(54) **Axial air gap type electric motor**

(57) The object is to provide an axial air gap type electric motor in which even if a large force to some extent is added to the vertical direction to the rotor output axis, the bearings don't damage and its long lifetime is realized. The axial air gap type electric motor (10) comprises a stator (11) and two rotors (12,13) each of which is configured almost with a discoid shape and which are arranged as facing an identical rotation axis (rotor output axis) (14) with a fixed gap. Said stator (11) has a stator core (16) comprising multiple pole members connected annually and one of the bearings (38) for fixing the rotor output axis is installed inside said stator configured annually and another bearing (41) is installed on the rotor output axis between the outside of said rotor and the load connected.

Description

TECHNICAL FIELD

[0001] The present invention relates to an axial air gap type motor comprising a stator and a rotor which are formed almost with a discoid shape and arranged as facing each other at a fixed gap at the identical rotation axis. More specifically, the present invention relates to a configuration of the axial air gap type motor for realizing a torque up without an increase of the coil diameter.

BACKGROUND ART

[0002] Conventionally, axial air gap motors (axial-direction gap type motors) exist as one of motor types. The axial air gap motors are motors in which rotors are arranged at a discoid stator as facing at a fixed gap in the axial direction and the length of the axial direction can be shortened in comparison with radial gap type motors, being advantageous to be able to make the motors thinner types. For example, JP-A-2004-282989 discloses an axial air gap motor in which the purpose is to conduct the assembly works of the stators including processing of crossovers in the axial air gap motors efficiently.

[0003] Recently, electric bicycles with a driving force by an electric motor assisted in addition to a driving force by man power which enables its comfortable running at slopes have been already proposed variously. It is desirable for electric bicycles to compactly accommodate the driving mechanism and have a light weight. From these viewpoints, the axial air gap type motor is suitable for electric bicycles because the electric motor itself can be made a thin type. This has been already proposed in JP-A-2003-219603.

[0004] When an axial air gap type electric motor is adopted for an electric bicycle, its auxiliary power is obtained by means of rotating a gear at a pedal axis by an output gear installed on a rotor output axis of the electric motor as described in JP-A-09(1997)-150777, not by installing the electric motor directly on the pedal axis of the electric bicycle. That is, a force from the load is added to the vertical direction to the rotor output axis of the axial air gap type electric motor.

[0005] Here, the axial air gap type electric motor described in the patent document 1 is one which is proposed with an assumption that a force from the load is added to the same direction as that of the rotor output axis such as rotating a fan, or that even if a force is added to the vertical direction to the rotor output axis, the force is small, and for example which is adopted for fan motors of outdoor air-conditioners.

[0006] However, when the axial air gap type electric motors are adopted for electric bicycles, it must be assumed that a strong force to some extent is added to the vertical direction to the rotor output axis. From this viewpoint, as for the axial air gap type electric motors described in the patent document 1, because two bearings

are installed as being close each other in the inner circumferential space of the stator, it is weak against a force from the vertical direction to the axis. When a force is added to the direction where such axes incline, a strong force is imposed on the ball bearing of the bearing part, which may cause damage or cause the bearing part to jounce. Moreover, if the bearing part jounces, the magnet and stator on the rotor may touch to cause a trouble.

[0007] In the present invention, the problems mentioned above are taken into considered. It is the object to provide the axial air gap type electric motor that even if a strong force to some extent is added to the vertical direction to the rotor output axis, its long lifetime is realized without damaging the bearing part.

DISCLOSURE OF THE INVENTION

[0008] In accordance with claim 1 of the present invention, an axial air gap type electric motor comprises a stator and two rotors each of which is molded substantially with a discoid shape and which are arranged as facing an identical rotation axis (rotor output axis) with a fixed gap, wherein one bearing is installed to fix a rotor output axis inside the projection surface of the stator from the vertical direction to the rotation axis and another bearing is installed in such a manner that at least a part is arranged outside the projection surface of the stator.

[0009] Because one of the bearings is installed in the inner circumferential space of the stator, even if a shock is imposed externally, no damage occurs. Because another bearing part is arranged near the load, even if a force is added to a radial direction in the rotor output axis, the force can be reduced in comparison with the conventional one. Moreover, because the interval between the bearings becomes larger than the conventional one, the force imposed on both the bearings can be reduced. These effects enable to prevent a damage of the bearing parts and prolong the lifetime.

[0010] Typically, the stator has a stator core comprising multiple pole members connected like a ring and one of the bearings for fixing the rotor output axis is installed inside the annularly molded stator and another bearing is installed on the rotor output axis between the outer side of the rotor and the connected load.

[0011] Since one of the bearings is installed in the inner circumferential space of the stator, even if a shock is imposed externally, no damage occurs. Because another bearing part is arranged near the load, even if a force is added to a radial direction in the rotor output axis, the force can be reduced in comparison with the conventional one. Moreover, because the interval between the bearings becomes larger than the conventional one, the force imposed on both the bearings can be reduced. These effects enable to prevent a damage of the bearing parts and prolong the lifetime.

[0012] Typically, multiple pole members in the stator core have a teeth with a magnetic material at each central part, the two rotors have multiple annular magnets con-

figured at positions facing the teeth of the annular stator core when each rotor faces the stator, the two rotors are fixed at the rotor output axes in such a manner that a difference is present between the distance of the magnet of one of the rotors and the teeth and the distance of the magnet of another rotor and the teeth in order to bias the rotor output axis to the axial direction by the difference of the magnetic force of the magnets.

[0013] Because a pre-compression is imposed on one of the bearings by biasing the rotor output axis to the axial direction and the ball contact face inside the ball bearing can be maintained constantly, the ball doesn't move violently and a long lifetime of the bearings can be thus realized.

[0014] Preferably, a direction to bias the rotor output axis is the same direction as the direction of a repulsion force of the axial direction from the load with which the rotor output axis is connected.

[0015] Since the direction to bias the rotor output axis is made the same direction as the direction of a repulsion force of the axial direction from the load with which the rotor is connected, a pre-compression can be imposed surely on the bearing parts and a long lifetime of the bearings can be thus realized.

[0016] One of the bearings may be fixed at the stator through a cylindrical metal bearing housing with one edge of a large opening in diameter and another edge of a small opening in diameter.

[0017] The adoption of the metal bearing housing enables to preserve the bearing parts even if a strong axial impelling force is added and protect the bearing parts firmly from shocks.

[0018] The bearing housing may have a flange part protruding to the outer circumferential direction outside the opening part with a large diameter, and the stator core and the bearing housing are molded by a synthetic resin as the flange part is pushed out to inside the resin in order to configure the stator.

[0019] Because the flange part is pushed out to inside the synthetic resin, which can disperse a compression, the bearing part can be maintained even if a strong impelling force is added and can be protected firmly from shocks.

[0020] One of the bearing part may be configured by a ball bearing, the inner circumferential side of the ball bearing is fixed at the rotor output axis, and as a bias means, the outer circumferential side is biased to the same direction as the direction to bias the rotor output axis.

[0021] Because a pre-compression is imposed on one of the bearings by bias means and the bias direction is made the same direction as the direction to bias the rotor output axis, the effect to maintain the ball contact face inside the ball bearing can be obtained more surely.

BRIEF DESCRIPTION OF THE DRAWINGS

[0022]

BEST MODE FOR CARRYING OUT THE INVENTION

[0023] The axial air gap type electric motor of the present invention comprises a stator and two rotors each of which is configured almost with a discoid shape and which are arranged as facing an identical rotation axis (rotor output axis) with a fixed gap, wherein the stator has a stator core comprising multiple pole members connected annually, one of bearings for fixing the rotor output axis is installed inside the stator configured annually and another bearing is installed on the rotor output axis between the outside of the rotor and the load connected.

[0024] Based on the following drawings, the present invention will be explained.

[0025] Fig.1 is an outlined cross-sectional diagram of the internal configuration of an axial air gap type electric motor of the present invention. As shown in Fig.1, the axial air gap type electric motor 10 comprises a roughly discoid stator 11 and a pair of rotors 12 and 13 arranged with a fixed gap on each side of the stator 11 facing each

other, wherein the rotors 12 and 13 share an identical rotor output axis 14, and the stator 11 has a bearing 15 supporting the rotor output axis 14 at the inner circumferential side.

[0026] The stator 11 comprises a stator core 16 formed like a ring (doughnut-like) with the bearing 15 inserted concentrically at the inner circumferential side of the stator core 16, which are molded by synthetic resin 18.

[0027] In addition, the word, "bearing" written in this specification, means whole configurations fixing the axes including near synthetic resins which mold pole bearing, bearing housing and bearing housing.

[0028] As shown in Fig.3 (d), the stator core 16 is formed by connecting multiple (nine in this example) pole members 17a-17i like a ring. Each of the pole members 17a-17i has an identical shape. Fig.3 (a)-(c) shows the configuration of one of the pole members 17a.

[0029] As shown in Fig.3 (a), the pole member 17a has teeth 19 (an iron core of the stator) comprising roughly H-letter shaped laminated multiple layers of metal plates. As shown in Fig.3 (b), an insulator 20 by synthetic resin is formed entirely around the teeth 19 except for the upper and lower surfaces (on the drawing). The insulator 20 can be formed in such a manner that the teeth 19 is placed in a cavity of a formed metal mold not shown in the diagram and a dissolved resin is then infused into the cavity.

[0030] In addition, besides laminated layers, the teeth can be formed uniformly by powder-formation or others. Although the teeth 19 is arranged at the center of each pole member 17a-17i in this example, the configuration of the present invention is applicable for the pole member 17a-17i without the teeth 19, namely with an air core coil.

[0031] In the insulator 20 formed as such, the whole including roughly sector shaped flanges 21 and 22 arranged as a pair of the upper and lower ones along the upper and lower surfaces of the teeth 19 is formed like a cross-sectional H-letter bobbin. In this example, the sector open angle of the flanges 21 and 22 is 40° (360°/9). Presence of the insulator 20 enables to wind a coil 23 on the teeth in an orderly manner, and also to preserve an electric insulation between the teeth 19 and coil 23. The pole member 17a shown in Fig.3 (c) is completed by winding the coil 23 at the insulator 20 formed as such. Similar procedures are taken for the other pole members 17b-17i.

[0032] As shown in Fig.3 (a)-(c), the flanges 21 and 22 of each of the pole members 17a-17i have a boss 24 formed at the outer circumferential side of either edge of the flanges 21 and 22 and an engaging chase 25 formed at the outer circumferential side of another edge as a connection means to connect adjacent pole members to each other. There are an engaging convex part 26 formed at the inner circumferential side of either edge of the flanges 21 and 22 and an engaging concave part 27 formed at the inner circumferential side of another edge. Among these connection means, the boss 24 engages with the engaging chase 25 at an adjacent pole member side, and the engaging convex part 26 engages with the

engaging concave part 27 at an adjacent pole member side.

[0033] Using the connection means, the ring-like shape of the stator core 16 is formed by 9 connections of the pole members 17a-17i. After the connections, the crossover of the coil 23 led from each pole member 17 is connected. At the flange 21, a crossover support material 28 is set to process the crossover of the coil 23.

[0034] Here, the connection method of the pole members 17a-17i is explained. Fig.2 (a) shows a circuit diagram when a conventional connection method is applied for a three-phase electric motor. The symbol of each resistive element in the diagram corresponds to the pole member (coil set). As shown in Fig.2 (a), in case of three-phase configuration of phases U, V and W, conventionally, coil sets were connected in series at each phase.

[0035] On the other hand, in the axial air gap type electric motor of the present invention, as shown in Fig.2 (b), the pole members 17a-17i are connected in parallel to form the three phases, phases U, V and W. Such parallel connection method in case of nine pole members enables to reduce the resistance level to 1/9 of that with the conventional serial connection method, consequently to increase the current level running through the coil without increasing the diameter of the coil and then to improve the torque. In addition, as for the pole members 17a-17i, they are connected in order to become phases U, V, W, U, V, W, ---. After the pole members 17a-17i are connected, as shown in Fig.3 (d), the stator core 16 is completed by connecting terminals 29 at three sites.

[0036] After the stator core 16 is formed, as shown in Fig.4, the whole stator core 16 is completed by infusing the synthetic resin 18 into the stator core for configuration of the mold insert. At that time, as shown in Fig.4 (a), a bearing housing 30 as the bearing 15 is also arranged at the center of the ring-like stator core 16 and the mold is conducted. The bearing housing 30 has a cylindrical shape whose one edge is closed except for a part through which the rotor output axis 14 passes and has a flange 31 protruding toward the outer side at the another edge. The flange 31 has a bottom-coming off preventive effect to prevent that the bearing housing 30 formed together with the stator 11 comes off from the stator 11 in configuration of the mold insert by means of decentralization of a force loaded from the rotor output axis 14 (In this example, mainly, a repulsion force of axial direction from the load and an aspiration force by a magnetic force between the rotor and stator (Fig.1)) to the synthetic resin 18.

[0037] Also, as shown in Fig.4 (a), screw receivers arranged at three sites are mold-insert formed together with the stator core 16. The screw receivers are used when a back cover 33 is fixed as shown in Fig.1 and also used to fix the cover at the output side which is not shown in the figure. As such, the stator 11 as shown in Fig.4 (b) is completed by mold-insert configuration.

[0038] Next, the configurations of the rotors 12 and 13 are explained in Fig. 5. Because the configurations of the

rotors 12 and 13 are identical, those are not distinguished in the explanation. As shown in Fig.5 (a), in a discoid back yoke 34, a circular hole 35 through which the rotor output axis 14 passes is set at the center and Mg-molded holes 36 for forming magnets 37 are set at multiple sites (In this example, 12 sites) which face the teeth 19 of the stator core 16 when the assembly is conducted at a position close to the outer circumference. Each Mg-molded hole 36 has a non-circular and long and slender shape like a crushed circle in the radial direction of the back yoke 34 at each position.

[0039] Each of the magnets 37 is formed at each of the Mg-molded hole in the back yoke 34. As shown in Fig.5 (b), each magnet 37, for example, is plastic-magnet-formed by a mixture (magnetic material) of a magnetic material and a thermoplastic resin. Fig.6 (a)-(c) are a front view showing the configurations of the rotors 12 and 13 and a cross-sectional view of A-A' line in (a) and a rear view. As shown in these views, each magnet 37 is formed to have a larger area at the front side facing the stator 11 and a smaller area at the rear side.

[0040] After plastic-magnet configuration, as shown in Fig.5(c), the magnetization is conducted in such a manner that a direction of the magnetic flux of adjacent magnets becomes toward the opposite direction in order to complete the rotors 12 and 13.

[0041] At last, the stator 11 and the rotors 12 and 13 are assembled. As shown in Fig.7, the rotor output axis 14 is formed with different diameters for individual parts in order to prevent each part to come off. First, a ball bearing 38 is fitted in the bearing housing 30 as the bearing 15 of the stator 11 and fixed and the rotor output axis 14 is then inserted from its upper part. The rotor 13 is fitted in from the back side of the stator 11 through a rotor locking part 39. Next, the rotor 12 is fitted in from the upper side of the rotor output axis 14 and a ball bearing 41 as another bearing 42 is fitted in from its upper part through a gap-maintaining part 40. As such the rotor 12 is fixed. At last, as shown Fig.1, the back cover 33 is mounted at the outer side of the rotor 13 to complete the axial air gap type electric motor of the present invention.

[0042] In addition, the ball bearing 41 as the bearing 42 installed at the outer side of the rotor 12 is not fixed under the conditions of Figs. 1 and 7, so that the axis is not stable under the conditions. However, the present invention presupposes to be used under a condition that the ball bearing 41 is fixed. For example, although not being shown in figures, it can be done that a cover can be installed at the output side similarly to the back cover and the ball bearing 41 is fixed by the cover, or parts of the opposite side connected are usable for fixation in electric bicycles applying the axial air gap type electric motor of the present invention. At that time, whatever it is a cover or a part of the opposite side, in these, a bearing 42 molding a bearing housing 43 in which the ball bearing 41 is fitted as shown in Fig.1 is installed. In fitting in the ball bearing 41, a part at the outer circumferential side of the ball bearing 41 is fitted in a bearing house 43 to-

gether with a spring part 44 at the rotor 12 side.

[0043] As shown in Fig.9, the spring part 44 is formed like a ring and with a wavy shape in which a top part 45 and a bottom part 46 are formed alternatively. For example, it is formed by metal materials. The wavy shape enables to have an elastic force to a power in axial direction and consequently to add a pre-compression at the outer circumferential side of the ball bearing 41.

[0044] Characteristics of the axial air gap type electric motor of the present invention with such configurations is explained. First, as one of characteristics, in connecting the pole members 17a-17i configuring the stator core 16, as shown in Fig.2 (b), a parallel connection is conducted. This connection method enables to reduce the resistance level of the coil to 1/9 of that with the serial connection and thus increase the current level running through the coil, consequently realizing the torque up.

[0045] However, when a parallel connection is applied for three-phase configuration, a circulating current occurs unless it is formed with a symmetry between the number of the pole members (hereafter, slot number) and the number of magnets on the rotors 12 and 13 (hereafter, pole number), which causes an adverse effect on the magnet 37, consequently on the torque. Thus, it is necessary to form with a symmetry between the slot number and the pole number in order to prevent such circulating current to occur. Because the present invention assumes the case of three-phase configuration and parallel connection, the slot number is decided to be $3n$ (n indicates an integer of 2 or higher). Thus, it is necessary to consider about a pole number to the slot number of $3n$.

[0046] Fig.8 (a) shows the relationship between the pole number and coil coefficient in case of the slot number of $3n$. In Fig.8 (a), it is assumed the case of that the connection is made as its phase changes with every one slot. Here, the coil coefficient indicates the performance (output) of the electric motor, in which a higher torque is obtained with its higher level. In Fig.8 (a), the part surrounded by a frame is with a symmetry between the slot number and the pole number, which is a combination not to cause a circulating current. Moreover, the part with a hatching has a symmetry with the highest coil coefficient, 0.866, and it is known that the ratio of the slot number: the pole number in this part is $3n:2n$ or $3n:4n$.

[0047] Next, to investigate which case of the slot number: the pole number, $3n:2n$ or $3n:4n$ results in a higher output, as shown in Fig.8 (b)-(d), comparative verifications about the efficiencies of the motors were conducted. Here, it is made: the motor efficiency = the output/the input, and the input = the output + the loss. A necessary input to obtain a constant output depends on amount of loss. Thus, as causes to reduce the efficiency, losses of the motor such as copper (due to the coil), iron (due to the iron core of the stator) and circuit (due to the inverter circuit) are listed. Among those, the loss of the iron increases with an increase of the pole number and the losses of the copper and circuit decrease with an

increase of the pole number.

[0048] Fig.8 (b) shows a comparison of the motor efficiencies between four and eight poles in case of six slots, in which the motor efficiency with four poles is made one. As shown in Fig.8 (b), in case of six slots, the eight pole case has about 1.2 times better efficiency. Similarly, its slightly better efficiency is found with 12 poles in the nine slot case shown in Fig.8 (c), and with 16 poles in the 12 slot case shown in Fig.8 (d). Thus, it can be said that as for the slot number: the pole number, $3n:4n$ results in a higher output. From this fact, the ratio of the slot number: the pole number = $3n:4n$ (n indicates an integer of 2 or higher) is adopted for the axial air gap type electric motor of the present invention.

[0049] The configuration of the magnet 37 in the rotors 12 and 13 is also one of characteristics for the present invention.

[0050] In conventional axial air gap type electric motors with an iron core, it is the slot number: the pole number = 9:8. Because the pole number is less than the slot number, the force which occurs with the iron core and is loaded on one magnet is higher. Because the use of the iron core increases the torque in comparison with coreless case, it was necessary to hold the magnets more firmly. Thus, as shown in Fig. 10 (a)-(c), in conventional rotors, one magnet is set for two holes. However, in such conventional rotors, as shown in Fig. 10 (d) or (e), the magnetic flux distribution becomes the largest at both the edges of the wave and flat at the center, which may cause a cogging torque and also influence the torque adversely.

[0051] On the other hand, in the present invention, it is the slot number: the pole number = $3n:4n$ (n indicates an integer of 2 or higher) and the number of slots is less than the number of poles. Thus, the force loaded on one magnet is reduced and the number of holes holding the magnets is one for one magnet. As shown in Fig.6 (d) or (e), because each of the magnet 37 is formed for each of the long and slender Mg-molded holes 36, the magnet at the central part is the thickest, by which the magnetic flux distribution becomes the largest at the central part of the wave. Because the wave as shown in Fig.6 (e) becomes one closer to a sine wave than the conventional wave, a cogging torque can be prevented, resulting in improvement of the torque.

[0052] Even if a higher force is added to the magnet 37 because the Mg-molded holes 36 are made with a long and slender shape as a circle is crushed in the radial direction of the back yoke 34, the magnet 37 doesn't rotate because the Mg-molded hole 36 is not a perfect circle. In addition, the Mg-molded holes 36 are not limited to the shape as shown in Fig.6 (a), shapes other than a perfect circle, for example such as ellipse, triangle, rectangle, lozenge or others, are applicable.

[0053] Moreover, the axial air gap type electric motor of the present invention is assumed to be used as an auxiliary power of electric bicycles. In such cases, as shown JP-A-2003-219603 (specifically, Fig.4) of the con-

ventional art, because the load is arranged as becoming adjacent to the rotor output axis 14 of the electric motor in the configuration to assist the pedal axis of the bicycle, a force is loaded on the bearing part by a repulsion force from the load, which may cause a damage. To solve this problem, in the present invention, among the two ball bearings 38 and 41 as the bearing parts, the ball bearing 38 is installed inside the projection plane of the stator from the vertical direction to the rotation axis, namely at the bearing housing 30 part molded with the stator core 16 in the central space of the stator 11, and another ball bearing 41 is installed outside the projection plane of the stator from the vertical direction to the rotation axis, namely outside the rotor 12 (between the rotor 12 and the load connected with the rotor output axis 14).

[0054] Such arrangement has an effect not to damage the ball bearing 38 even if a shock is added externally because the bearing part 15 is installed in the inner circumferential space of the stator 11. Because another bearing part 42 is near the load, even if a repulsion force from the load (a repulsion force in the direction of the rotor diameter and a repulsion force in the axial direction (refer to Fig.1)) is added to the rotor output axis 14, the force loaded on the ball bearing 41 can be reduced in comparison with the conventional one. Moreover, because the gap between the bearing 15 and bearing 42 becomes larger than the conventional one, the force loaded on both the bearings can be reduced. This enables to prevent a damage of the ball bearings as bearing parts and prolong the lifetime.

[0055] The bias of the rotor output axis 14 in the axial direction is made for constantly maintaining the ball contact surface inside the ball bearing 38 and prolonging the lifetime of the ball bearing 38 as the bearing part 15. The force biasing the rotor output axis 14 in the axial direction comprises a repulsion force in the axial direction receiving from the load when a driving force is transmitted to the load connected with the rotor output axis 14 and an aspiration force by a magnetic force produced between the magnet 37 set at the rotor 12 and the stator core 16. In the axial air gap type electric motor of the present invention, the two forces are loaded toward the same direction (Fig.1). Thus, a pre-compression is imposed surely on the ball bearing 38, which leads to prolong the lifetime. As for specific loading of the aspiration force by the magnetic force, a difference is set between the distance of the magnet 37 installed at the rotor 12 and the teeth 19 at the stator core 16 and the distance of the magnet 37 installed at the rotor 13 and the teeth 19 at the stator core 16. The difference enables to increase the aspiration force by the magnetic force produced between the magnet 37 and teeth 19 at one of the rotor sides and to bias the rotor output axis 14. For example, in Fig.1, it is configured in such a manner that the distance between the magnet 37 and teeth 19 in the rotor 12 becomes closer than the distance between the magnet 37 and teeth 19 in the rotor 13. Such configuration biases the whole rotor output axis 14 fixing the rotors 12 and 13 toward the right

direction as shown in Fig.1. By means of this, because a pre-compression is added to the ball bearing 38 and the ball contact surface inside the bearing becomes at a site, the ball doesn't move violently inside the bearing and consequently, a long lifetime of the ball bearing 38 as the bearing 15 can be realized. A longer lifetime effect is obtained by adjusting the direction for biasing the rotor output axis 14 to fit with the axial direction of the repulsion force from the load connected.

[0056] When the rotor output axis 14 is biased and the repulsion force of the axial direction from the load connected is added, a large force is added to the bearing part 15 and moreover, a shock from the load side may be added to the same direction. Thus, a shock resistance is required for the bearing part 15. Under the condition that the ball bearing 38 is molded directly with the synthetic resin 18, the problem of bottom-coming off may occur because the synthetic resin 18 cannot tolerate a shock. Thus, in the present invention, the bearing housing 30 is molded with the synthetic resin 18 and the ball bearing 38 is fixed in the bearing housing 30. Making the bearing housing 30 by metal improves the shock resistance. Because the flange 31 is installed in the bearing housing 30 and molded as being pushed out into the inside of the synthetic resin 18, the compression from the rotor output axis 14 can be dispersed, which improves the shock resistance. The metal-made bearing housing 30 enables to adjust the degree of thermal expansion to become roughly identical to that of the metal-made ball bearing 38, and consequently to prevent the looseness of the bearing part 15.

[0057] As for the ball bearing 41, using a spring material 44 as a bias means, the outer circumferential side of the bearing is biased to the same direction as that biasing the rotor output axis 14. In an example as shown in Fig. 1, the rotor output axis 14 is biased to the right direction by the magnetic force of the magnet 37, and the outer circumferential side of the ball bearing 41 is also biased to the right direction, using the spring material 44.

[0058] Such bias of the ball bearing intends to make the ball contact surface inside the ball bearing 41 constantly at an identical site and consequently to prolong the lifetime. A specific reason why the spring material 44 is needed as its bias means is related to the assembly processes of the axial air gap type electric motor of the present invention.

[0059] As shown in Figs. 1 and 7, the rotor output axis 14 is inserted from the upper side of the ball bearing 38 fitted in the bearing housing 30 of the stator 11, and the rotor 13 is fitted in through the rotor locking material 39 from the back face of the stator 11. Moreover, the ball bearing 41 is fitted in through the gap-holding material 40 from the upper side of the rotor 12 fitted in from the upper side of the rotor output axis 14. As such, the rotor 12 is fixed. From the stage when the rotor 12 is mounted as such, a pre-compression is added to the rotor output axis 14 toward the right direction as shown in Fig.1 because of the difference in the distance to the teeth be-

tween the rotors 12 and 13. At that time, because the outer circumferential side of the ball bearing 38 is fixed at the bearing housing 30 and the inner circumferential side is fixed at the rotor output axis 14, the inner circumferential side is pulled to the right direction by the influence of the pre-compression, and a displacement occurs as shown in Fig. 1. On the other hand, because the inner circumferential side of the ball bearing 41 is fixed at the rotor output axis 14 and the outer circumferential side is not fixed, even if a pre-compression is added, the inner and outer circumferences are influenced together and no displacement thus occurs. That is, it cannot be done to set a site as a ball contact face inside the ball bearing 41 by means of the pre-compression by the magnetic force of the magnet 37.

[0060] Thus, using another spring material 44 between the ball bearing 41 and bearing housing 43, the outer circumferential side of the ball bearing 41 is biased to the right direction and a site is set for the ball contact surface inside the ball bearing 41 in order to prolong the lifetime.

[0061] In addition, although a wavy shape material is adopted as the spring material 44 as shown in Fig.9, the material is not limited to this shape and other materials which can bias the outer circumferential side of the ball bearing 41 to the right direction are applicable.

Claims

1. An axial air gap type electric motor comprising a stator and two rotors each of which is configured substantially with a discoid shape and which are arranged about a common axis (rotor output axis) facing each other and with a fixed gap, wherein one of bearings for fixing the rotor output axis is installed inside a projection face of the stator from the vertical direction to said rotation axis and another bearing is installed in such a manner that at least a part is arranged outside the projection face of said stator.
2. The axial air gap type electric motor defined in claim 1, wherein said stator has a stator core comprising multiple pole members connected like a ring, one of the bearings for fixing the rotor output axis is installed inside said stator configured annually, and another bearing is installed on the rotor output axis between the outside of said rotor and the load connected.
3. The axial air gap type electric motor defined in claim 2, wherein the multiple pole members comprising said stator core have a teeth of a magnetic body at each of the central parts, said two rotors have multiple magnets arranged annually at positions facing said teeth of the annular stator core when each of the rotors faces said stator, the two rotors are fixed at the rotor output axis in such a manner that a difference is present between the distance of the magnets of one of the rotors and the teeth and the dis-

tance of the magnets of another rotor and the teeth in order to bias the rotor output axis to the axial direction by the difference in magnetic force of the magnets.

5

4. The axial air gap type electric motor defined in claim 3, wherein the bias direction of the rotor output axis is the same direction as the axial direction of the repulsion force from the load that said rotor output axis is connected with.

10

5. The axial air gap type electric motor defined in claims 2 and 4, wherein one of said bearings is fixed at the stator through a metal bearing housing which is cylindrical with one opening edge of a large diameter and another opening edge of a small diameter.

15

6. The axial air gap type electric motor in defined in claim 5, wherein said bearing housing has a flange which protrudes toward the outer direction outside the opening of a large diameter, and said stator is configured by molding said stator core and said bearing housing with a synthetic resin as the flange is pushed out inside the resin.

20

25

7. The axial air gap type electric motor, wherein one of said bearing comprises a ball bearing, the inner side of the ball bearing is fixed with the rotor output axis, and the outer side is biased to the same direction as the bias direction of the rotor output axis.
