result of said determination to a decoder of the block, B_e .

[00045] An embodiment of the decoding part of the procedure of reference indicator prediction will now be described with reference to figure 8. The procedure could be performed in a video decoding entity, which could be a video decoder or an entity comprising further functional units in addition to a video decoder. An encoded block B_e and a set of neighboring blocks of B_e are obtained in an action 802. The block B_e has been encoded by a video encoder at some point, e.g. in the manner described above, and is provided to the decoding entity, e.g. by means of wireless and/ or wired transmission using suitable transmission protocol(s). Each of the neighboring blocks is associated with one or more reference pictures or frames, which were used when encoding the blocks in the encoder.

[00046] The frequency of occurrence of a plurality of the reference pictures amongst the reference pictures associated with the set of neighboring blocks, is determined in an action 804. It could also be the frequency of occurrence of combinations of the pictures that is determined, e.g. combinations of certain

reference pictures used for bi-, or tri-prediction. The reference pictures may be represented or identified by a combination of a reference mode parameter, such as a reference mode index, and one or more reference picture parameters, such as reference picture indices, associated with the neighboring block. Further, the combinations of reference mode parameters and one or more reference picture parameters may be jointly encoded, such as to be represented or identified by a single syntax element, e.g. denoted “reference indicator”, “reference index”, or “reference index symbol”, as previously described.

[00047] When having determined the frequency of occurrence of the respective reference pictures or combinations of reference pictures, typically represented by a reference mode parameter and one or more reference picture parameters, possibly represented by a reference indicator, one of the reference pictures or combinations of reference pictures having the highest frequency of occurrence is selected to be or represent a prediction, C_{pred} , of the one or more reference pictures or frames, C , used when encoding the block B_e in an encoder, and thus is/ are to be used when decoding the block B_e .

[00048] Further, an indication specifying whether the prediction, C_{pred} , corresponds to the actual one or more reference pictures, C , to be used when decoding the block B_e , is obtained in an action 808. The action 808 may be performed before, during or after the actions 802-806. The indication may be obtained, e.g., as a one bit code word or a flag in a bit stream. When it is specified that C_{pred} corresponds to C , which could be manifested, e.g., by the arrival of the code word “0” in a predefined position (cf. figure 4), the encoded block, B_e , is decoded in an action 812, based on the prediction C_{pred} . That is, B_e is decoded using the one or more reference pictures having the highest frequency of occurrence amongst the reference pictures associated with the neighboring blocks,

and being selected to be the prediction C_{pred} . By the decoding of B_e , a decoded block, B , of pixels, is obtained or provided.

[00049] The indication specifying whether C_{pred} corresponds to C could further be implicit, e.g. manifested by the omission of performing some action, e.g. adding “1” to a counter, or by refraining from toggling of a flag.

[00050] When the prediction, C_{pred} , is indicated **not** to correspond to C , further information may be obtained in an action 814, in order to determine which reference picture(s) to use when decoding the encoded block, B_e . When having obtained further information identifying the appropriate one or more reference pictures, block B_e is decoded using said information in an action 816.

[00051] Below, an example arrangement 900, adapted to enable the performance of the above described procedure of reference indicator prediction, will be described with reference to figure 9. The arrangement is illustrated as being located in a video decoding entity, 901, which could be a video decoder or an entity comprising further functional units in addition to a video decoder, such as e.g. a computer, a mobile terminal or a video-dedicated device. The arrangement 900 is further illustrated to communicate with other entities via a communication unit 902 which may be considered to comprise conventional means for any type of wired or wireless communication.

[00052] The arrangement 900 comprises an obtaining unit 904, which is adapted to obtain an encoded block, B_e , to be decoded, and a set of neighboring blocks of the encoded block, B_e , where each neighboring block is associated with one or more reference pictures, i.e. the pictures used when encoding the block, also to be used when decoding the block. The reference picture(s) associated with a neighboring block may be identified based on a combination of a reference mode parameter and one or more reference picture parameters associated with the block,

or alternatively, e.g. based on a single syntax element associated with the block. The obtaining unit 904 may also be regarded as part of the communication unit 902.

[00053] The arrangement 900 further comprises a determining unit 906, which is adapted to determine the frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks. For example, by counting the respective number of neighboring blocks that are associated with e.g. both of the reference pictures A and B; that are associated with only D; only A, etc., or similar. This could also be described as counting the number of occurrences of association with certain reference pictures or combinations of reference pictures amongst the neighboring blocks, or as counting the number of occurrences of e.g. a reference picture amongst the set of neighboring blocks.

[00054] The different associated reference pictures and combinations could be assigned different weights. For example, when counting the number of occurrences of (association with) the combination of reference picture A and B, the occurrences of association with only reference picture B could be assigned a low weight, and thus contribute to a minor extent to the sum of occurrences of "A + B". Further, one occurrence of association with reference picture D could be assigned a higher weight than another occurrence of association with reference picture D, when in the first occurrence, D is associated with a block having e.g. a lower number of transform coefficients.

[00055] The arrangement 900 further comprises a selecting unit 908, which is adapted to select a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures or combinations of reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C,

which (C) is to be used when decoding the encoded block, B_e . There may be several reference pictures or combinations of reference pictures sharing the same frequency of occurrence. In such a situation, one of these pictures or combinations should be selected based on a predefined scheme or rules defining how to select reference pictures.

[00056] The obtaining unit 904 is further adapted to obtain an indication specifying whether the prediction, C_{pred} , corresponds to C. For example, when C_{pred} corresponds to C, a predefined bit obtained from a bit stream may be “0”, and when C_{pred} does not correspond to C, the predefined bit could be “1”. The arrangement 900 further comprises a decoding unit 910, which is adapted to decode the encoded block, B_e , based on the prediction C_{pred} , when the prediction, C_{pred} , is indicated to correspond to C. The decoding unit 910 thus provides a decoded block, B, of pixels, which may e.g. be stored or displayed.

[00057] The arrangement 900 may further be adapted to obtain further information in order to determine which reference picture(s) to use when decoding the encoded block, B_e , when the prediction, C_{pred} , is indicated **not** to correspond to C, i.e. when further information is needed in order to identify the true C. Such information may be available e.g. in form of a VIC code word.

[00058] Figure 10 schematically shows an embodiment of an arrangement 1000 in a video decoding entity, which also can be an alternative way of disclosing an embodiment of the arrangement for reference indicator prediction in a video decoding entity illustrated in figure 9. Comprised in the arrangement 1000 are here a processing unit 1006, e.g. with a DSP (Digital Signal Processor). The processing unit 1006 can be a single unit or a plurality of units to perform different actions of procedures described herein. The arrangement 1000 may also comprise an input unit 1002 for receiving signals from other entities, and an output unit 1004

for providing signal(s) to other entities. The input unit 1002 and the output unit 1004 may be arranged as an integrated entity.

[00059] Furthermore, the arrangement 1000 comprises at least one computer program product 1008 in the form of a non-volatile memory, e.g. an EEPROM (Electrically Erasable Programmable Read-Only Memory), a flash memory and a hard drive. The computer program product 1008 comprises a computer program 1010, which comprises code means, which when executed in the processing unit 1006 in the arrangement 1000 causes the arrangement and/ or the video decoding entity to perform the actions of the procedure described earlier in conjunction with figure 8.

[00060] The computer program 1010 may be configured as a computer program code structured in computer program modules. Hence in the example embodiments described, the code means in the computer program 1010 of the arrangement 1000 comprises an obtaining module 1010a for obtaining an encoded block, B_e , and a set of neighboring blocks of the encoded block, B_e , e.g., from a bit stream originating from a data transmitting entity or from a storage, e.g. a memory. The obtaining module 1010a is also for obtaining an indication of the result of a comparison. The computer program further comprises a determining module 1010b for determining the frequency of occurrence of a plurality of reference pictures or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks.

[00061] The computer program 1010 further comprises a selecting module 1010c for selecting a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , where C is to be used when decoding the encoded block, B_e . The computer program 1010 further comprises a

decoding module 1010d for decoding the encoded block, B_e , based on the prediction C_{pred} , when the prediction, C_{pred} , is indicated to correspond to C .

[00062] The modules 1010a-d could essentially perform the actions of the flow illustrated in figure 8, to emulate the arrangement in a video decoding entity illustrated in figure 9. In other words, when the different modules 1010a-d are executed in the processing unit 1006, they correspond to the units 904-910 of figure 9.

[00063] Similarly, a corresponding alternative to the arrangement illustrated in figure 7 is possible.

[00064] Although the code means in the embodiment disclosed above in conjunction with figure 10 are implemented as computer program modules which when executed in the processing unit causes the arrangement and/ or video decoding entity to perform the actions described above in the conjunction with figures mentioned above, at least one of the code means may in alternative embodiments be implemented at least partly as hardware circuits.

[00065] The processor may be a single CPU (Central processing unit), but could also comprise two or more processing units. For example, the processor may include general purpose microprocessors; instruction set processors and/ or related chips sets and/ or special purpose microprocessors such as ASICs (Application Specific Integrated Circuit). The processor may also comprise board memory e.g. for caching purposes. The computer program may be carried by a computer program product connected to the processor. The computer program product comprises a computer readable medium on which the computer program is stored. For example, the computer program product may be a flash memory, a RAM (Random-access memory) ROM (Read-Only Memory) or an EEPROM, and the computer program modules described above could in alternative embodiments be

distributed on different computer program products in the form of memories within the decoding entity.

[00066] As previously described, it is assumed in this document that the indicators of the reference mode and one or more reference pictures used when encoding a block of pixels are jointly encoded, and thus all reference information necessary for decoding an encoded block will be represented by a single syntax element, which for example could be denoted “reference indicator”, “reference index”, “reference index symbol” or “RIS index”. This joint encoding will now be further described. The joint encoding is a procedure for representing and conveying reference information, i.e. reference mode(s) and reference picture(s), to be used for inter predictive coding and decoding. The procedure may be referred to as Reference Index Signaling, or Reference information Indicator Signaling (RIS).

[00067] When using RIS, instead of e.g. encoding an indicator of the reference mode in close association with an indicator of the partition structure, i.e. MB/ sub-MB mode, and encoding indicators of reference pictures separately, e.g. as in AVC, the indicator of reference mode and the indicator(s) of reference picture(s) associated with an encoded block are “bundled together in one place”, i.e. are jointly encoded. The joint encoding of the indicators of reference mode and reference picture(s), i.e. reference information, results in that one single syntax element, or indicator, represents all information on reference mode(s) and reference picture(s) needed, in order to decode the encoded block in a satisfactory manner. That is, once this single syntax element is given for an encoded block, a decoder should be able to identify the reference picture(s) required for decoding the block. The “syntax element” may also be denoted e.g. “syntax unit”, “joint indication unit” or “joint identification unit”.

[00068] The use of such a syntax element may provide increased error resilience for the reference information identified by the syntax element. Further the

use of such a syntax element will enable the utilization of that some combinations of reference index and reference mode are more probable than others, by enabling efficient coding of these combinations. For example, shorter code words could be assigned to more probable combinations of reference index and reference mode.

[00069] One way to describe RIS is to describe a “conversion” or mapping from a traditional representation, such as e.g. the AVC representation of reference information using two separate lists, to an illustrative representation of reference information according to RIS. Such a conversion to RIS representation could basically be made in three steps, as illustrated in figure 11.

[00070] The first step 1102 could be to form one single reference index list from multiple index lists. For example, instead of managing two reference index lists, as in AVC, all reference picture indices may be sorted in a certain order into a single joint list, as an alternative or a complement to the two lists of AVC. This is illustrated in figure 11, where the picture reference index lists I_0 and I_1 are merged, or multiplexed, into a new list L_{RIS} , in an interleaved way. Further, in a second step, 1104, the index numbers may be re-assigned accordingly, to follow a consecutive order, i.e. 0-5 in the new list L_{RIS} .

[00071] The index numbers, or entries, in the list L_{RIS} after step 1104, represent information regarding both a reference mode (backward or forward uni prediction) and a reference picture. An index to an entry in L_{RIS} may be denoted, e.g. a “RIS index” or “RIS-parameter”. The RIS index numbers 0 - 5 in L_{RIS} , after step 1104 in this example, represent uni-prediction from four past pictures (originally in $I_0 = (0,1,2,3)$), and two future pictures (originally in $I_1 = (0,1)$).

[00072] Further, one or more list entries representing bi-prediction may be added to L_{RIS} , e.g. by insertion or appending. Thus, RIS indices indicative of the entries representing bi-prediction do not point to a single reference picture but rather

to two reference pictures. Thus, a RIS index can identify a combination of a reference mode and one or more reference pictures.

[00073] Consequently, in a final step 1106, entries related to bi-prediction mode, where two reference pictures are used for prediction, may be appended consecutively to L_{RIS} , and be indicated or represented by RIS indices. For example, the entry with RIS index number 7 can be set to signal or imply that the current picture is using picture number 0 and picture number 1 as bi-prediction references. Thus, this information is inherent in the RIS index 7. Index number 8 can in a similar way be set to imply that the current picture is using picture number 0 and picture number 2 as bi-prediction references. Analogously, the list L_{RIS} may further be extended with entries representing tri-prediction, identifying three reference pictures, and so forth.

[00074] Alternatively, the steps 1104 and 1106 may be performed in the reverse order, such that the entries related to bi-prediction mode are first added, e.g. inserted or appended, and then the index numbers are re-assigned accordingly. As previously described the entries related to bi-prediction mode could also be inserted, e.g. between the entries related to uni-prediction, which would require that re-assignment of index numbers was performed after the insertion, as a complement or alternative to step 1104. In this example, the mapping is represented by a single reference list, of which the indices of the different entries represent a reference mode and one or more reference pictures. It should be noted that this is just an optional example, and that the mapping may involve several steps, and that no explicit list or record of the exemplified type is requisite for performing the mapping.

[00075] An example of the difference between an AVC reference index representation and a RIS index representation, according to an example embodiment, is shown in a table in figure 12. In this example, it is assumed that

there are four reference pictures available for coding of a current picture, of which two reference pictures are past reference pictures and two are future reference pictures. In this example RIS representation, the indices 0, 1, 3 and 4 are set to indicate uni prediction from a respective one of the four reference pictures. The indices 2 and 5 are set to indicate bi-prediction from a respective pair of the four reference pictures. It should be noted that the AVC-signaling of the reference indices also would comprise information related to partitions, since this information is coded together with the reference mode index, such as e.g. "INTER_16x16_I0". This is, however, not shown in figure 12.

[00076] In the example shown in the table in figure 12, some of the RIS indices indicating or representing bi-prediction are placed immediately after the "closest" uni-prediction RIS indices, i.e. interleaved with the indices representing uni-prediction. This RIS index representation is further illustrated in figure 13, which shows a so-called 7B hierarchical Group Of Pictures (BGOP). In the figure, the so-called "current frame" i.e. the frame to be encoded, is frame 3 in the 7B GOP. The RIS indices shown in figure 13 correspond to the RIS indices 0-7 in the table in figure 12. An alternative RIS representation could be to let the RIS indices 0-3 indicate uni-prediction, and the following RIS indices indicate bi-prediction, as in the example illustrated in figure 11.

[00077] In state of the art, e.g. using H.264, the generation of a bi-prediction block using two MVs/ reference pictures, blocks or areas, involves averaging over the two reference areas. When an MV points to a sub-pel (sub-pixel) position in a reference area, the sub-pel position pixel values need to be generated first, before averaging. The generation of sub-pel position pixel values is referred to as "spatial filtering.", i.e. the generation process involves spatial filtering of the respective reference areas. Thus, the state of the art process for generation of a bi-prediction block using two reference areas involves spatial filtering of the first area; spatial

filtering of the second area, and finally averaging over the filtered areas. Spatial filtering is relatively demanding in terms of computational complexity.

[00078] It is realized that this computational complexity could be reduced, which will be described below. In order to reduce complexity, a block may first be constructed based on integer motion, e.g. by adding the two reference blocks together (without performing spatial filtering). This adding is an operation which is relatively cheap in terms of computational complexity. Then, the resulting block may be filtered, e.g. interpolated, in order to obtain e.g. half or quarter-pel resolution. The sub-pel adjustment can be performed according to one of the MVs, or based on e.g. separately coded/ decoded additional information.

[00079] When a block is associated with more than one MV and reference index, which is here referred to as “multi-prediction”, the respective uni-directional prediction components of the multi-prediction can be determined. Uni-prediction may be referred to as “single-prediction”, as can also e.g. intra prediction. It is realized that partitioning information could be derived based on the absolute difference between these uni-directional predictions. The partitioning information could be derived both in the encoder and the decoder, in order to avoid overhead when conveying fine grained partition information.

[00080] In regions where the absolute difference between the uni-directional predictions is relatively large, a single uni-directional prediction or a special bi-prediction could be used. The single uni-directional prediction could be made according to the reference index and MV indicated in the bit stream for one of the uni-prediction components of the bi-prediction (or multi-prediction). In other regions of the block, where the absolute difference between the uni-directional predictions is relatively small, bi-prediction can be used as indicated in the bit stream for the block. The decision of whether to use a single bi-prediction/ special bi-prediction for a region, or to use the bi-prediction indicated in the bitstream, could be based e.g.

on a comparison of the absolute difference between the uni-directional predictions associated with the region and a predefined threshold.

[00081] Assuming a bi-prediction block associated with 2 MVs and 2 reference areas. Conventionally, at this stage, this block is not further divided, but is encoded as is. However, it is realized that the “implicit” information obtained from analyzing the absolute differences or the “difference map”, could be used for dividing the block into further partitions, both in the encoder and decoder.

[00082] When the absolute difference of 2 reference areas or predictions is calculated, there will be some region(s) in the difference map with higher absolute value(s) and some region(s) with lower absolute value(s). A low value of the absolute difference in a region usually represents that the same object is depicted in this region in both reference areas. If different objects would be depicted in the region in the respective reference areas, the absolute difference would be relatively large. If the same object is depicted in a corresponding region in the respective reference areas, it is suitable and appropriate to average the regions. If the corresponding regions depict different objects, it does not make sense to average them.

[00083] For example, a threshold could be defined, where difference values higher than a threshold represent “different objects regions”, and difference values lower than the threshold represent “same object regions”. The block could be partitioned in accordance with these regions, according to a predefined scheme. As previously stated, the partitioning could be performed based on implicit information, i.e. without explicit signaling describing the partitioning. Another advantage of this is that “non square partitioning” can be supported. For example, when half of a ball is depicted in one block, the partitioning of the block could be made very precise around the outline, or contour, of the ball.

[00084] The encoder could signal to the decoder if the partitioning approach described above should be used. When having signaled that the partitioning approach should be used, the encoder may optionally signal, for regions having a relatively high absolute difference value, which of the uni-directional predictions to use or which special bi-prediction to use. For example, weighted bi-prediction (other than average and possibly with DC offset) could be used. In some cases it may be needed to code/ decode some additional information to determine local parameters to be able to produce the special bi-prediction. The obtained partition information can also be used for prediction of partition information and the encoder may code changes compared to the predicted partition to be decoded and used by the decoder. Deriving partition information based on the difference between the reference areas can give a rough indication of how the partitioning should be done. Further refinement by sending refinements of the predicted partition information is also possible

[00085] One example of how to obtain the partition information is to divide the block into e.g. 4 equally sized sub-blocks. Then, the sub-block with largest normalized SAD (Sum of Absolute Differences (divided by the number of pixels on which it was calculated)) may be divided, iteratively, into 4 equally sized regions if the normalized SAD of the sub-block is e.g. equal to or larger than the normalized SAD of the 4 times larger "parent" block. Normalized SAD refers to SAD per pixel or SAD per one specific sub-block size. Instead of SAD, other metrics of pixel differences could alternatively be used. One example is a metric with more weight on strong local image structure, e.g. edges/ lines. A remaining sub-block, which is not divided further, is then set to be the partition that should use e.g. some modification of the bi-prediction or multi-prediction.

[00086] The figure 14 shows an exemplifying embodiment of the partitioning method. The block on the left side, 1402:a, is bi-predicted. SAD calculation is performed, and the high SAD areas are identified and selected out, and are

handled accordingly. In this example, the high SAD area is handled by changing to uni-directional prediction with only backward MV. Thus, the original block may be partitioned into two partitions, of which one uses the bi-prediction indicated in the bit stream, and one (illustrated as comprising circles) uses uni-prediction (one of the components of the bi-prediction). Rate Distortion Optimization (RDO) could be used to select the best uni-prediction (component of the bi-prediction).

[00087] Another example of how to obtain partitioning information is to divide e.g. a bi-prediction block into a number of e.g. equally sized sub-blocks; determine the maximum SAD of the sub-block size in question, and select the sub-blocks having a SAD “close” to, e.g. within a certain interval from, this maximum value, to be part of a region that is to use some modified version of the bi-prediction, or a uni-directional prediction.

[00088] Besides partitioning, this approach can be used e.g. to determine the previously described RIS index or state of the art reference indices, when a bi-prediction mode is used. For example, a smooth difference map for a region may suggest, and be interpreted as, that the region is possibly associated with a “bi-RIS index”. The approach could further be used as an alternative prediction or in combination with the previously described Reference Indicator index Prediction. The selection can be made in both the encoder and the decoder based on the SAD between possible candidates of bi-prediction to select the combination with least SAD.

[00089] It should be noted that with the above described multi-prediction based partitioning approach, instead of deriving a block-based partitioning, other kinds of partitioning could be derived both at the encoder and the decoder. This includes linear (e.g. horizontal, vertical, or diagonal) or non-linear partitioning of the block into two or more partitions, e.g. according to non-linear image processing methods such as edge detection and/ or segmentation. For example, the multi-prediction

difference signal can be segmented according to an image-segmentation method such as edge detection or region-growing, and then the block partition is derived based on the segmented difference signal.

[00090] The number of sub-partitions could be either derived through image-processing methods such as image segmentation, or could be signaled from the encoder to the decoder. As an alternative to linear or non-linear partitioning, also pixel-based partitioning can be applied. One variant would be to signal from the encoder to the decoder which partitioning method is used, another variant would be that the partitioning method is agreed between encoder and decoder through other signaling means. The advantage with multi-prediction based methods is that the partitioning information can be derived based on information that is already available at the encoder and the decoder, i.e. it does not have to be explicitly signaled, thus reducing the number of bits used for coding.

[00091] It should be noted that according to multi-prediction based partitioning, instead of switching from bi-prediction to uni-prediction with uni-directional MVs derived from the MVs used for bi-prediction, it is also possible to signal additional MVs and/ or prediction modes (uni-directional inter-picture prediction, bi-directional inter-picture prediction, or intra-picture prediction) for sub-partitions. In other words, the number and shapes of the partitions for a block could either be explicitly signaled and/ or be derived from implicit information, based on e.g. a segmentation method. Further, MVs and/ or prediction mode may be signaled for some or all of the resulting sub-partitions.

[00092] While the procedure as suggested above has been described with reference to specific embodiments provided as examples, the description is generally only intended to illustrate the inventive concept and should not be taken as limiting the scope of the suggested methods and arrangements, which are defined by the appended claims. While described in general terms, the methods and

arrangements may be applicable e.g. for different types of communication systems, using commonly available communication technologies, such as e.g. GSM/ EDGE, WCDMA or LTE or broadcast technologies over satellite, terrestrial, or cable e.g. DVBS, DVB-T, or DVBC, but also for storage/ retrieval of video to/ from memory.

[00093] It is also to be understood that the choice of interacting units or modules, as well as the naming of the units are only for exemplifying purpose, and video handling entities suitable to execute any of the methods described above may be configured in a plurality of alternative ways in order to be able to execute the suggested process actions.

[00094] It should also be noted that the units or modules described in this disclosure are to be regarded as logical entities and not with necessity as separate physical entities.

CLAIMS

1. Method in a video decoding entity, the method comprising:
 - obtaining (802) an encoded block, B_e , and a set of neighboring blocks of the encoded block, B_e , each neighboring block being associated with one or more reference pictures,
 - determining (804) the frequency of occurrence of a plurality of reference pictures and/or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks,
 - selecting (806) a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , to be used when decoding the encoded block, B_e ,
 - obtaining (808) an indication specifying whether the prediction, C_{pred} , corresponds to the reference picture or combination of reference pictures, C , which is to be used when decoding the encoded block, B_e , and,
 - decoding (812) the encoded block, B_e , based on the prediction, C_{pred} , when the prediction, C_{pred} , is indicated to correspond to C , thus providing a decoded block, B , of pixels.
2. Method according to claim 1, wherein the one or more reference pictures associated with each neighboring block are identified by a combination of a reference mode parameter and one or more reference picture parameters associated with the neighboring block.

3. Method according to claim 1 or 2, wherein each neighboring block is associated with one syntax element identifying the one or more reference pictures associated with the neighboring block.
4. Method according to any of the claims 1-3, wherein the determining of the frequency of occurrence of reference pictures and/or combinations of reference pictures involves the counting of reference pictures and/or combinations of reference pictures associated with the neighboring blocks.
5. Method according to claim 4, wherein at least one occurrence of a reference picture or combination of reference pictures is assigned a higher weight than another occurrence of the reference picture or combination of reference pictures, and thus contributes more to a count.
6. Method according to claim 5, wherein the assigning of weights is based on at least one of the following:
 - the match of a reference picture or combination of reference pictures associated with a neighboring block and the reference picture or combination of reference pictures of which the frequency of occurrence is determined,
 - the number of transform coefficients associated with a neighboring block,
 - the magnitude of a motion vector partition associated with a neighboring block.
7. Method according to any of the preceding claims, wherein the obtained indication is a syntax element in a received bit stream.
8. Method according to any of the claims 1-6, wherein the obtained indication is implicit.

9. Method according to any of the preceding claims, further comprising:
- when the prediction, C_{pred} , is indicated not to correspond to C :
 - obtaining (814) further information to determine which reference picture(s) to use when decoding the encoded block, B_e .
10. Method according to any of the preceding claims, wherein the determined frequency of occurrence of the reference pictures and/or combinations of reference pictures is used for mapping indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture having a higher frequency of occurrence than another is mapped to a shorter variable length codeword than the other.
11. Method according to claim 10, wherein the obtained indication is one of said code words.
12. Method according to claim 9, wherein the determined frequency of occurrence of the reference pictures and/or combinations of reference pictures is used for mapping indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture having a higher frequency of occurrence than another is mapped to a shorter variable length codeword than the other, and wherein the obtained information used for determining C is one of said code words.
13. Method according to any of the preceding claims, further comprising:
- identifying one or more sub-regions of a block associated with multi-prediction, for which sub-regions the respective corresponding regions of the multi-prediction reference blocks have a relatively low correlation

between them, and

-using an alternative prediction, instead of the multi-prediction, for the identified one or more sub-regions of the block.

14. Method according to claim 13, wherein the alternative prediction is a single-prediction or weighted multi-prediction.
15. Method according to claim 13 or 14, wherein the alternative prediction is a prediction using one of the reference blocks associated with the multi-prediction.
16. Arrangement (900) in a video decoding entity, the arrangement comprising:
 - an obtaining unit (904), adapted to obtain an encoded block, B_e , and a set of neighboring blocks of the encoded block, B_e , each neighboring block being associated with one or more reference pictures,
 - a determining unit (906), adapted to determine the frequency of occurrence of a plurality of reference pictures and/or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks,
 - a selecting unit (908), adapted to select a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , to be used when decoding the encoded block, B_e ,
 - the obtaining unit (904) being further adapted to obtain an indication specifying whether the prediction, C_{pred} , corresponds to the reference picture or combination of reference pictures, C , to be used when

decoding the encoded block, B_e , and
-a decoding unit (910), adapted to decode the encoded block, B_e ,
based on the prediction C_{pred} , when the prediction, C_{pred} , is
indicated to correspond to C , thus providing a decoded block, B , of
pixels.

17. Arrangement according to claim 16, adapted to identify the one or more reference pictures associated with each neighboring block based on a combination of a reference mode parameter and one or more reference picture parameters associated with the neighboring block.
18. Arrangement according to claims 16 or 17, further adapted to that each neighboring block is associated with one syntax element identifying the one or more reference pictures associated with the neighboring block.
19. Arrangement according to any of the claims 16-18, further adapted to determine the frequency of occurrence of reference pictures and/or combinations of reference pictures by the counting of reference pictures and/or combinations of reference pictures associated with the neighboring blocks.
20. Arrangement according to claim 19, further adapted to assign a higher weight to at least one occurrence of a reference picture or combination of reference pictures than to another occurrence of the reference picture or combination of reference pictures, the reference picture or combination of reference pictures having the higher weight thus contributing more to a count.
21. Arrangement according to claim 20, adapted to assign weights based on at least one of the following:

- the match between a reference picture or combination of reference pictures associated with a neighboring block and the reference picture or combination of reference pictures of which the frequency of occurrence is determined,
 - the number of transform coefficients associated with a neighboring block,
 - the magnitude of a motion vector partition associated with a neighboring block.
22. Arrangement according to any of the claims 16-21, adapted to obtain the indication by the decoding of a syntax element in a bit stream.
 23. Arrangement according to any of the claims 16-21, adapted to obtain the indication by the interpretation of implicit information.
 24. Arrangement according to any of claims 16-23, further adapted to obtain further information to determine which reference picture(s) to use when decoding the encoded block, B_e , when the prediction, C_{pred} , is indicated not to correspond to C.
 25. Arrangement according to any of claims 16-24, further adapted to map indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture or combination of reference pictures, having a higher frequency of occurrence than another is mapped to a shorter variable length codeword than the other.
 26. Arrangement according to claim 25, further adapted to obtain one of said code words as the indication specifying whether the prediction, C_{pred} , corresponds to C.

27. Arrangement according to claim 24, further adapted to map indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture, or combination of reference pictures, having a higher frequency of occurrence than another is mapped to a shorter variable length codeword than the other, and further adapted to obtain one of said code words as the information to use for determining C.
28. Arrangement according to any of the claims 16-27, further comprising
an identifying unit, adapted to identify one or more sub-regions of a block associated with multi-prediction, for which sub-regions the respective corresponding regions of the multi-prediction reference blocks have a relatively low correlation between them, and,
the arrangement being further adapted to use an alternative prediction, instead of the multi-prediction, for the identified one or more sub-regions of the block.
29. Arrangement according to claim 28, wherein the alternative prediction is a single-prediction or weighted multi-prediction.
30. Arrangement according to claim 28 or 29, wherein the alternative prediction is a prediction using one of the reference blocks associated with the multi-prediction.
31. Method in a video encoding entity, the method comprising:

for a block, B, of pixels having a set of encoded neighboring blocks, each neighboring block being associated with one or more reference pictures used when encoding said neighboring block:
-determining (602) the frequency of occurrence of a plurality of reference pictures and/or combinations of reference pictures amongst

the reference pictures associated with the set of neighboring blocks,
-selecting (604) a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C , used when encoding the block, B ,
-determining (608) whether the prediction, C_{pred} , corresponds to C , used when providing an encoded block B_e , by encoding of the block, B , and
-providing (610, 612) an indication specifying the result of said determination to a decoder of the block, B_e , thus enabling the decoder to determine whether a prediction derived in the decoder corresponds to the reference picture or combination of reference pictures, C , used by the encoding entity.

32. Method according to claim 31, wherein the one or more reference pictures associated with each neighboring block are identified by a combination of a reference mode parameter and one or more reference picture parameters associated with the neighboring block.
33. Method according to claim 31 or 32, wherein each neighboring block is associated with one syntax element identifying the one or more reference pictures associated with the neighboring block.
34. Method according to any of the claims 31-33, wherein the determining of the frequency of occurrence of reference pictures and/or combinations of reference pictures involves the counting of reference pictures and/or combinations of reference pictures associated with the neighboring blocks.

35. Method according to claim 34, wherein at least one occurrence of a reference picture or combination of reference pictures is assigned a higher weight than another occurrence of the reference picture or combination of reference pictures, and thus contributes more to a count.
36. Method according to claim 35, wherein the assigning of weights is based on at least one of the following:
- the match between a reference picture or combination of reference pictures associated with a neighboring block and the reference picture or combination of reference pictures of which the frequency of occurrence is determined,
 - the number of transform coefficients associated with a neighboring block,
 - the magnitude of a motion vector partition associated with a neighboring block.
37. Method according to any of the claims 31-36, wherein the result of the determining of whether the prediction, C_{pred} , corresponds to C is indicated to a decoder of the block, B_e , by means of a single syntax element.
38. Method according to any of the claims 31-36, wherein the result of the determining of whether the prediction, C_{pred} , corresponds to C is indicated to a decoder of the block, B_e , by means of implicit signaling.
39. Method according to any of the claims 31-38, further comprising:
- when the prediction, C_{pred} , is determined **not** to correspond to C :
 - providing further information identifying C to a decoder of the block B_e .

40. Method according to any of the claims 31-39, wherein the determined frequency of occurrence of the reference pictures and/or combinations of reference pictures is used for mapping indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture having a higher frequency of occurrence than another is mapped to a shorter variable length code word than the other.
41. Method according to claim 40, wherein the indication to an encoder of B_e is provided in form of one of said code words.
42. Method according to claim 39, wherein the determined frequency of occurrence of the reference pictures and/or combinations of reference pictures is used for mapping indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture having a higher frequency of occurrence than another is mapped to a shorter variable length codeword than the other, and wherein the further information identifying C to a decoder of the block B_e is provided in form of one of said code words.
43. Method according to any of the claims 31-42, further comprising:
- identifying one or more sub-regions of a block associated with multi-prediction, for which sub-regions the respective corresponding regions of the multi-prediction reference blocks have a relatively low correlation between them, and
 - using an alternative prediction, instead of the multi-prediction, for the identified one or more sub-regions of the block.
44. Method according to claim 43, wherein the alternative prediction is a single-prediction or weighted multi-prediction.

45. Method according to claim 43 or 44, wherein the alternative prediction is a prediction using one of the reference blocks associated with the multi-prediction.
46. Arrangement in a video encoding entity, the arrangement comprising:
- a determining unit (706), adapted to determine, for a block, B, having a set of encoded neighboring blocks, each being associated with one or more reference pictures used when encoding said neighboring block, the frequency of occurrence of a plurality of reference pictures and/or combinations of reference pictures amongst the reference pictures associated with the set of neighboring blocks,
 - a selecting unit (708), adapted to select a reference picture or combination of reference pictures having the highest determined frequency of occurrence amongst the reference pictures associated with the neighboring blocks, to be a prediction, C_{pred} , of the reference picture or combination of reference pictures, C, used when providing an encoded block B_e by encoding the block, B, and
- wherein the determining unit (706) is further adapted to determine whether the prediction, C_{pred} , corresponds to C, and wherein the arrangement further comprises:
- a providing unit (710), adapted to provide an indication specifying the result of said determination to a decoder of the block, B_e , thus enabling the decoder to determine whether a prediction derived in the decoder corresponds to the reference picture or combination of reference pictures, C, used by the encoding entity.
47. Arrangement according to claim 46, adapted to identify the one or more reference pictures associated with each neighboring block based

on a combination of a reference mode parameter and one or more reference picture parameters associated with the neighboring block.

48. Arrangement according to claims 46 or 47, further adapted to that each neighboring block is associated with one syntax element identifying the one or more reference pictures associated with the neighboring block.
49. Arrangement according to any of the claims 46-48, further adapted to determine the frequency of occurrence of reference pictures and/or combinations of reference pictures by the counting of reference pictures and/or combinations of reference pictures associated with the neighboring blocks.
50. Arrangement according to claim 49, further adapted to assign a higher weight to at least one occurrence of a reference picture or combination of reference pictures than to another occurrence of the reference picture or combination of reference pictures, the reference picture or combination of reference pictures having the higher weight thus contributing more to a count.
51. Arrangement according to claim 50, adapted to assign weights based on at least one of the following:
 - the match between a reference picture or combination of reference pictures associated with a neighboring block and the reference picture or combination of reference pictures of which the frequency of occurrence is determined,
 - the number of transform coefficients associated with a neighboring block,

- the magnitude of a motion vector partition associated with a neighboring block.
52. Arrangement according to any of the claims 46-51, adapted to indicate the result of the determining of whether the prediction, C_{pred} , corresponds to C by means of a single syntax element.
53. Arrangement according to any of the claims 46-51, adapted to indicate the result of the determining of whether the prediction, C_{pred} , corresponds to C by means of implicit signaling.
54. Arrangement according to any of the claims 46-53, adapted to provide further information identifying C to a decoder of the block B_e when the prediction, C_{pred} , is determined **not** to correspond to C .
55. Arrangement according to any of claims 46-54, further adapted to map indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture, or combination of reference pictures, having a higher frequency of occurrence than another is mapped to a shorter variable length codeword than the other.
56. Arrangement according to claim 55, further adapted to provide one of said code words as the indication specifying whether the prediction, C_{pred} , corresponds to C .
57. Arrangement according to claim 54, further adapted to map indicators of the reference pictures and/or combinations of reference pictures to variable length code words, such that a reference picture, or combination of reference pictures, having a higher frequency of occurrence than another is mapped to a shorter variable length

codeword than the other, and further adapted to provide one of said code words as the information to use for determining C.

58. Arrangement according to any of the claims 46-57, further comprising
-an identifying unit, adapted to identify one or more sub-regions of a block associated with multi-prediction, for which sub-regions the respective corresponding regions of the multi-prediction reference blocks have a relatively low correlation between them, and, the arrangement being further adapted to use an alternative prediction, instead of the multi-prediction, for the identified one or more sub-regions of the block.
59. Arrangement according to claim 58, wherein the alternative prediction is a single-prediction or weighted multi-prediction.
60. Arrangement according to claim 58 or 59, wherein the alternative prediction is a prediction using one of the reference blocks associated with the multi-prediction.
61. A computer program (1010), comprising computer readable code means, which when executed in one or more processing units, causes the arrangement according to any of the claims 16-30 or 46-60 to perform the corresponding procedure according to one of claims 1-15 or 31-45.
62. A computer program product (1008), comprising the computer program according to claim 61.
