FIELD

[0002] This disclosure relates generally to electrical perturbations, and more particularly, to systems and methods for analyzing effects of power quality issues on equipment in an electrical system.

BACKGROUND

[0003] As is known, power quality issues are one of the most significant and costly impacts on electrical systems (also sometimes referred to as “electrical networks”). Poor power quality is estimated to cost the European economy up to €150 billion annually, according to the Leonardo Power Quality Initiative.¹ Additionally, the U.S. economy experiences losses ranging from \$119 billion to \$188 billion annually, according to research by the Electric Power Research Institute (EPRI).² Perhaps the most important statistic is the EPRI finding that 80 percent of power-

¹ <https://adipowertuning.com/en/about-us/news-stories/148-leonardo-energy-qpan-european-power-quality-surveyq-shows-g150bn-annually-in-cost-for-low-power-quality.html>

² <https://blog.schneider-electric.com/power-management-metering-monitoring-power-quality/2015/10/16/why-poor-power-quality-costs-billions-annually-and-what-can-be-done-about-it/>

quality disturbances are generated within a facility. One exemplary economic model summarizes the total cost associated with power quality events as follows:

Total losses = production losses + restart losses + product/material losses + equipment losses + third-party costs + other miscellaneous costs³

[0004] Other miscellaneous costs associated with power quality issues may include intangible losses such as a damaged reputation with customers and suppliers or more direct losses such as the devaluation of credit ratings and stock prices.

SUMMARY

[0005] Described herein are systems and methods related to analyzing effects of power quality issues/events and other types of electrical perturbations on equipment in an electrical system. The electrical system may be associated with at least one load, process, building, facility, watercraft, aircraft, or other type of structure, for example. In one aspect of this disclosure, a method for analyzing effects of electrical perturbations on equipment in an electrical system includes processing energy-related signals from at least one intelligent electronic device (IED) in the electrical system to identify an electrical perturbation in the electrical system. The method also includes determining an end time of the electrical perturbation and analyzing electrical measurement data from prior to (e.g., immediately prior to or a predetermined time prior to), during, and/or after (e.g., immediately after or a predetermined time after) the end time of the electrical perturbation to identify and quantify the effects of the electrical perturbation on equipment in the electrical system. The effects may include equipment restarts/re-energizations due to the electrical perturbation, for example. In some embodiments, one or more actions may be taken to reduce the effects of the electrical perturbation, and thus, extend the life of the equipment. The actions may include, for example, at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system. As is known, the equipment restarts/re-energizations may produce or lead to stresses (e.g., electrical, thermal and mechanical) that may shorten the life

³ The Cost of Poor Power Quality, Roman Targosz and David Chapman, October 2015, ECI Publication No. Cu0145

of the equipment. Therefore, it is desirable to reduce the effects of the electrical perturbation (e.g., equipment restarts/re-energizations) and extend the operational life of the equipment. [0006] In some embodiments, the above method may be implemented on the at least one IED. Additionally, in some embodiments the above method may be implemented partially or fully remote from the at least one IED, for example, in a gateway, a cloud-based system, on-site software, a remote server, etc. (which may alternatively be referred to as a “head-end” system herein). In some embodiments, the at least one IED may be coupled to measure energy-related signals, receive electrical measurement data from or derived from the energy-related signals at an input, and configured to generate at least one or more outputs. The outputs may be used to analyze effects of electrical perturbations on equipment in an electrical system. Examples of the at least one IED may include a smart utility meter, a power quality meter, and/or another metering device (or devices). The at least one IED may include breakers, relays, power quality correction devices, uninterruptible power supplies (UPSs), filters, and/or variable speed drives (VSDs), for example. Additionally, the at least one IED may include at least one virtual meter in some embodiments.

[0007] In embodiments, the above method is generally applicable to aperiodic power quality issues or events such as transients, short-duration rms variations (e.g., sags, swells, momentary interruptions, temporary interruptions, etc.), and some long-duration rms variations (e.g., that may be as long as about 1-5 minute(s)).

[0008] Examples of electrical measurement data that may be captured by the at least one IED may include at least one of continuously or semi-continuously measured voltage and current signals and their derived parameters and characteristics. Electrical parameters and events may be derived, for example, from analyzing energy-related signals (e.g., real power, reactive power, apparent power, harmonic distortion, phase imbalance, frequency, voltage/current transients, voltage sags, voltage swells, etc.). More particularly, the at least one IED may evaluate a power quality event’s magnitude, duration, load impact, recovery time from impact,

unproductive recovery energy consumed, CO₂ emissions from recovery energy, costs associated with the event, and so forth.

[0009] It is understood there are types of power quality events and there are certain characteristics of these types of power quality events, as described further below in connection with paragraph [0030] and the table from IEEE Standard 1159-2009 (known art) provided beneath paragraph [0030], for example. A voltage sag is one example type of power quality event. The distinctive characteristics of voltage sag events are the magnitude of the voltage sag and its duration, for example. As used herein, examples of power quality events may include voltage events impacting phase, neutral, and/or ground conductors and/or paths.

[0010] The above method, and the other methods (and systems) described below, may include one or more of the following features either individually or in combination with other features in some embodiments. For example, in some embodiments the energy-related signals captured by the at least one IED include at least one of: a voltage signal, a current signal, and a derived energy-related value. In some embodiments, the derived energy-related value includes at least one of: a calculated, derived, developed, interpolated, extrapolated, evaluated, and otherwise determined additional energy-related value from the at least one of the voltage signal and the current signal. Additionally, in some embodiments the derived energy-related value(s) include(s) at least one of: active power, apparent power, reactive power, energy, harmonic distortion, power factor, harmonic power, harmonic voltages, harmonic currents, interharmonic currents, interharmonic voltages, interharmonic power, individual phase currents, phase angle, impedance, sequence component, total voltage harmonic distortion, total current harmonic distortion, three-phase currents, phase voltage(s), line voltage(s) or other similar parameters. Further, in some embodiments the derived energy-related value(s) include(s) at least one energy-related characteristic, the energy-related characteristic including magnitude, phase angle, duration, associated frequency components, impedance, energy-related parameter shape, and decay rate. It is understood that the energy-related signals may

include (or leverage) substantially any electrical parameter derived from voltage and current signals (including the voltages and currents themselves), for example.

[0011] In some embodiments, communicating the equipment restarts/re-energizations may include communicating the equipment restarts/re-energizations via at least one of: a report, a text, an email, audibly, and an interface of a screen/display. The report, text, etc. may provide actionable recommendations for responding to the electrical perturbation. In some embodiments, communicating the equipment restarts/re-energizations may additionally or alternatively include indicating the equipment restarts/re-energizations on at least one dynamic tolerance curve associated with the electrical system. Each dynamic tolerance curve of the at least one dynamic tolerance curve may, for example, characterize a response characteristic of the electrical system at a respective metering point of a plurality of metering points in the electrical system. In some embodiments, at least one of severity, magnitude, phase, phase angle, duration, location, process and equipment/load(s) impacted by the electrical perturbation may be indicated on the at least one dynamic tolerance curve.

[0012] In some embodiments, data (e.g., the above reference severity, magnitude, etc.) from the at least one dynamic tolerance curve may be selectively aggregated to analyze effects of electrical perturbations on equipment in an electrical system. In some embodiments, electrical measurement data from or derived from energy-related signals captured by the at least one IED may continue to be processed to optimize the at least one dynamic tolerance curve and the analysis of the effects of the electrical perturbations.

[0013] In some embodiments, at least one dynamic tolerance curve is tagged with relevant and characterizing information based on information extracted about the electrical perturbation. Examples of relevant and characterizing information may include at least one of: severity (magnitude), phase, phase angle, duration, power quality type (e.g., sag, swell, interruption, oscillatory transient, impulsive transient, etc.), time of occurrence, process(es) involved, location, equipment impacted, relative or absolute impact, recovery time, periodicity of events

or event types, etc. Additionally, examples of relevant and characterizing information may include at least one of: information about activities occurring before, during, or after the electrical perturbation, such as a measured load change correlating with an electrical perturbation, or a particular load or apparatus switching on or off before, during or after the electrical perturbation. In some embodiments, the information about the electrical perturbation may be extracted from portions of the electrical measurement data taken prior to a start time of the electrical perturbation, during the electrical perturbation, and/or after the conclusion of the electrical perturbation. In some embodiments, the electrical measurement data taken prior to a start time of the electrical perturbation corresponds to electrical measurement data taken immediately (or a predetermined time) prior to the electrical perturbation, and the electrical measurement data taken after the conclusion (i.e., the end time) of the electrical perturbation corresponds to electrical measurement data taken immediately (or a predetermined time) after the electrical perturbation.

[0014] In some embodiments, power quality event(s) which impact a load/equipment and lead to restarts/re-energizations, power quality event(s) which impact a load/equipment but do not lead to restarts/ re-energizations, and power quality event(s) which do not impact a load/equipment and do not lead to restarts/re-energizations, are identified and indicated on the at least one dynamic tolerance curve. Power quality event(s) which impact a load/equipment and lead to restarts/re-energizations may be identified and indicated through a process, for example, in which a power quality event occurs, a load loss event is identified, and data (e.g., captured by the at least one IED, and presented on the at least one dynamic tolerance curve) indicates restarts/re-energizations successfully or unsuccessfully attempted after the power quality event has concluded. Additionally, power quality event(s) which impact a load/equipment but do not lead to restarts/ re-energizations may be identified and indicated through a process, for example, in which a power quality event occurs, a load loss event is identified, and data (e.g., captured by the at least one IED, and presented on the at least one dynamic tolerance curve) indicates no restarts/no re-energization attempted after the power quality event has concluded. Further, power quality event(s) which do not impact a

load/equipment and do not lead to restarts/re-energizations may be identified and indicated through a process, for example, in which a power quality event occurs, and no load loss event is identified, resulting in no indications of restarts/re-energization attempts being presented on the at least one dynamic tolerance curve. In some embodiments, attempts to restart/re-energize loads/equipment may also be determined (e.g., by analyzing power factor levels, as described further in the Detail Description section) and indicated on the at least one dynamic tolerance curve.

[0015] In some embodiments, the tolerance curve may be displayed in a graphical user interface (GUI) of at least one IED, or a GUI of a control system used for monitoring or controlling one or more parameters associated with the electrical system. In embodiments, the control system may be a meter, an IED, on-site/head-end software (i.e., a software system), a cloud-based control system, a gateway, a system in which data is routed over the Ethernet or some other communications system, etc. A warning/alarm may be displayed in the GUI of the IED, the monitoring system or the control system, for example, in response to a determined impact (or severity) of the electrical perturbation being outside of a range or threshold. In some embodiments, the range is a predetermined range, for example, a user configured range. Additionally, in some embodiments the range is automatic, for example, using standards-based thresholds. Further, in some embodiments the range is “learned,” for example, by starting with a nominal voltage and pushing out the thresholds as non-impactful events occur in the natural course of the electrical network’s operation. A warning/alarm may also be displayed/triggered in response to equipment restarting/re-energizing immediately after the electrical perturbation, for example.

[0016] The GUI may be configured to display factors contributing to the electrical perturbation. Additionally, the GUI may be configured to indicate a location of the electrical perturbation in the electrical system. Further, the GUI may be configured to indicate how loads (or another specific system or piece of equipment in the electrical system) will respond to the electrical perturbation. It is understood that any number of information may be displayed in the GUI. As

part of this invention, any electrical parameter, impact to a parameter, I/O status input, I/O output, process impact, recovery time, time of impact, phases impacted, potentially discrete loads impacted beneath a single IED, etc. may be displayed in the GUI. FIG. 20, for example, as will be discussed further below, shows a simple example of incorporating percent load impacted with an indication of recovery time.

[0017] In some embodiments, the tolerance curve displayed in the GUI does not have fixed scaling but, rather, can (and needs to) auto-scale, for example, to capture or display a plurality of power quality events. In accordance with various aspects of the disclosure, the benefit of having a dynamic tolerance curve is not being constrained to a static curve or curves (e.g., with fixed scaling). For example, referring briefly to FIG. 2 (which will be discussed further below), while the y-axis is shown as a percent of nominal in FIG. 2, it can also be shown as an absolute nominal value (e.g., 120 volts, 208 volts, 240 volts, 277 volts, 480 volts, 2400 volts, 4160 volts, 7.2kV, 12.47kV, etc.). In this case, auto-scaling would be required because different voltage ranges would require different scaling for the y-axis. Additionally, the x-axis may be scaled in different units (e.g., cycles, seconds, etc.) and/or may have a variable maximum terminus point (e.g., 10 seconds, 1 minute, 5 minutes, 600 cycles, 3600 cycles, 18,000 cycles, etc.). In other words, in some embodiments there is no reason for the GUI to show more than it has to.

[0018] In some embodiments, the control system associated with the GUI (or otherwise) may automatically control at least one component in response to the electrical perturbation (and communicated equipment restarts/re-energizations), for example, based on an analysis of the dynamic tolerance curve. The at least one component may correspond to at least one of the equipment experiencing restarts/re-energizations due to the electrical perturbation, for example. In some embodiments, the at least one component is controlled in response to a control signal generated by the control system, with the control signal indicating/providing for adjustment of at least one parameter associated with the at least one component, other associated components/loads/equipment, or the electrical system.

[0019] In some embodiments, the energy-related signals processed to identify the electrical perturbation, and the electrical measurement data analyzed to identify and quantify the effects of the electrical perturbation on equipment in the electrical system, may be continuously or semi-continuously captured by the at least one IED, and the tolerance curves may be dynamically updated in response thereto. For example, the tolerance curve may initially be generated in response to electrical perturbations identified from energy-related signals captured at a first time, and may be updated or revised in response to (e.g., to include or incorporate) electrical perturbations identified from energy-related signals captured at a second time. As events are captured, the tolerance curve (also sometimes referred to herein as “a dynamic tolerance curve”) may be continuously (e.g., dynamically) updated according to the unique response of the electrical system.

[0020] In some embodiments, analyzing electrical measurement data, for example, from prior to, during, and/or after the end time of the electrical perturbation, includes: considering changes with respect to the time prior to the electrical perturbation in the at least one of the voltage signal, the current signal, and the derived energy value. In some embodiments, the changes to be considered include at least one of a change in the true and/or displacement power factor, impedance, signal shape, voltage signal distortion, current signal distortion, and power signal distortion. Additionally, the changes to be considered indicate the equipment restarts/re-energizations. In accordance with embodiments of this disclosure, it is possible to see a restart during an electrical perturbation, for example, where a voltage sag moves from Phase A (i.e., a first phase) to Phase B (i.e., a second phase). In this example, the entire perturbation would include the period of time when Phase A and Phase B were in a voltage sag period, but single-phase loads on phase A could begin to recover while phase B was still experiencing a voltage sag.

[0021] In some embodiments, the electrical perturbation identified in the electrical system includes at least one of a voltage perturbation, a current perturbation, and a derived energy value perturbation. In some embodiments, the voltage perturbation includes at least one of a

voltage sag, a voltage swell, a voltage transient, a voltage interruption, and a long-duration root-mean-square (rms) variation.

[0022] In some embodiments, the end time of the electrical perturbation is determined by the at least one IED indicating the voltage has recovered to a range within the nominal voltage. In one aspect, a threshold above the nominal voltage is indicative of transients, swells, or overvoltages. Additionally, in one aspect the threshold below the nominal voltage is indicative of sags, interruptions, notches, or undervoltages.

[0023] In another aspect of this disclosure, a method for analyzing effects of electrical perturbations on equipment in an electrical system includes processing energy-related signals from at least one IED in the electrical system to identify an electrical perturbation in the electrical system. Electrical measurement data from or derived from the energy-related signals is analyzed to identify and quantify the effects of the electrical perturbation on equipment in the electrical system. The effects may include, for example, equipment restarts/re-energizations due to the electrical perturbation. In some embodiments, one or more actions are taken to reduce the effects of the electrical perturbation and extend the life of the equipment. The actions may include, for example, at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.

[0024] In a further aspect of this disclosure, a system for analyzing effects of electrical perturbations on equipment in an electrical system is provided. The system includes at least one processor and at least one memory device coupled to the at least one processor. The at least one processor and the at least one memory device are configured to process energy-related signals from at least one IED in the electrical system to identify an electrical perturbation in the electrical system. The at least one processor and the at least one memory device are also configured to determine an end time of the electrical perturbation and analyze electrical measurement data from prior to, during, and/or after the end time of the electrical

perturbation to identify and quantify the effects of the electrical perturbation on equipment in the electrical system. The effects may include, for example, equipment restarts/re-energizing due to the electrical perturbation. The at least one processor and the at least one memory device are further configured to take one or more actions to reduce the effects of the electrical perturbation and extend the life of the equipment. The actions may include, for example, at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.

[0025] In some embodiments, the metering devices (e.g., IEDs) and equipment/loads of the above and below described systems and methods are installed, located or derived from different respective locations (i.e., a plurality of locations) or metering points in the electrical system. A particular IED (e.g., a second IED) may be upstream from another IED (e.g., a third IED) in the electrical system while being downstream from a further IED (e.g., a first IED) in the electrical system, for example.

[0026] As used herein, the terms “upstream” and “downstream” are used to refer to electrical locations within an electrical system. More particularly, the electrical locations “upstream” and “downstream” are relative to an electrical location of an IED collecting data and providing this information. For example, in an electrical system including a plurality of IEDs, one or more IEDs may be positioned (or installed) at an electrical location that is upstream relative to one or more other IEDs in the electrical system, and the one or more IEDs may be positioned (or installed) at an electrical location that is downstream relative to one or more further IEDs in the electrical system. A first IED or load that is positioned on an electrical circuit upstream from a second IED or load may, for example, be positioned electrically closer to an input or source of the electrical system (e.g., a utility feed) than the second IED or load. Conversely, a first IED or load that is positioned on an electrical circuit downstream from a second IED or load may be positioned electrically closer to an end or terminus of the electrical system than the other IED.

[0027] A first IED or load that is electrically connected in parallel (e.g., on an electrical circuit) with a second IED or load may be considered to be “electrically” upstream from said second IED or load in embodiments, and vice versa. In embodiments, algorithm(s) used for determining a direction of a power quality event (i.e., upstream or downstream) is/are located (or stored) in the IED, cloud, on-site software, gateway, etc. As one example, the IED can record an electrical event’s voltage and current phase information (e.g., by sampling the respective signals) and communicatively transmit this information to a cloud-based system. The cloud-based system may then analyze the voltage and current phase information (e.g., instantaneous, root-mean-square (rms), waveforms and/or other electrical characteristic) to determine if the source of the power quality event was electrically upstream or downstream from where the IED is electrically coupled to the electrical system (or network).

[0028] With respect to the present invention, it is understood that the at least one IED responsible for capturing the energy-related signals may be upstream or downstream from the equipment/loads for which it is identifying equipment restarts/re-energizations due to a power quality event, and other types of electrical perturbations.

[0029] As used herein, a load loss (sometimes also referred to as a “loss of load”) is the unexpected, unplanned and/or unintentional removal of one or more equipment/loads from the electrical system. In this application, a voltage perturbation or event, and the subsequent load loss, is likely a result of one or more external influences on the electrical system (e.g., a fault, etc.), or the normal or abnormal operation of loads, protective devices, mitigation devices, and/or other equipment intentionally connected to the electrical system. Load losses may be indicated by measured parameters such as voltage, current, power, energy, harmonic distortion, imbalance, etc., or they may be indicated by discrete (digital) and/or analog input-output (I/O) signals originating from equipment directly and/or indirectly connected to the electrical system and/or other energy-related signals derived from the energy-related (e.g., voltage and/or current) signals. For example, breakers often provide an output indication on their present position (e.g., open/closed, off/on, etc.) to communicate their operational status.

[0030] As discussed above, a voltage event is one example type of power quality event, and a power quality event is one example type of electrical perturbation. A power quality event may include at least one of a voltage sag, a voltage swell, and a voltage transient, for example. According to IEEE Standard 1159-2009, for example, a voltage sag is a decrease to between 0.1 and 0.9 per unit (pu) in rms voltage or current at the power frequency for durations of 0.5 cycle to 1 min. Typical values are 0.1 to 0.9 pu. Additionally, according to IEEE Standard 1159-2009, a voltage swell is an increase in rms voltage or current at the power frequency for durations from 0.5 cycles to 1 min. Below is a table from IEEE Standard 1159-2009 (known art), which defines various categories and characteristics of power system electromagnetic phenomena.

Categories	Typical spectral content	Typical duration	Typical voltage magnitude
1.0 Transients			
1.1 Impulsive			
1.1.1 Nanosecond	5 ns rise	< 50 ns	
1.1.2 Microsecond	1 μ s rise	50 ns–1 ms	
1.1.3 Millisecond	0.1 ms rise	> 1 μ s	
1.2 Oscillatory			
1.2.1 Low frequency	< 3 kHz	0.5–50 ms	0–4 pu
1.2.2 Medium frequency	5–500 kHz	20 μ s	0–8 pu
1.2.3 High frequency	0.5–5 MHz	5 μ s	0–4 pu
2.0 Short duration variations			
2.1 Instantaneous			
2.1.1 Sag		0.5–30 cycles	0.1–0.9 pu
2.1.2 Swell		0.5–30 cycles	1.1–3.8 pu
2.2 Momentary			
2.2.1 Interruption		0.5 cycles–3 s	< 0.1 pu
2.2.2 Sag		30 cycles–3 s	0.1–0.9 pu
2.2.3 Swell		30 cycles–3 s	1.1–3.4 pu
2.3 Temporary			
2.3.1 Interruption		3 s–1 min	< 0.1 pu
2.3.2 Sag		3 s–1 min	0.1–0.9 pu
2.3.3 Swell		3 s–1 min	1.1–3.2 pu
3.0 Long duration variations			
3.1 Interruption, sustained		> 1 min	0.0 pu
3.2 Undervoltages		> 1 min	0.8–0.9 pu
3.3 Overvoltages		> 1 min	1.1–3.2 pu
4.0 Voltage imbalance		steady state	0.5–2%
5.0 Waveform distortion			
5.1 DC offset		steady state	0–0.1%
5.2 Harmonics	0–1000 Hz	steady state	0–20%
5.3 Interharmonics	0–6 kHz	steady state	0–2%
5.4 Notching		steady state	
5.5 Noise	broad-band	steady state	0–1%
6.0 Voltage fluctuations	< 25 Hz	intermittent	0.1–7%
7.0 Power frequency variations		< 10 s	

[0031] It is understood that the above table is one standards body's (IEEE in this case) way of defining/characterizing power quality events. It is understood there are other standards that

define power quality categories/events as well, such as the International Electrotechnical Commission (IEC), American National Standards Institute (ANSI), etc., which may have different descriptions or power quality event types, characteristics, and terminology. It is also understood that the types and descriptions of power quality events may change over time, and the systems and methods disclosed herein are intended to be applicable to current and future types and descriptions of power quality events. For example, IEEE approved a revision to IEEE 1159-2009 in June 2019, which standard (IEEE 1159-2019) may have ways for defining the power quality categories/events set forth in the above table. In accordance with embodiments of this disclosure, power quality events may additionally or alternatively be customized power quality events (e.g., defined by a user).

[0032] As used herein, an IED is a computational electronic device optimized to perform a particular function or set of functions. As discussed above, examples of IEDs include smart utility meters, power quality meters, and other metering devices. IEDs may also be imbedded in variable speed drives (VSDs), uninterruptible power supplies (UPSs), circuit breakers, relays, transformers, or any other electrical apparatus. IEDs may be used to perform monitoring and control functions in a wide variety of installations. The installations may include utility systems, industrial facilities, warehouses, office buildings or other commercial complexes, campus facilities, computing co-location centers, data centers, power distribution networks, and the like. For example, where the IED is an electrical power monitoring device, it may be coupled to (or be installed in) an electrical power distribution system and configured to sense and store data as electrical parameters representing operating characteristics (e.g., voltage, current, waveform distortion, power, etc.) of the power distribution system. These parameters and characteristics may be analyzed by a user to evaluate potential performance, reliability or power quality-related issues. The IED may include at least a controller (which in certain IEDs can be configured to run one or more applications simultaneously, serially, or both), firmware, a memory, a communications interface, and connectors that connect the IED to external systems, devices, and/or components at any voltage level, configuration, and/or type (e.g., AC,

DC). At least certain aspects of the monitoring and control functionality of a IED may be embodied in a computer program that is accessible by the IED.

[0033] In some embodiments, the term “IED” as used herein may refer to a hierarchy of IEDs operating in parallel and/or tandem. For example, an IED may correspond to a hierarchy of energy meters, power meters, and/or other types of resource meters. The hierarchy may comprise a tree-based hierarchy, such a binary tree, a tree having one or more child nodes descending from each parent node or nodes, or combinations thereof, wherein each node represents a specific IED. In some instances, the hierarchy of IEDs may share data or hardware resources and may execute shared software.

[0034] The features proposed in this disclosure evaluate specific power quality events to quantify their impact on equipment, including operational effects considered potentially detrimental to many types of loads. Its scope may include discrete metered points, network zones, and/or the aggregated electrical system in total. This feature may be deployed in hardware, gateways, on-site (edge) software, cloud-based applications and/or other on-site/off-site usages. It may also provide opportunities for additional products and services as described below. Novel ideas to evaluate and display potentially damaging characteristics associated with various power quality events are provided, allowing the end-user to more efficiently and cost-effectively identify, mitigate, and manage their electrical networks.

[0035] Of the seven recognized power quality categories defined by IEEE 1159-2009, short-duration root mean square (rms) variations are generally the most disruptive and have the largest universal economic impact on energy consumers. Short-duration rms variations include voltage sags/dips, swells, momentary interruptions and temporary interruptions. One example study by the Electric Power Research Institute (EPRI) estimates an average of about 66 voltage sags are experienced by industrial customers each year. As the trend of industries becoming more dependent on sag-sensitive equipment has increased, so has the impact of these events.

[0036] The prevalence of voltage sags and the consequences of a growing install base of sag-sensitive equipment present many additional opportunities for electric solutions and services providers. The table below illustrates several example opportunities:

Opportunities	Benefits
<i>Solutions</i>	Increased monitoring systems components
	More suitable sag-immunity equipment
	Targeted sag mitigation equipment
<i>Services</i>	Engineering and consulting
	Remote monitoring and diagnostics
	Equipment installation

BRIEF DESCRIPTION OF THE DRAWINGS

[0037] The foregoing features of the disclosure, as well as the disclosure itself may be more fully understood from the following detailed description of the drawings, in which:

[0038] FIG. 1 shows a graphical view of several example power quality categories;

[0039] FIG. 1A shows an example electrical system in accordance with embodiments of the disclosure;

[0040] FIG. 1B shows an example intelligent electronic device (IED) that may be used in an electrical system in accordance with embodiments of the disclosure;

[0041] FIG. 2 shows an example Information Technology Industry (ITI) curve (also sometimes referred to as a “power acceptability curve”);

[0042] FIG. 3 shows an example baseline voltage tolerance curve which could be the ITI curve (as illustrated) or some other unique relationship between an event’s voltage magnitude and duration;

[0043] FIG. 4 shows an example voltage sag event on a baseline voltage tolerance curve;

[0044] FIG. 5 shows an example recommended change to the baseline voltage tolerance curve of FIG. 3 based on an impact of the voltage sag event shown in FIG. 4;

[0045] FIG. 6 shows an example dynamically customized and updated voltage tolerance curve;

[0046] FIG. 7 shows an example of a multitude of impactful and non-impactful voltage sags, swells, and transients on a voltage tolerance curve;

[0047] FIG. 8 shows a dynamically customized and updated voltage tolerance curve for a multitude of impactful and non-impactful events;

[0048] FIG. 9 shows an example three-dimensional (3-D) tolerance-impact curve with load(s) impact;

[0049] FIG. 10 shows an example 3-D tolerance-impact curve with gradient color shading indicating severity of load(s) impact;

[0050] FIG. 11 shows an example 3-D tolerance-impact curve with a sample event indicating severity of load(s) impact;

[0051] FIG. 12 shows an example 3-D tolerance-impact curve with recovery time;

[0052] FIG. 13 shows an example 3-D tolerance-impact curve with gradient color shading indicating length of recovery time;

[0053] FIG. 14 shows an example 3-D tolerance-impact curve with a sample event indicating length of recovery time;

[0054] FIG. 15 shows another example 3-D tolerance-impact curve with a sample event indicating production losses as an economic impact;

[0055] FIG. 16 shows an example simple electrical network with a fault;

[0056] FIG. 16A shows another example electrical network with a fault;

[0057] FIG. 17 shows an example customized tolerance curve with a multitude of impactful and non-impactful upstream and downstream events;

[0058] FIG. 18 shows an example customized tolerance curve with a multitude of impactful and non-impactful disaggregated upstream events;

[0059] FIG. 19 shows an example customized tolerance curve with a multitude of impactful and non-impactful disaggregated downstream events;

[0060] FIG. 20 shows an example 3-D tolerance-impact curve with load impact, recovery time and upstream/downstream event sources indicated for a multitude of events;

[0061] FIG. 21 is a diagram showing an example progression of costs to mitigate voltage events;

[0062] FIG. 22 shows an example customized and updated tolerance curve for the voltage sag event illustrated in FIG. 4;

[0063] FIG. 23 shows the SEMI F47 curve superimposed on the plot illustrated in FIG. 22;

[0064] FIG. 24 shows example ride-through benefits of a sag mitigation device in an electrical system, one example of which is SagFighter® by Schneider Electric;

[0065] FIG. 25 shows an example of a multitude of potentially avoided load impact events with a sag mitigation device;

[0066] FIG. 26 shows another example of a multitude of potentially avoided load impacting events and their aggregated recovery time with a sag mitigation device;

[0067] FIG. 27 shows an example of the predicted impact of installing a voltage event mitigation device;

[0068] FIG. 28 shows an example of the actual impact of installing a voltage event mitigation device;

[0069] FIG. 29 shows an example of a simple electrical system with a plurality of IEDs;

[0070] FIG. 30 shows an example recovery timeline for a plurality of IED types experiencing a voltage event;

[0071] FIG. 30A illustrates an example of virtual metering being used to identify an impact of a voltage event on unmetered loads;

[0072] FIG. 30B shows an example electrical system in accordance with embodiments of this disclosure;

[0073] FIGS. 30C-30E show example dynamic tolerance curves in accordance with embodiments of this disclosure;

[0074] FIG. 30F-30I show further example electrical systems in accordance with embodiments of this disclosure;

[0075] FIG. 31 shows an example fault on the simple electrical system of FIG. 29;

[0076] FIG. 32 shows example zones of the simple electrical system of FIG. 29, for example, based on step-down transformer locations;

[0077] FIG. 33 shows an example customized zone configuration of the simple electrical system of FIG. 29;

[0078] FIG. 34 shows an example of a simple voltage tolerance curve (also sometimes referred to as a power acceptability curve);

[0079] FIG. 35 shows an example voltage sag event shown on the simple voltage tolerance curve of FIG. 34;

[0080] FIG. 36 shows an example updated voltage tolerance curve after the voltage sag event illustrated in FIG. 35;

[0081] FIG. 37 shows an example second voltage sag event on the voltage tolerance curve illustrated in FIG. 36;

[0082] FIG. 38 shows an example updated voltage tolerance curve after the second voltage sag event illustrated in FIG. 37;

[0083] FIG. 39 shows a third example voltage sag event on the voltage tolerance curve illustrated in FIG. 38;

[0084] FIG. 40 shows an example voltage tolerance curve after the third voltage sag event illustrated in FIG. 39;

[0085] FIG. 41 is a plot showing measured load(s) versus time for an example impactful voltage event;

[0086] FIG. 42 is a plot showing measured load(s) versus time for multiple example impactful voltage events;

[0087] FIG. 43 is a plot showing measured, typical and expected load(s) versus time for an example voltage event;

[0088] FIG. 44 is a plot showing percent load impact versus time;

[0089] FIG. 45 is a flowchart illustrating an example method for managing power quality events (or disturbances) in an electrical system;

[0090] FIG. 46 is a flowchart illustrating an example method for quantifying power quality events (or disturbances) in an electrical system;

[0091] FIG. 47 is a flowchart illustrating an example method for expanded qualified lead generation for power quality;

[0092] FIG. 48 is a flowchart illustrating an example method for generating a dynamic tolerance curve for power quality;

[0093] FIG. 49 shows an illustrative waveform;

[0094] FIG. 50 shows another illustrative waveform;

[0095] FIG. 51 is a flowchart illustrating an example method for characterizing power quality events in an electrical system;

[0096] FIG. 52 is a flowchart illustrating an example method for characterizing an impact of a power quality event on an electric system;

[0097] FIG. 53 is a flowchart illustrating an example method for reducing recovery time from a power quality event in an electrical system, for example, by tracking a response characteristic of the electrical system.

[0098] FIG. 54 is a flowchart illustrating an example method for analyzing power quality events in an electrical system;

[0099] FIG. 55 is a flowchart illustrating an example method for analyzing effects of electrical perturbations on loads/equipment in an electrical system;

[0100] FIG. 56 is a flowchart illustrating an example method for identifying, quantifying and communicating the effects of electrical perturbations;

[0101] FIG. 57 illustrates an example process for analyzing electrical measurement data to identify and quantify the effects of an electrical perturbation on loads/equipment in an electrical system;

[0102] FIGS. 57A illustrates an example dynamic tolerance curve that may be generated based on the example method illustrated in FIG. 56, and the example process illustrated in FIG. 57, for example;

[0103] FIG. 58 illustrates another example process for analyzing electrical measurement data to identify and quantify the effects of an electrical perturbation on loads/equipment in an electrical system;

[0104] FIG. 59 illustrates how slip frequencies may indicate that a motor (or another load) is restarting or has restarted;

[0105] FIG. 59A shows an example root mean square (rms) real power waveform of a voltage sag event resulting in a load/equipment restart;

[0106] FIG. 59B shows an example voltage waveform signature;

[0107] FIG. 59C shows an example current waveform signature for a single-phase rectifier;

[0108] FIG. 59D shows an example current waveform signature for a three-phase rectifier;

[0109] FIG. 60 is a flowchart illustrating an example method for taking actions to reduce stresses and extend the life of loads/equipment in an electrical system; and

[0110] FIG. 61 is a flowchart illustrating an example method for evaluating the effectiveness of actions taken to reduce stresses and extend the life of loads/equipment in an electrical system.

DETAILED DESCRIPTION

[0111] The features and other details of the concepts, systems, and techniques sought to be protected herein will now be more particularly described. It will be understood that any specific embodiments described herein are shown by way of illustration and not as limitations of the disclosure and the concepts described herein. Features of the subject matter described herein can be employed in various embodiments without departing from the scope of the concepts sought to be protected.

[0112] For convenience, certain introductory concepts and terms used in the specification (and adopted from IEEE Standard 1159-2009) are collected here. Several of these concepts and terms are shown in Fig. 1, for example. It is notable that Fig. 1 does not include all power quality categories such as waveform distortion, imbalance, voltage fluctuations, and power frequency deviations.

[0113] As used herein, the term “aperiodic event” is used to describe an electrical event that occurs non-cyclically, arbitrarily or without specific temporal regularity. For the sake of this paper, both short-duration root-mean-square (rms) variations and transients are considered to be aperiodic events (i.e., notching is considered as a harmonic phenomenon).

[0114] As used herein, the term “momentary interruption” is used to describe a deviation to 0-10% of the nominal value for a duration of 30 cycles to 3 seconds.

[0115] As used herein, the term “sag” (of which a “voltage sag” is one example) is used to describe a deviation to 10-90% of the nominal value, for example, for a duration of ½ cycle to 1 minute, as shown in FIG. 1.

[0116] As used herein, the term “short-duration rms variations” is used to describe a deviation from the nominal value with a duration of ½ cycle to 1 minute. Sub-categories of short-

duration rms variations include momentary interruptions, temporary interruptions, sags and swells.

[0117] As used herein, the term “swell” is used to describe a deviation greater than 110% of the nominal value, for example, for a duration of ½ cycle to 1 minute, as shown in FIG. 1.

[0118] As used herein, the term “temporary interruption” is used to describe a deviation to 0-10% of the nominal value for a duration of 3 seconds to 1 minute.

[0119] As used herein, the term “transient” is used to describe a deviation from the nominal value with a duration less than 1 cycle. Sub-categories of transients include impulsive (uni-direction polarity) and oscillatory (bi-directional polarity) transients.

[0120] In embodiments, the degree of impact a short-duration rms variation has on an energy consumer’s facility is primarily dependent on four factors:

1. The nature and source of the event,
2. The susceptibility of the load(s) to the event,
3. The event’s influence on the process or activity, and
4. The cost sensitivity to this event.

[0121] Consequently, each customer system, operation or load may respond differently to a given electrical perturbation. For example, it is possible for a voltage sag event to significantly impact one customer’s operation while the same voltage sag may have little or no noticeable impact on another customer’s operation. It is also possible for a voltage sag to impact one part of a customer’s electrical system differently than it does another part of the same electrical system.

[0122] Each end-user facility is unique, and voltage sag/swell/transient/interruption events may produce unintended operational consequences to equipment, processes and systems. Depending on the event's characteristics, some unintended operational consequences may include:

- Reset/reboot
- Circuit breaker trips
- Low/high voltage inhibit
- Process interrupt
- Soft errors

[0123] A very important (and often overlooked) aspect of electrical perturbations is the equipment's response to voltage events. The most stressful operational period for most equipment is when it changes states (on to off/off to on). Energizing/de-energizing electrical equipment can produce significant electrical, mechanical and thermal stresses, which may damage and shorten equipment life or even result in catastrophic failure. Ideally, loads ride-through voltage events without experiencing electrical/mechanical/thermal stresses or influencing its output productivity and/or quality; however, reality is another matter.

[0124] For example, voltage sags and undervoltage conditions may cause motor contactor bouncing/chattering, pitting and damaging the contact surfaces. In some cases, motor contacts may weld closed or burn open, resulting in damage to the motor or even potential safety/fire hazards. Moreover, bouncing contactors may induce voltage transients at a motor's terminals due to disconnecting and reconnecting the motor to the source voltage. In this case, the motor becomes slightly out of phase with the source voltage as it decelerates. When the motor reconnects, significant voltages differentials are produced between the motor and the source at the contacts. The result is pitted and damaged contacts and undue motor stresses.

[0125] Some motors have limitations on the number of starts experienced within a prescribed time period due to the stresses they undergo when energized. A motor start results in very high inrush currents (6-10 times FLA) that cause additional heat and mechanical stresses on the motor. Excessive restarts (intentional or inadvertent) may degrade a motor stator's insulation and shorten the motor's operational life, potentially leading to unscheduled downtime. Moreover, a motor may be expensive to replace, and alternatives (e.g., rewinding the motor) result in reduced energy efficiency of the motor (as well as even longer downtime).

[0126] The systems and methods disclosed herein seek to address the above issues, and various other issues, as will become apparent from discussions below.

[0127] Referring to Fig. 1A, an example electrical system in accordance with embodiments of the disclosure includes one or more loads (here, loads 111, 112, 113, 114, 115) and one or more intelligent electronic devices (IEDs) (here, IEDs 121, 122, 123, 124) capable of sampling, sensing or monitoring one or more parameters (e.g., power monitoring parameters) associated with the loads. In embodiments, the loads 111, 112, 113, 114, 115 and IEDs 121, 122, 123, 124 may be installed in one or more buildings or other physical locations or they may be installed on one or more processes and/or loads within a building. The buildings may correspond, for example, to commercial, industrial or institutional buildings.

[0128] As shown in Fig. 1A, the IEDs 121, 122, 123, 124 are each coupled to one or more of the loads 111, 112, 113, 114, 115 (which may be located "upstream" or "downstream" from the IEDs in some embodiments). The loads 111, 112, 113, 114, 115 may include, for example, machinery or apparatuses associated with a particular application (e.g., an industrial application), applications, and/or process(es). The machinery may include electrical or electronic equipment, for example. The machinery may also include the controls and/or ancillary equipment associated with the equipment.

[0129] In embodiments, the IEDs 121, 122, 123, 124 may monitor and, in some embodiments, analyze parameters (e.g., energy-related parameters) associated with the loads 111, 112, 113, 114, 115 to which they are coupled. The IEDs 121, 122, 123, 124 may also be embedded within the loads 111, 112, 113, 114, 115 in some embodiments. According to various aspects, one or more of the IEDs 121, 122, 123, 124 may be configured to monitor utility feeds, including surge protective devices (SPDs), trip units, active filters, lighting, IT equipment, motors, and/or transformers, which are some examples of loads 111, 112, 113, 114, 115, and the IEDs 121, 122, 123, 124 may detect ground faults, voltage sags, voltage swells, momentary interruptions and oscillatory transients, as well as fan failure, temperature, arcing faults, phase-to-phase faults, shorted windings, blown fuses, and harmonic distortions, which are some example parameters that may be associated with the loads 111, 112, 113, 114, 115. The IEDs 121, 122, 123, 124 may also monitor devices, such as generators, including input/outputs (I/Os), protective relays, battery chargers, and sensors (for example, water, air, gas, steam, levels, accelerometers, flow rates, pressures, and so forth).

[0130] According to another aspect, the IEDs 121, 122, 123, 124 may detect overvoltage and undervoltage conditions, as well as other parameters such as temperature, including ambient temperature. According to a further aspect, the IEDs 121, 122, 123, 124 may provide indications of monitored parameters and detected conditions that can be used to control the loads 111, 112, 113, 114, 115 and other equipment in the electrical system in which the loads 111, 112, 113, 114 and IEDs 121, 122, 123, 124 are installed. A wide variety of other monitoring and/or control functions can be performed by the IEDs 121, 122, 123, 124, and the aspects and embodiments disclosed herein are not limited to IEDs 121, 122, 123, 124 operating according to the above-mentioned examples.

[0131] It is understood that the IEDs 121, 122, 123, 124 may take various forms and may each have an associated complexity (or set of functional capabilities and/or features). For example, IED 121 may correspond to a “basic” IED, IED 122 may correspond to an “intermediate” IED, and IED 123 may correspond to an “advanced” IED. In such embodiments, intermediate IED

122 may have more functionality (e.g., energy measurement features and/or capabilities) than basic IED 121, and advanced IED 123 may have more functionality and/or features than intermediate IED 122. For example, in embodiments IED 121 (e.g., an IED with basic capabilities and/or features) may be capable of monitoring instantaneous voltage, current energy, demand, power factor, averages values, maximum values, instantaneous power, and/or long-duration rms variations, and IED 123 (e.g., an IED with advanced capabilities) may be capable of monitoring additional parameters such as voltage transients, voltage fluctuations, frequency slew rates, harmonic power flows, and discrete harmonic components, all at higher sample rates, etc. It is understood that this example is for illustrative purposes only, and likewise in some embodiments an IED with basic capabilities may be capable of monitoring one or more of the above energy measurement parameters that are indicated as being associated with an IED with advanced capabilities. It is also understood that in some embodiments the IEDs 121, 122, 123, 124 each have independent functionality.

[0132] In the example embodiment shown, the IEDs 121, 122, 123, 124 are communicatively coupled to a central processing unit 140 via the “cloud” 150. In some embodiments, the IEDs 121, 122, 123, 124 may be directly communicatively coupled to the cloud 150, as IED 121 is in the illustrated embodiment. In other embodiments, the IEDs 121, 122, 123, 124 may be indirectly communicatively coupled to the cloud 150, for example, through an intermediate device, such as a cloud-connected hub 130 (or a gateway), as IEDs 122, 123, 124 are in the illustrated embodiment. The cloud-connected hub 130 (or the gateway) may, for example, provide the IEDs 122, 123, 124 with access to the cloud 150 and the central processing unit 140.

[0133] As used herein, the terms “cloud” and “cloud computing” are intended to refer to computing resources connected to the Internet or otherwise accessible to IEDs 121, 122, 123, 124 via a communication network, which may be a wired or wireless network, or a combination of both. The computing resources comprising the cloud 150 may be centralized in a single location, distributed throughout multiple locations, or a combination of both. A cloud computing system may divide computing tasks amongst multiple racks, blades, processors,

cores, controllers, nodes or other computational units in accordance with a particular cloud system architecture or programming. Similarly, a cloud computing system may store instructions and computational information in a centralized memory or storage, or may distribute such information amongst multiple storage or memory components. The cloud system may store multiple copies of instructions and computational information in redundant storage units, such as a RAID array.

[0134] The central processing unit 140 may be an example of a cloud computing system, or cloud-connected computing system. In embodiments, the central processing unit 140 may be a server located within buildings in which the loads 111, 112, 113, 114, 115, and the IEDs 121, 122, 123, 124 are installed, or may be remotely-located cloud-based service. The central processing unit 140 may include computing functional components similar to those of the IEDs 121, 122, 123, 124 in some embodiments, but may generally possess greater numbers and/or more powerful versions of components involved in data processing, such as processors, memory, storage, interconnection mechanisms, etc. The central processing unit 140 can be configured to implement a variety of analysis techniques to identify patterns in received measurement data from the IEDs 121, 122, 123, 124, as discussed further below. The various analysis techniques discussed herein further involve the execution of one or more software functions, algorithms, instructions, applications, and parameters, which are stored on one or more sources of memory communicatively coupled to the central processing unit 140. In certain embodiments, the terms “function”, “algorithm”, “instruction”, “application”, or “parameter” may also refer to a hierarchy of functions, algorithms, instructions, applications, or parameters, respectively, operating in parallel and/or tandem. A hierarchy may comprise a tree-based hierarchy, such a binary tree, a tree having one or more child nodes descending from each parent node, or combinations thereof, wherein each node represents a specific function, algorithm, instruction, application, or parameter.

[0135] In embodiments, since the central processing unit 140 is connected to the cloud 150, it may access additional cloud-connected devices or databases 160 via the cloud 150. For

example, the central processing unit 140 may access the Internet and receive information such as weather data, utility pricing data, or other data that may be useful in analyzing the measurement data received from the IEDs 121, 122, 123, 124. In embodiments, the cloud-connected devices or databases 160 may correspond to a device or database associated with one or more external data sources. Additionally, in embodiments, the cloud-connected devices or databases 160 may correspond to a user device from which a user may provide user input data. A user may view information about the IEDs 121, 122, 123, 124 (e.g., IED makes, models, types, etc.) and data collected by the IEDs 121, 122, 123, 124 (e.g., energy usage statistics) using the user device. Additionally, in embodiments the user may configure the IEDs 121, 122, 123, 124 using the user device.

[0136] In embodiments, by leveraging the cloud-connectivity and enhanced computing resources of the central processing unit 140 relative to the IEDs 121, 122, 123, 124, sophisticated analysis can be performed on data retrieved from one or more IEDs 121, 122, 123, 124, as well as on the additional sources of data discussed above, when appropriate. This analysis can be used to dynamically control one or more parameters, processes, conditions or equipment (e.g., loads) associated with the electrical system.

[0137] In embodiments, the parameters, processes, conditions or equipment are dynamically controlled by a control system associated with the electrical system. In embodiments, the control system may correspond to or include one or more of the IEDs 121, 122, 123, 124 in the electrical system, central processing unit 140 and/or other devices within or external to the electrical system.

[0138] Referring to FIG. 1B, an example IED 200 that may be suitable for use in the electrical system shown in FIG. 1A, for example, includes a controller 210, a memory device 215, storage 225, and an interface 230. The IED 200 also includes an input-output (I/O) port 235, a sensor 240, a communication module 245, and an interconnection mechanism 220 for communicatively coupling two or more IED components 210-245.

[0139] The memory device 215 may include volatile memory, such as DRAM or SRAM, for example. The memory device 215 may store programs and data collected during operation of the IED 200. For example, in embodiments in which the IED 200 is configured to monitor or measure one or more electrical parameters associated with one or more loads (e.g., 111, shown in FIG. 1A) in an electrical system, the memory device 215 may store the monitored electrical parameters.

[0140] The storage system 225 may include a computer readable and writeable nonvolatile recording medium, such as a disk or flash memory, in which signals are stored that define a program to be executed by the controller 210 or information to be processed by the program. The controller 210 may control transfer of data between the storage system 225 and the memory device 215 in accordance with known computing and data transfer mechanisms. In embodiments, the electrical parameters monitored or measured by the IED 200 may be stored in the storage system 225.

[0141] The I/O port 235 can be used to couple loads (e.g., 111, shown in FIG. 1A) to the IED 200, and the sensor 240 can be used to monitor or measure the electrical parameters associated with the loads. The I/O port 235 can also be used to coupled external devices, such as sensor devices (e.g., temperature and/or motion sensor devices) and/or user input devices (e.g., local or remote computing devices) (not shown), to the IED 200. The I/O port 235 may further be coupled to one or more user input/output mechanisms, such as buttons, displays, acoustic devices, etc., to provide alerts (e.g., to display a visual alert, such as text and/or a steady or flashing light, or to provide an audio alert, such as a beep or prolonged sound) and/or to allow user interaction with the IED 200.

[0142] The communication module 245 may be configured to couple the IED 200 to one or more external communication networks or devices. These networks may be private networks within a building in which the IED 200 is installed, or public networks, such as the Internet. In

embodiments, the communication module 245 may also be configured to couple the IED 200 to a cloud-connected hub (e.g., 130, shown in FIG. 1A), or to a cloud-connected central processing unit (e.g., 140, shown in FIG. 1A), associated with an electrical system including IED 200.

[0143] The IED controller 210 may include one or more processors that are configured to perform specified function(s) of the IED 200. The processor(s) can be a commercially available processor, such as the well-known Pentium™, Core™, or Atom™ class processors available from the Intel Corporation. Many other processors are available, including programmable logic controllers. The IED controller 210 can execute an operating system to define a computing platform on which application(s) associated with the IED 200 can run.

[0144] In embodiments, the electrical parameters monitored or measured by the IED 200 may be received at an input of the controller 210 as IED input data, and the controller 210 may process the measured electrical parameters to generate IED output data or signals at an output thereof. In embodiments, the IED output data or signals may correspond to an output of the IED 200. The IED output data or signals may be provided at I/O port(s) 235, for example. In embodiments, the IED output data or signals may be received by a cloud-connected central processing unit, for example, for further processing (e.g., to identify power quality events, as briefly discussed above), and/or by equipment (e.g., loads) to which the IED is coupled (e.g., for controlling one or more parameters associated with the equipment, as will be discussed further below). In one example, the IED 200 may include an interface 230 for displaying visualizations indicative of the IED output data or signals. The interface 230 may correspond to a graphical user interface (GUI) in embodiments, and the visualizations may include tolerance curves characterizing a tolerance level of the equipment to which the IED 200 is coupled, as will be described further below.

[0145] Components of the IED 200 may be coupled together by the interconnection mechanism 220, which may include one or more busses, wiring, or other electrical connection apparatus. The interconnection mechanism 220 may enable communications (e.g., data, instructions, etc.) to be exchanged between system components of the IED 200.

[0146] It is understood that IED 200 is but one of many potential configurations of IEDs in accordance with various aspects of the disclosure. For example, IEDs in accordance with embodiments of the disclosure may include more (or fewer) components than IED 200. Additionally, in embodiments one or more components of IED 200 may be combined. For example, in embodiments memory 215 and storage 225 may be combined.

[0147] Returning now to FIG. 1A, in order to accurately describe aperiodic events such as voltage sags in an electrical system (such as the electric system shown in FIG. 1A), it is important to measure the voltage signals associated with the event. Two attributes often used to characterize voltage sags and transients are magnitude (deviation from the norm) and duration (length in time) of the event. Both parameters are instrumental in defining, and thus, mitigating these types of power quality issues. Scatter plots of an event's magnitude (y-axis) versus its corresponding duration (x-axis) are typically shown in a single graph called a "Magnitude-Duration" plot, "Power Tolerance Curve", or as referred to herein, a Tolerance Curve.

[0148] FIG. 2 illustrates a well-known Magnitude-Duration plot 250: the Information Technology Industry (ITI) Curve (sometimes referred to as an ITIC or CBEMA Curve) 260. The ITIC Curve 260 shows "an AC input voltage envelope which typically can be tolerated (no interruption in function) by most Information Technology Equipment (ITE)," and is "applicable to 120V nominal voltages obtained from 120V, 208Y/120V, and 120/240V 60 Hertz systems." The "Prohibited Region" in the graph includes any surge or swell which exceeds the upper limit of the envelope. Events occurring in this region may result in damage to the ITE. The "No Damage Region" includes sags or interruptions (i.e., below the lower limit of the envelope) that are not expected to damage the ITE. Additionally, the "No Interruption in Function Region" describes the area between the blue lines where sags, swells, interruptions and transients can normally be tolerated by most ITE.

[0149] As is known, constraints of the ITIC Curve 260 include:

1. It is a static/fixed envelope/curve,
2. It is proposed for IT,
3. It is intended for 120V 60Hz electrical systems,
4. It is a standardized/generic graph describing what “normally” should be expected,
5. It inherently provides no information regarding the consequences of an event,
6. It is solely a voltage-based graph, and does not consider any other electrical parameter(s), and
7. It is presented on a semi-log graph for multiplicative efficiency.

[0150] It is understood that prior art tolerance curves such as the ITIC/CBEMA, SEMI Curve, or other manually configured curves are often nothing more than suggestions for specific applications. They do not indicate how a specific system or piece of equipment, apparatus, load, or controls associated with the equipment, apparatus, or load will actually respond to a sag/swell event, what the event’s impact will be the electrical system, or how and where to economically mitigate the issues. Furthermore, zones (sub-systems) within the electrical system are all treated the same, even though the majority of IEDs monitor multiple loads. A good analogy is a road atlas: while the atlas illustrates the location of the road, it does not indicate the location of road hazards, expected gas mileage, condition of the vehicle, construction, and so forth. A better approach is required to improve managing voltage sags and swells in electrical systems.

[0151] With the foregoing in mind, the ability to provide customized tolerance curves allows an energy consumer (and the systems and methods disclosed herein) to better manage their system through simplified investment decisions, reduced CAPEX and OPEX costs, identified and characterized issues and opportunities, improved event ride-through, and ultimately, higher productivity and profitability.

[0152] A few example factors to be considered when leveraging the benefits of providing dynamic tolerance curves for energy consumers include:

1. No two customers are exactly alike, and no two metering points are identical. A dynamic tolerance curve is uniquely customized to the point at which the metering data is collected on a specific electrical system.
2. As events occur and are captured, a dynamic tolerance curve is continuously updated according the unique responses of the electrical system.
3. A dynamic tolerance curve can be applied to any type of electrical system/any type of customer; it is not limited to ITE systems.
4. A dynamic tolerance curve can also be used for substantially any voltage level; it is not limited to 120-volt systems.
5. A dynamic tolerance curve does not have fixed scaling; it can (and may need to) auto-scale.
6. It is possible to automatically aggregate dynamic tolerance curves from discrete devices into a single dynamic system tolerance curve.

[0153] With the foregoing in mind, there are a plurality of new potential features according to this disclosure that can produce numerous benefits for energy consumers. In embodiments, the goal of these features is to simplify a generally complex topic into actionable opportunities for energy consumers. Example features according to this disclosure are set forth below for consideration.

I. Dynamic Tolerance Curves

[0154] This embodiment of the disclosure comprises automatically adjusting a sag/swell tolerance curve based on load impact as measured by a discrete IED. In this embodiment, “load impact” is determined by evaluating a pre-event load against a post-event load (i.e., the load after the event’s onset). The difference between the pre-event and post event loads (i.e., kW,

current, energy, etc.) is used to quantify the event's impact. The measure of "impact" may be calculated as a percent value, absolute value, normalized value, or other value useful to the energy consumer. Further evaluations may include changes in voltage, current, power factor, total harmonic distortion (THD) levels, discrete harmonic component levels, total demand distortion (TDD), imbalance, or any other electrical parameter/characteristic that can provide an indication of the type (load or source), magnitude, and location of change within the electrical system. The source of data may originate from logged data, waveform data, direct MODBUS reads, or any other means.

[0155] Fig. 3 illustrates a typical tolerance curve (e.g., ITIC curve), which is used as a baseline (also shown in Fig. 2). It should be noted that in embodiments substantially any known uniquely described tolerance curve (e.g., SEMI F47, ANSI, CBEMA, other custom curve) may be used as the baseline tolerance curve because an intent of this embodiment of the disclosure is to dynamically customize (i.e., change, update, revise, etc.) the tolerance curve so that it reflects the unique electrical voltage event tolerance characteristics at the IED's point of installation. As more events are captured and quantified by the IED, the accuracy and characterization of the dynamic voltage tolerance curve may improve at that IED's point of installation. Fig. 3 is also shown as a semi-logarithmic graph; however, the dynamic tolerance curve may be scaled in any practical format for both analyses and/or viewing purposes.

[0156] Fig. 4 illustrates an example voltage sag event (50% of nominal, 3 milliseconds duration) on a standard/baseline tolerance curve that results in the loss of 20% of the load as determined by the IED. The shaded area in Fig. 5 illustrates the difference between the baseline tolerance curve (e.g., as shown in Fig. 3) and the actual tolerance of the downstream metered load(s) due to the particular sensitivity at this location in the electrical system to this degree (magnitude and duration) of voltage sag. Fig. 6 illustrates an example automatically customized and updated tolerance curve built from the event data point and determined for the point where the IED is installed on the electrical system. In embodiments, it assumes that any sag/swell/transient event with more severe characteristics (i.e., deeper voltage sag, greater

voltage swells, larger transient, longer duration, etc.) will impact the load at least as severely as the event presently being considered.

[0157] Fig. 7 illustrates a multitude of voltage sags/swells/transients on a standard/baseline tolerance curve. Some events are indicated as impactful and some are indicated as not impactful, based on one or more changing parameters at the moment of the event. Fig. 8 illustrates an automatically customized and updated tolerance curve for the multitude of impactful and non-impactful voltage sags/swells/transients as determined by the measured data taken from the point where the IED is installed on the electrical system.

- a. Three-Dimension (3-D) Dynamic Tolerance Curves with Load Impact (also sometimes referred to herein as “Dynamic Tolerance-Impact Curves”)

[0158] Standard tolerance curves (e.g., ITIC Curve, SEMI Curve, etc.) are described in two-dimensional graphs with percent of nominal voltage on the y-axis and duration (e.g., cycles, second, milliseconds, etc.) on the x-axis, for example, as shown in Fig. 7. While the y-axis is presented in units of percent of nominal voltage, it is understood that the y-axis units may also be in absolute units (e.g., real values such as voltage), or substantially any other descriptor of the y-axis parameter’s magnitude. Additionally, while the x-axis is logarithmic in Fig. 7, for example, it is understood that the x-axis does not have to be logarithmic (for example, it can be linear as well). These 2-D standard tolerance curve graphs provide only a limited description of an event’s characteristics (magnitude and duration); they don’t provide information related to an event’s impact on the load(s). While the energy consumer knows an event occurred, they cannot tell whether (and if so, to what degree) an event impacted their electrical system (and likely, their operation).

[0159] Adding a third dimension to the tolerance curve graph allows the energy consumer to visually identify the characterization of their system’s sag/swell/transient tolerance (at the metering point) related to magnitude, duration, and a third parameter such as load impact. Again, load impact is determined by analyzing changes in the load (or other electrical

parameter) before and after an event using logged data, waveform data, direct MODBUS read data, other data, or any combination thereof.

[0160] Three-dimensional (3-D) tolerance curves in accordance with embodiments of the disclosure may be adapted and/or oriented to any axis, perspective, scale, numerically ascending/descending, alphabetized, color, size, shape, electrical parameter, event characteristic, and so forth to usefully describe an event or events to the energy consumer. For example, Fig. 9 illustrates an exemplary orthographic perspective of a tolerance-impact curve incorporating three parameters: 1) percent of nominal voltage on the y-axis, 2) duration in cycles and seconds on the x-axis, and 3) percent load impacted on the z-axis. While the y-axis is presented in units of percent of nominal voltage in the illustrated embodiment, it is understood that the y-axis units may also be in absolute units (e.g., real values such as voltage), or substantially any other descriptor of the y-axis parameter's magnitude. Additionally, while the x-axis is logarithmic in the illustrated embodiment, it is understood that the x-axis does not have to be logarithmic (for example, it can be linear as well). Fig. 10 illustrates an exemplary single-point perspective 3-D view of the same tolerance-impact curve shown in Fig. 9, and incorporates the same respective parameters for the three axes. It also attempts to integrate color shading to help illustrate the severity of the impact due to specific magnitude and duration events (least to worst; yellow to red, in the illustrated embodiment). Fig. 11 attempts to illustrate an exemplary single-point perspective 3-D view of a tolerance-impact curve incorporating magnitude, duration, percent load impact, shading, and event shape (to provide more event characteristics in a single graph). Again, the load impact may be as a relative percentage of the total load before the event (as shown in the graph), as a real value (e.g., kW, Amps, etc.), ascending or descending in value, or any other manipulation of these or any other electrical parameters.

b. Three-Dimension (3-D) Dynamic Tolerance-Recovery Time Curves

[0161] Building on the previous section discussing load impact, in embodiments it is also possible to use tolerance-impact curves to more directly quantify the effect of a voltage

sag/swell/transient event on an energy consumer's operation. The time to recover from an event may directly affect the overall cost of a voltage event.

[0162] For the purpose of this disclosure, "recovery time" is defined as the period of time required to return the electrical system parameters back to (or approximately back to) their original state prior to the event that prompted their initial perturbation. In embodiments, recovery time and load impact are independent variables; neither is dependent on the other. For example, a voltage event may impact a small percentage of load, yet the recovery time may be considerable. Conversely, the recovery time from an extremely impactful event could be relatively short. Just as the impact of an event is dependent on a number of factors (some examples of which are set forth in the summary section of this disclosure), so too is the recovery time. A few examples of factors that can heavily influence the duration of recovery time include: ability to quickly locate event source (if it's within the facility), extent of equipment damage, spare parts availability, personnel availability, redundant systems, protection schemes, and so forth.

[0163] One example method for calculating the recovery time includes measuring the elapsed time between the occurrence of a first impactful event and the point when the load exceeds a predetermined threshold of the pre-event load. For example, a 500kW pre-event load with a 90% recovery threshold will indicate the recovery has occurred at 450kW. If it takes 26 minutes for the metered load to meet or exceed 450kW (i.e., 90% of the pre-event load), then the recovery time is equal to 26 minutes. The recovery threshold can be determined using a relative percentage of the pre-event load, an absolute value (kW), the recovery of the voltage or current levels, an external or manual trigger, a recognized standard value, a subjective configuration, or by some other method using an electrical or non-electrical parameter(s).

[0164] Fig. 12 illustrates an exemplary orthographic perspective of a tolerance-recovery time curve incorporating three parameters: 1) percent of nominal voltage on the y-axis, 2) duration in cycles and seconds (or alternatively, milliseconds) on the x-axis, and 3) recovery time or

period in days, hours, and/or minutes on the z-axis. While the y-axis is presented in units of percent of nominal voltage in the illustrated embodiment, it is understood that the y-axis units may also be in absolute units (e.g., real values such as voltage), or substantially any other descriptor of the y-axis parameter's magnitude. Additionally, while the x-axis is logarithmic in the illustrated embodiment, it is understood that the x-axis does not have to be logarithmic (for example, it can be linear as well). In embodiments, the z-axis (recovery time) may be configured to substantially any fixed scale (or auto-scaled), may be listed in ascending or descending order, and may use substantially any known temporal unit. Fig. 13 illustrates an exemplary single-point perspective 3-D view of the same tolerance-recovery time curve shown in Fig. 12, and incorporates the same respective parameters for the three axes. Fig. 13 also integrates color shading to help illustrate the severity of the recovery time due to specific magnitude and duration events (least to worst; yellow to red in the illustrated embodiment). Fig. 14 illustrates an exemplary single-point perspective 3-D view of a tolerance-recovery time curve incorporating magnitude, duration, recovery time, shading, and event shape (to provide more event characteristics in a single graph).

c. 3-D Dynamic Tolerance-Economic Impact Curves

[0165] The 3-D curves discussed above may also be used to illustrate economic impact (e.g., production losses, restart losses, product/material losses, equipment losses, third-party losses, total losses, etc.) as it relates to voltage events. Obviously, configuration may be time-consuming; however, the relationship between recovery time and any relevant economic factor can easily be shown and understood using dynamic tolerance-economic impact curves. The cost of downtime (CoD) may be initially used to determine a given economic cost during the recovery period (assuming the CoD value is reasonable). Some studies indicate each minute of downtime costs energy consumers in the automotive industry more than \$22K. By contrast, the similar studies indicate that healthcare industry energy consumers lose more than \$10K/minute of downtime. Over time, energy consumers (and the systems and methods disclosed herein) can quantify their typical recovery time costs (whether it's linear or non-linear), or they may have a study done to determine this relationship at their facility or business. Determining the

relationship between voltage events and economic factors will allow energy consumers to make faster and better decisions regarding capitalization expenditures and/or the retention of services.

[0166] For example, Fig. 15 illustrates the production losses with respect to a 50% of nominal voltage sag event with a duration of 3 milliseconds. Assuming the recovery time was 8 hours (see, e.g., Fig. 13) and production losses are an average of \$2.5K/hour, the total production losses will be \$20K. If ride-through capabilities can help avoid an operational disruption at a cost of \$50K, the payback for investing in voltage sag ride-through equipment is may only be about 2.5 voltage events, for example. As mentioned at the beginning of this document, studies have shown the average industrial customer experiences about 66 voltage sags each year so a decision to mitigate should be straightforward in this case.

d. Upstream/Downstream Tolerance-Impact Curves

[0167] As has been stated and is widely known, electrical systems are sensitive to voltage events in varying degrees. For some energy consumers, voltage events may just be a nuisance (no significant impact); for other energy consumers, any small voltage anomaly may be catastrophic. As previously discussed, quantifying the impact of voltage events helps energy consumers determine the severity, prevalence, and influence of these events on their operation. If voltage events impact the energy consumer's operation, the next step is identifying the source of the problem.

[0168] Metering algorithms and other associated methods may be used to determine whether a voltage event's source is upstream or downstream from a metering point (e.g., an IED's electrical point of installation in an electrical system). For example, Fig. 16 illustrates a simple electrical network with three metering points (M_1 , M_2 , and M_3). A fault (X) is shown to occur between M_1 and M_2 . In embodiments, algorithms in M_1 may indicate the source of the fault to be downstream ($\downarrow$) from its location, and algorithms in M_2 may indicate the source of the fault to be upstream ($\uparrow$) from its location. Additionally, in embodiments algorithms in M_3 may

indicate the source of the fault to be upstream (↑). By evaluating the fault as a system event (i.e., using data from all three IEDs), in embodiments it is possible to generally identify the location of the fault's source within the electrical network (i.e., with respect to the metering points).

[0169] This embodiment evaluates the impact of a voltage event against the indicated location (upstream or downstream from the metering point) related to the voltage event's source. This is very useful because upstream voltage event sources often require different mitigative solutions (and associated costs) than downstream voltage event sources. Furthermore, there will likely be different economic considerations (e.g., impact costs, mitigation costs, etc.) depending on where the voltage event source is located within the electrical system. The larger the impacted area, the more expensive the cost may be to mitigate the problem. Upstream voltage events can potentially impact a larger portion of the electrical network than downstream voltage events, and therefore, may be more expensive to mitigate. Again, the cost to mitigate voltage events will be determined on a case-by-case basis since each metering point is unique.

[0170] In embodiments, the IEDs installed at the metering points are configured to measure, protect, and/or control a load or loads. The IEDs are typically installed upstream from the load(s) because current flow to the load(s) may be a critical aspect in measuring, protecting and/or controlling the load(s). However, it is understood that the IEDs may also be installed downstream from the load(s).

[0171] Referring to Fig. 16A, another example electrical system includes a plurality of IEDs (IED1, IED2, IED3, IED4, IED5) and a plurality of loads (L1, L2, L3, L4, L5). In embodiments, loads L1, L2 correspond to a first load type, and loads L3, L4, L5 correspond to a second load type. The first load type may be the same as or similar to the second load type in some embodiments, or different from the second load type in other embodiments. Loads L1, L2 are positioned at a location that is "electrically" (or "conductively") downstream relative to at least IEDs IED1, IED2, IED3 in the electrical system (i.e., IEDs IED1, IED2, IED3 are upstream from

loads L1, L2). Additionally, loads L3, L4, L5 are positioned at a location that is “electrically” downstream relative to at least IEDs IED1, IED4, IED5 in the electrical system (i.e., IEDs IED1, IED4, IED5 are upstream from loads L3, L4, L5).

[0172] In the illustrated embodiment, a power quality event (or fault) X is shown occurring upstream relative to loads L1, L2. Up arrows indicate “upstream” and down arrows indicate “downstream” in the example embodiment shown. As illustrated, IEDs IED1, IED2 are shown pointing towards the fault X. Additionally, IEDs IED3, IED4, IED5 are shown pointing upstream. In embodiments, this is because the path leading to the fault X is upstream from IEDs IED3, IED4, IED5 respective location in the electrical system, and downstream from IEDs IED1, IED2 respective location in the electrical system. In embodiments, algorithms that determine a direction of the fault X may be located (or stored) in the IEDs, on-site software, cloud-based systems, and/or gateways, etc., for example.

[0173] Fig. 17 illustrates a 2-D graph voltage tolerance curve of voltage events captured by an IED similar to Fig. 7 above; however, the upstream and downstream voltage events are uniquely denoted and superimposed/overlaid together. Fig. 18 illustrates a 2-D voltage tolerance curve that shows only the upstream voltage events which are disaggregated from the total set of voltage events shown in Fig. 17. Similarly, Fig. 19 illustrates a 2-D voltage tolerance curve showing only the downstream voltage events as disaggregated from the total set of voltage events shown in Fig. 17. These graphs allow energy consumers (and the systems and methods disclosed herein) to distinguish the upstream events from the downstream events, thus, helping to provide a better visually intuitive view for identifying the primary location of voltage event sources (and perhaps, their causes). Of course, additional or alternative characteristics, parameters, filters, and/or other related information (e.g., electrical data, time, metadata, etc.) may be used, displayed and/or plotted to further effectively and productively embellish the voltage tolerance curves.

[0174] For example, Fig. 20 illustrates an exemplary orthographic perspective of a tolerance-impact-source location curve incorporating five parameters: 1) percent of nominal voltage on the y-axis, 2) duration in cycles and seconds on the x-axis, and 3) percent load impacted on the z-axis. While the y-axis is presented in units of percent of nominal voltage in the illustrated embodiment, it is understood that the y-axis units may also be in absolute units (e.g., real values such as voltage), or substantially any other descriptor of the y-axis parameter's magnitude. Additionally, while the x-axis is logarithmic in the illustrated embodiment, it is understood that the x-axis does not have to be logarithmic (for example, it can be linear as well). Additional dimensions are also included in Fig. 20 such as the recovery time (size of data point) and whether a particular event was upstream or downstream from the metering point (data point center is white or black, respectively). Moreover, the z-axis could be made to show the recovery time while the size of the data point could be used to indicate the percent load impacted. It is understood that many other parameters/dimensions may be incorporated as makes sense and/or is useful.

e. Mitigation of Sag/Swell/Transient Impact Using Dynamic Tolerance Curves

[0175] As noted above, electrical systems are typically sensitive to voltage events in varying degrees. For some energy consumers, voltage events may just be a nuisance (no significant impact); for other energy consumers, any voltage event may be catastrophic. As previously discussed, quantifying the impact of voltage events helps energy consumers determine the severity, prevalence, and influence of these events on their operation. If voltage events have an impact the energy consumer's operation, the next step should be identifying the problem so it can be reduced or eliminated altogether.

[0176] In embodiments, eliminating or reducing the impact of voltage sags/swells/transients (and momentary and temporary interruptions) for the various embodiments discussed throughout the disclosure, can be generally accomplished in three ways: 1) removing the source of the voltage events, 2) reducing the number or severity of voltage events produced by the source, or 3) minimizing the effects of the voltage events on impacted equipment. In some

embodiments, it is substantially difficult to remove the source (or sources) of voltage events because these same sources are usually an integral component or load within the facility's electrical infrastructure, process, and/or operation. Additionally, the voltage event's source may be located on the utility, and thus, hamper the ability to directly address a problem. If the voltage event's source is located inside the energy consumer's facility, it may be possible to minimize voltage events at the source by using different techniques or technologies (e.g., "soft-start" motors instead of "across the line" motor starting). In some embodiments, removing or replacing the source (or sources) of voltage events may cost-prohibitive and require an extensive redesign of an electrical system or subsystem. It is also possible to "desensitize" equipment against the effects of voltage events such as sags, swells, and transients. As always, there are economic trade-offs when considering the best approach to reduce or eliminate voltage issues. Fig. 21 is a generally recognized illustration showing the progression in cost to mitigate voltage events and other PQ-related issues, which tends to increase as the solution moves closer to the source. A thorough economic evaluation may include both the initial and total life cycle costs for a given solution. Furthermore, it may be very important to consider the response of any prospective solution to both internal and external sources of system voltage perturbations.

[0177] As an example, motors are an important electrical apparatus used in most processes. Standard (across the line) motor starts typically produce voltage sags due to the impedance between the source and motor and the motor's inrush current, which is typically 6-10 times the full-load current rating. Removing the motor from the process would most likely be impractical; however, reducing the voltage sag or minimizing its effects on adjacent equipment may be viable alternatives. A few example solutions may include using different motor technologies such as variable speed drives or to employ motor soft-start techniques to control or limit the inrush current (and thus, reduce or eliminate the voltage sag at start-up). Another example solution is to deploy one or more of several mitigative devices or equipment to reduce the voltage event's impact on sensitive equipment. Again, each electrical system is unique, so

the cost to mitigate power quality disturbances may vary from location to location, system to system, and customer to customer.

[0178] This embodiment includes evaluating the ride-through characteristics of a multitude of mitigative devices against the dynamic tolerance-impact curves provided by each capable IED. The output of the evaluation may indicate the additional ride-through benefits of applying any particular mitigative device to any specific metering location. Moreover, a comparison of the economic, operational, and/or other benefits between two or more ride-through technologies or techniques for a specific system or sub-system may also be provided. In embodiments, in order to perform the evaluation, a managed collection (or library) of mitigative devices' ride-through characteristics may be assessed. The managed collection (or library) of mitigative devices may include (but not be limited to) characteristics and/or capabilities such as type, technology, magnitude vs. duration behavior, load constraints, typical applications, purchase costs, installation costs, operational costs, availability, purchase sources, dimensions/form factors, brands, and so forth for each known variety. In embodiments, the characteristics and capabilities described in the managed collection of mitigative devices will be considered (as required and as available) for application at every (or substantially every) discretely metered point (or sub-system) where data is obtainable and assessable. One or more ride-through characteristics curves (indicating magnitude vs. duration ride-through capabilities) for any or every mitigative device found in the managed collection (library) may be superimposed/overlaid on the dynamic tolerance curve for at least one or more discrete metering point(s). Alternatively, the evaluation may be provided through some other means accordingly. One or more characteristics and/or capabilities of the mitigative device(s) may be included in the evaluation against the dynamic tolerance curve based on factors such as those listed and available in the managed collection (or library). In embodiments, this evaluation may be alarm-driven, manually or automatically triggered, scheduled, or otherwise initiated.

[0179] The dynamic tolerance-impact curves provided by each capable IED for the electrical system's hierarchy (or portions of its hierarchy) may be evaluated against the ride-through

characteristics of one or more mitigative devices. In embodiments, it may be more feasible, cost-effective, or otherwise beneficial to provide ride-through improvements as part of a system, sub-system process, and/or discrete location. Whereas it may be economical/practical/feasible to apply one type of ride-through mitigative solution for one device or one sub-system/zone, it may be more economical/practical/feasible to provide a different ride-through mitigative solution for another device or subsystem/zone within the electrical system. In short, the most economical/practical/feasible ride-through mitigative solution may be provided for the entire (or portion of the) electrical system based on the information available. In embodiments, other factors may be considered when determining ride-through improvements for one or more locations within an electrical system; however, this application emphasizes the importance of leveraging discretely established dynamic tolerance curves from one or more IEDs.

[0180] Fig. 22 illustrates the 2-D dynamic tolerance curve from Fig. 5. Again, this example shows a tolerance curve that has been customized and updated based on a single 50% voltage sag lasting 3 milliseconds and having a 20% load impact. An evaluation may be performed to ascertain the most economic/practical/feasible approach to improve the ride-through performance for this particular location in the electrical system. The managed collection (library) of mitigative devices may be assessed against suitable options and viable solutions. Fig. 23 shows the ride-through characteristics (magnitude vs. duration) of SagFighter® by Schneider Electric, which claims to meet SEMI F47, superimposed/overlaid on top of the updated dynamic tolerance curve. Fig. 24 provides the energy consumer with a graphical indication of SagFighter's ride-through benefits at this particular location in the electrical system (as indicated by the shaded area in Fig. 24, for example). Of course, the final mitigation device recommendation provided to the energy consumer may be dependent on more than the ride-through characteristic of the mitigative device (e.g. economical/practical/feasible/etc.). Additionally, this approach may be provided to multiple metered points across the electrical system or subsystems.

f. Determining Opportunity Costs for Ride-Through Mitigative Solutions Using Dynamic Tolerance Curves

[0181] As is known, opportunity cost refers to a benefit or gain that could have achieved, but was forgone in lieu of taking an alternative course of action. For example, a facility manager with a fixed budget may be able to invest funds to expand the facility OR to improve the reliability of the existing facility. The opportunity cost would be determined based on the economic benefit of the choice not taken by the facility manager.

[0182] In this embodiment of the disclosure, the “opportunity cost” is expanded to include other benefits such as production losses, material losses, recovery time, load impact, equipment losses, third-party losses, and/or any other loss that is quantifiable by some measure. Additionally, an “alternative course of action” may be the decision to take no action at all. A few benefits of taking no action include resource savings, monetary savings, time savings, reduced operational impact, deferral, and so forth. That is to say, decision-makers often consider the benefits of taking no action greater than the benefits of taking specific action(s).

[0183] The decision not to take an action is often based on the lack of information related to a given problem. For example, if someone cannot quantify the benefits of taking a particular action, they are less likely to take that action (which may be the wrong decision). Conversely, if someone is able to quantify the benefits of taking a particular action, they are more likely to make the right decision (whether to take action or not take action). Moreover, having quality information available provides the tools to produce other economic assessments such as cost/benefit analyses and risk/reward ratios.

[0184] This embodiment of this disclosure may continuously (or semi-continuously) evaluate the impact of voltage events (sags/swells/transients) against the ride-through tolerance characteristics of one or more mitigative devices, apparatuses and/or equipment. The evaluation may consider historical data to continuously track voltage events, associated

discrete and combined system impact (e.g., as a relative value, absolute value, demand, energy, or other quantifiable energy-related characteristic), sub-system and/or system perspective, hierarchical impact from two or more devices, zones, cross-zones, or combination thereof. Information taken from the evaluation may be used to provide feedback and metrics regarding the operational repercussions that could have been avoided if one or more mitigative devices, apparatuses, and/or equipment would have been installed at a location (or locations).

[0185] For example, Fig. 25 provides a 2-D graph that illustrates events (and any associated impacts) that could have been avoided (green circles) if the decision had been made to install SagFighter® prior to the respective voltage event. Fig. 26 illustrates a similar graph as shown in Fig. 25, but also includes the estimated recovery time that could have been avoided had mitigative solutions been implemented prior to the voltage events. Metrics associated with these potentially avoided events (e.g., relative impact (%), absolute impact (W, kW, etc.), recovery time per event, accumulated recovery time, downtime, losses, other quantifiable parameters, etc.) may also be provided to an energy consumer to help justify investments to resolve voltage sag issues. The energy consumer (or systems and methods of the disclosure herein) could also choose what level of mitigation would be justifiable by comparing differing mitigation techniques to the historical tolerance curve data (i.e., the point of diminishing region of interest (ROI)). Metrics may be listed per event or accumulated, provided in a table or graphed, analyzed as a discrete point or from two or more devices (i.e., a system level perspective), or otherwise manipulated to indicate and/or quantify the impact and/or opportunity cost for not installing voltage event mitigation. The same information could be displayed a 3-D orthographic perspective of a tolerance-impact curve incorporating at least three parameters such as: 1) percent of nominal voltage on the y-axis, 2) duration in cycles and seconds on the x-axis, and 3) percent load impacted (or recovery time in days, hours or minutes) on the z-axis. While the y-axis is presented in units of percent of nominal voltage in the illustrated embodiment, it is understood that the y-axis units may also be in absolute units (e.g., real values such as voltage), or substantially any other descriptor of the y-axis parameter's magnitude. Additionally, while the x-axis is logarithmic in the illustrated embodiment, it is

understood that the x-axis does not have to be logarithmic (for example, it can be linear as well). Other parameters, characteristics, metadata, and/or mitigative apparatus may similarly be incorporated into a graph and/or table.

g. Verifying the Effectiveness of Mitigation Techniques Using Dynamic Tolerance Curves

[0186] Re-evaluating or reassessing the decision to invest in a facility's infrastructure is often overlooked, presumed, or merely based on speculation and supposition. In most cases the benefits of installing mitigative technologies are just assumed, but never quantified. Measurement and Verification (M&V) processes focus on quantifying energy savings and conservation; however, steps to improve reliability and power quality are not considered.

[0187] Embodiments of this disclosure periodically or continuously provide the following example benefits:

- Allocate risks between contractors and their customer (e.g., for performance contracts),
- Accurately assess voltage events to quantify savings (in impact, recovery time, uptime, losses, or other economic factors),
- Reduce voltage quality uncertainties to reasonable levels,
- Aid in monitoring equipment performance,
- Identify additional monitoring and/or mitigation opportunities,
- Reduce impact to targeted equipment, and
- Improve operations and maintenance.

[0188] The dynamic voltage-impact tolerance curve provides a baseline of voltage events at each discretely metered point that captures impacted or potentially impacted processes, operations or facilities. Post-installation evaluations may be performed using data taken from the areas predicted to experience the benefits. In embodiments, these post-installation evaluations compare "before vs. after" to quantify the real benefits of installing the mitigative equipment. Determined quantities may include reduced event impact, recovery time,

operational costs, maintenance costs, or any other operational or economic variable. An exemplary equation to determine the calculated savings due to installing mitigative equipment may be:

$$Savings = (baseline\ costs - reduced\ downtime\ costs) \pm Adjustments$$

where “reduced downtime costs” may include all or some combination of the following:

- Reduced production losses,
- Reduced restart losses,
- Reduced product/material losses,
- Reduced equipment losses,
- Reduced 3rd party costs, and
- ...and/or some other loss reduction.

[0189] Installation costs for the mitigative equipment may need to be considered, likely as an “adjustment,” in some embodiments.

[0190] Fig. 27 illustrates an example 2-D dynamic voltage tolerance curve according to the disclosure where the blue threshold lines (—) represent the ride-through baseline thresholds at a discretely metered point and the pink line (—) represents the predicted improvement to the voltage event ride-through thresholds by installing a certain type of mitigation equipment. The green circles in Fig. 27 indicate the voltage events (and consequently, the recovery time) expected to be avoided by installing the mitigation equipment. Fig. 28 illustrates an example 2-D dynamic voltage tolerance curve according to the disclosure showing the actual voltage events and recovery time avoided due to the installation of the mitigation equipment. The orange line (—) illustrates the actual improvement to the voltage ride-through thresholds by installing the mitigation equipment. In this example, the mitigation equipment surpassed its expectations by avoiding three additional voltage events and 22 hours (42 actual events – 20 predicted events) of additional recovery time.

[0191] Each electrical system is unique and will perform differently to some degree. Embodiments of this disclosure use empirical data to characterize the actual performance of the mitigation equipment. For example, the actual thresholds for voltage ride-through (—) may perform better than expected as shown in Fig. 28 because the downstream load on the mitigation equipment was/is less than expected. This allows the mitigation device to ride-through longer than anticipated. Conversely, exceeding the mitigation equipment's load rating would likely result in a worse-than-expected performance. As the mitigation equipment's load continues to be increased beyond its rating, the voltage ride-through thresholds (—) will approach the original voltage ride-through threshold (—) or possibly be even more severe.

[0192] A 3-D dynamic tolerance curve similar to the one shown in Fig. 15 may be produced to better demonstrate the effect of mitigation on other parameters such as load impact, recovery time, economic factors, etc. In this case, at least three dimensions would be used to characterize the electrical system at the point of the IED's installation. A 3-D evaluation would provide an even better intuitive understanding of a mitigation equipment's historical, present and/or future performance. It would also make the selection of mitigation equipment for future applications less complicated and more cost-effective.

[0193] Metrics associated with the expected (based on historical data) and actually avoided events (e.g., relative impact (%), absolute impact (W, kW, etc.), reduced losses, other quantifiable parameters, etc.) may be provided to an energy consumer to help justify the original or additional investments to resolve voltage sag issues. Metrics may be listed per event or accumulated, provided in a table or graphed, analyzed as a discrete point or from two or more devices (i.e., a system level perspective), or otherwise manipulated to indicate and/or quantify the benefits and/or costs per avoided minute of impact due to the installation of voltage event mitigation. The same information could be displayed as a 3-D orthographic perspective of a tolerance-impact curve incorporating at least three parameters such as: 1) percent of nominal voltage on the y-axis, 2) duration in cycles and seconds on the x-axis, and 3) percent load impacted (or recovery time) on the z-axis. While the y-axis is presented in units of

percent of nominal voltage in the illustrated embodiment, it is understood that the y-axis units may also be in absolute units (e.g., real values such as voltage), or substantially any other descriptor of the y-axis parameter's magnitude. Additionally, while the x-axis is logarithmic in the illustrated embodiment, it is understood that the x-axis does not have to be logarithmic (for example, it can be linear as well). Other parameters, characteristics, metadata, and/or mitigative apparatus could similarly be incorporated into a graph and/or table, for example.

II. Using Non-PQ IEDs to Help Quantify Voltage Event Impact

[0194] The ability to quantify the impact of a voltage event may be derived from measured changes in energy, current, or power flows (i.e., consumption). An IED may be used to provide these measurements. The measurements may be acquired in real-time (e.g., via direct MODBUS reads), historically (e.g., logged data), or by some other means.

[0195] Power monitoring systems often incorporate a diverse array of IEDs that are installed throughout the energy consumer's electrical system. These IEDs may have different levels of capabilities and feature sets; some more and some less. For example, energy consumers often install high-end (many/most capabilities) IEDs at the location where electrical energy enters their premises (M_1 in Fig. 29). This is done to acquire the broadest understanding possible of the electrical signals' quality and quantity as received from the source (typically, the utility). Because the budget for metering is usually fixed and the energy consumer often wants to meter as broadly as possible across their electrical system, conventional wisdom stipulates using IEDs with progressively lower capabilities as the installed meter points get closer to the loads (see Fig. 29, for example). In short, the majority of facilities incorporate many more low/mid-range IEDs than high-end IEDs.

[0196] "High-end" metering platforms (and some "mid-range" metering platforms) are more expensive and generally capable of capturing PQ phenomena including high-speed voltage events. "Low-end" metering platforms are less expensive and generally have reduced processor bandwidth, sample rates, memory, and/or other capabilities as compared to high-

end IEDs. The emphasis of low-end IEDs, including energy measurements taken in most breakers, UPSs, VSDs, etc., is typically energy consumption or other energy-related functions, and perhaps some very basic PQ phenomena (e.g., steady-state quantities such as imbalance, overvoltage, undervoltage, etc.).

[0197] This feature leverages (i.e., interrelates, correlates, aligns, etc.) one or more voltage event indicators, statistical derivations and/or other information from a high-end IED with one or more similar and/or disparate measured parameters from a low-end IED with the goal of quantifying the impact, recovery time, or other event characteristic at the low-end IED. One exemplary method to do this is by using the voltage event timestamp (indicator of the moment a voltage event occurs) from the high-end IED as a reference point for evaluating a measurable parameter corresponding with the same timestamp at a low-end that does not inherently have the capability to capture voltage events. Data evaluated at both the high-end, mid-range, and low-end IEDs may include (but not be limited to) the event magnitude, duration, phase or line values, energy, power, current, sequential components, imbalance, timestamp, pre/during/post-event changes, any other measured or calculated electrical parameter, metadata, meter characteristics, and so forth. Again, the measurements may be acquired in real-time (e.g., via direct MODBUS reads), historically (e.g., logged data), or by some other means.

[0198] Another example way to leverage non-PQ IEDs is to extend the use of event alarms (including voltage events) derived from high-end IEDs. For example, when a high-end IED detects a voltage event, coincident data from low-end IEDs is analyzed to ascertain the impact, recovery time, or other event characteristic and/or parameter. If analysis of data from the low-end IED indicates some level of impact did occur, a voltage event alarm, impact alarm, and/or other alarm type may be generated by the system performing the analysis of the coincident data. The alarm information may include any relevant parameter and/or information as measured by the low-end IED, high-end IED, metadata, meter characteristics, load impact, recovery time, which one or more high-end IEDs triggered the low-end IED alarm, and so forth.

[0199] Figs. 29 and 30 illustrate a relatively simple example of this embodiment of the disclosure. At time t_0 , a high-end IED installed a respective metering point or location M_1 indicates the beginning of a voltage event. The pre-event load is measured, and the recovery time clock begins for the IED installed at the metering location M_1 . Other relevant data, metrics and/or statistically derived information may also be measured or calculated as required. Simultaneously, the software (on-site and/or cloud-based) and/or hardware managing the metering system evaluates the other connected IEDs to determine whether any other IED installed at another respective metering point or location (e.g., M_2 , M_3 , M_4 , M_5 , M_6 , M_7 , M_8 , M_9 , M_{10}) concurrently experienced an impactful event. In this example, the IED installed at metering location M_7 is found to have experienced a coincident impactful event (the other devices are ignored in this example for the sake of simplicity). The pre-event load is determined from M_7 and the recovery time clock begins for M_7 using the voltage event's timestamp as a reference. With the IEDs installed at metering locations M_1 and M_7 identified as impacted by the voltage event, the impact is quantified based on pre/during/post-event electrical parameters (e.g., power, current, energy, voltage, etc.) with t_0 derived from the IED installed at metering location M_1 and used as a reference point for both devices M_1 and M_7 . The IED installed at metering location M_7 is located downstream from the IED installed at metering location M_1 and experiences a more significant relative impact (i.e., bigger percentage of its pre-event load) due to system impedance and uniquely affected loads. The recovery time counters for the IEDs installed at metering locations M_1 and M_7 are independent of each other, as will be the case for all IEDs. In this example, the IED installed at metering location M_7 experiences approximately the same recovery time as the IED installed at metering location M_1 (i.e., $t_{M1r} \approx t_{M7r}$); however, that may not always be the case since recovery time may be unique at each metered location.

[0200] In embodiments, virtual metering may also be used to identify an impact of a voltage event on unmetered loads. For example, there are two electrical paths downstream from the IED installed at metering location M_1 in Fig. 30A. The electrical path on the right is metered through a physical IED (e.g., installed at metering location M_2); however, the electrical path on

the left is not directly metered by a physical IED. If the load data measured by the IEDs installed at metering locations M_1 and M_2 are measured synchronously or pseudo-synchronously, it is possible to determine (within the accuracy and synchronization constraints of the IEDs installed at metering locations M_1 and M_2) the load flowing through the unmetered path, V_1 , by the following equation: $V_1 = M_1 - M_2$. V_1 represents a location of a “virtual meter” or a “virtual IED” in the electrical system, and it signifies the difference between the IEDs installed metering locations M_1 and M_2 for any synchronous (or pseudo-synchronous) load measurement.

[0201] For this example, consider a fault that occurs downstream from the IED installed at metering location M_1 and upstream from the virtual meter located at metering location V_1 in Fig. 30A. Using the concept of virtual metering as described above, a load change is determined to have occurred in the unmetered path. Because the load data through the unmetered path may be derived from the IEDs installed at metering locations M_1 and M_2 , it is possible to calculate the load impact to the unmetered path due to the fault. In this example, other important parameters related to this embodiment of the disclosure may also be derived from virtual meters including recovery time, economic impact, and so forth.

[0202] In one embodiment, the data sample rate (e.g., power, current, energy, voltage, or other electrical parameters) for IEDs installed at metering locations M_1 , M_7 , and/or any other IEDs may be dependently or independently increased as required after a voltage event has been indicated in order to provide more accurate results (e.g., recovery time). Data may be shown in a tabular format, graphically in 2-D or 3-D, color coded, as timelines from discrete IEDs, zonally, hierarchically, or as a system (aggregated) view, linearly or logarithmically, or in any other structure or method considered relevant and/or useful. The output of this embodiment may be via report, text, email, audibly, screen/display, or by some other interactive means.

[0203] Referring to Figs. 30B-30I, several example figures are provided to further illustrate the concept of virtual metering in accordance with embodiments of this disclosure. As discussed

above, an electrical system typically includes one or more metering points or locations. As also discussed above, one or more IEDs (or other meters, such as virtual meters) may be installed or located (temporarily or permanently) at the metering locations, for example, to measure, protect, and/or control a load or loads in the electrical system.

[0204] Referring to Fig. 30B, an example electrical system including a plurality of metering locations (here, M_1 , M_2 , M_3) is shown. In the illustrated embodiment, at least one first IED is installed at the first metering location M_1 , at least one second IED is installed at the second metering location M_2 , and at least one third IED is installed at the third metering location M_3 . The at least one first IED is a so-called “parent device(s),” and the at least one second IED and the at least one third IED are so-called “child devices.” In the example embodiment shown, the at least one second IED and the at least one third IED are children of the at least one first IED (and, thus siblings with each other), for example, due to the at least one second IED and the at least one third IED both being installed at respective metering locations M_2 , M_3 in the electrical system that “branch” from a common point (here, connection 1) associated with the metering location M_1 at which the at least one first IED is installed. Connection 1 is the physical point in the electrical system where the energy flow (as measured at M_1 by the at least one first IED) diverges to provide energy to the left and right electrical system branches (as measured at M_2 and M_3 by the at least one second IED and the at least one third IED, respectively).

[0205] The electrical system shown in Fig. 30B is an example of a “completely metered” system, where all branch circuits are monitored by a physical IED (here, the at least one first IED, the at least one second IED, and the at least one third IED). In accordance with various aspects of this disclosure, dynamic tolerance curves can be independently developed for each discrete metered location (M_1 , M_2 , M_3) without any dependence on external input(s) from other IEDs. For example, electrical measurement data from energy-related signals captured by the at least one first IED installed at the first metering location M_1 may be used to generate a unique dynamic tolerance curve for the metering location M_1 (e.g., as shown in Fig. 30C) without any input (or data) from the at least one second IED or the at least one third IED. Additionally, electrical measurement data from energy-related signals captured by the at least

one second IED installed at the second metering location M_2 may be used to generate a unique dynamic tolerance curve for the metering location M_2 (e.g., as shown in Fig. 30D) without any input (or data) from the at least one first IED or the at least one third IED. Further, electrical measurement data from energy-related signals captured by the at least one third IED installed at the third metering location M_3 may be used to generate a unique dynamic tolerance curve for the metering location M_3 (e.g., as shown in Fig. 30E) without any input (or data) from the at least one first IED or the at least one second IED.

[0206] Referring to Fig. 30F, in which like elements of Fig. 30B are shown having like reference designations, another example electrical system is shown. Similar to the electrical system shown in Fig. 30B, the electrical system shown in Fig. 30F includes a plurality of metering locations (here, M_1 , M_2 , V_1). Also, similar to the electrical system shown in Fig. 30B, the electrical system shown in Fig. 30F includes at least one metering device installed or located at each of the metering locations (M_1 , M_2). Here, however, unlike the electrical system shown in Fig. 30B, the electrical system shown in Fig. 30F includes a virtual meter (V_1) accordance with embodiments of this disclosure.

[0207] In the illustrated embodiment, at least one first IED is installed at a first “physical” metering location M_1 , at least one second IED is installed at a second “physical” metering location M_2 , and at least one virtual meter is derived (or located) at a “virtual” (non-physical) metering location V_1 . The at least one first IED is a so-called “parent device” and the at least one second IED and the at least one virtual meter are so-called “child devices”. In the example embodiment shown, the at least one second IED and the at least one virtual meter are children of the at least one first IED (and, thus considered to be siblings with each other). In the illustrated embodiment, the at least one second IED and the at least one virtual meter are installed and derived, respectively, at respective metering locations M_2 , V_1 in the electrical system that “branch” from a common point (here, connection 1) associated with the metering location M_1 at which the at least one first IED is installed. Connection 1 is the physical point in the electrical system where the energy flow (as measured at M_1 by the at least one first IED)

diverges to provide energy to the left and right branches (as measured at M_2 by the at least one second IED, and as calculated for V_1 by the at least one virtual meter).

[0208] In accordance with embodiments of this disclosure, electrical measurement data associated with the virtual metering location V_1 may be created/derived by calculating the difference between the synchronous (or pseudo-synchronous) data from the at least one first IED (here, a parent device) installed at the first metering location M_1 and the at least one second IED (here, a child device) installed at the second metering location M_2 . For example, electrical measurement data associated with the virtual metering location V_1 may be derived by calculating the difference between electrical measurement data from energy-related signals captured by the at least one first IED and electrical measurement data from energy-related signals captured by the at least one second IED, at a specific point in time (e.g., $V_1 = M_1 - M_2$, for synchronous or pseudo-synchronous data). It is understood that virtual meters (e.g., the at least one virtual meter located at virtual metering location V_1) may include data from one or more unmetered branch circuits, which are inherently aggregated into a single representative circuit.

[0209] The electrical system shown in Fig. 30F is an example of a “partially metered” system, where only a subset of the total circuits is monitored by physical IEDs (here, the at least one first IED and the at least one second IED). In accordance with various aspects of this disclosure, dynamic tolerance curves can be independently developed for each physically metered point (M_1 , M_2) without any dependence on external input(s) from other IEDs. Additionally, in accordance with various aspects of this disclosure, the dynamic tolerance curve for a virtually metered point (V_1) is derived using select synchronous (or pseudo-synchronous) and complementary data (e.g., power, energy, voltage, current, harmonics, etc.) from physical IEDs (here, the at least one first IED, and the at least one second IED), and is dependent (sometimes, completely dependent) on these devices (here, the at least one first IED, and the at least one second IED). For example, returning briefly to Figs. 30C-30E, the dynamic tolerance curve for virtual metered point V_1 may be derived from the dynamic tolerance curve data for physical

metered points M_1 , M_2 (e.g., as shown in Figs. 30C and 30D, respectively). Because of this dependency, it is understood that issues (e.g., accuracy, missing data, non-synchronous data, etc.) with the at least one first IED and the at least one second IED will be reflected in the resulting virtual meter data in the illustrated embodiment. In the illustrated embodiment, the dynamic tolerance curve for virtual metered point V_1 may be the same as (or similar to) the dynamic tolerance curve shown in Fig. 30E as an example.

[0210] Referring to Fig. 30G, a further example electrical system includes at least one virtual meter located at a “virtual” metering location V_1 , at least one first IED installed at a first “physical” metering location M_1 , and at least one second IED installed at a second “physical” metering location M_2 . The at least one virtual meter is a so-called “parent device” or “virtual parent device,” and the at least one first IED and the at least one second meter are “child devices.” In the example embodiment shown, the at least one first IED and the at least one second IED are children of the at least one virtual meter (and, thus considered to be siblings with each other).

[0211] As illustrated, the at least one first IED and the at least one second IED are both installed (or located) at respective metering locations M_1 , M_2 in the electrical system that “branch” from a common point (here, connection 1) associated with the virtual metering location V_1 at which the at least one virtual meter is derived (or located). Connection 1 is the physical point in the electrical system where the energy flow (as calculated at V_1) diverges to provide energy to the left and right branches (as measured at M_1 and M_2 by the at least one first IED and the at least one second IED, respectively).

[0212] In accordance with embodiments of this disclosure, electrical measurement data associated with the first metering location V_1 is created/derived through a slightly different approach than described above in connection with Fig. 30F, for example. In particular, the electrical measurement data associated with the first metering location V_1 may be determined by calculating the summation of synchronous (or pseudo-synchronous) data from the at least

one first child IED installed at metering location M_1 and the at least one second child IED device installed at metering location M_2 (e.g., $V_1 = M_1 + M_2$, for synchronous or pseudo-synchronous data).

[0213] The electrical system shown in Fig. 30G is an example of a “partially metered” system, where only a subset of the total circuits is monitored by physical IEDs. In accordance with various aspects of this disclosure, dynamic tolerance curves can be independently developed for each physically metered point (M_1 , M_2) without any dependence on external input(s) from other IEDs. Additionally, in accordance with various aspects of this disclosure, the dynamic tolerance curve for the virtual parent meter (V_1) is derived using select complementary data (e.g., power, energy, voltage, current harmonics, etc.) from physical IEDs (M_1 , M_2), and is completely dependent on these devices (M_1 , M_2). Because of this dependency, it is understood that any issue (e.g., accuracy, missing data, non-synchronous data, etc.) with meters M_1 and M_2 will be reflected in virtual parent device V_1 .

[0214] Referring to Fig. 30H, another example electrical system includes at least one first virtual meter located at a first “virtual” metering location V_1 , at least one first IED installed at a first “physical” metering location M_1 , and at least one second virtual meter installed at a second “virtual” metering location V_2 . The at least one virtual meter is a “parent device” or a “virtual parent device”, and the at least one first IED and the at least one second virtual meter are “child devices”. In the example embodiment shown, the at least one first IED and the at least one second virtual meter are children of the at least one first virtual meter (and, thus considered to be siblings with each other).

[0215] As illustrated, the at least one first IED and the at least one second virtual meter are installed and derived, respectively, at respective metering locations M_1 , V_2 in the electrical system that “branch” from a common point (here, connection 1) associated with the first virtual metering location V_1 at which the at least first one virtual meter is located (or derived). Connection 1 is the physical point in the electrical system where the energy flow (as calculated

at V_1) diverges to provide energy to the left and right branches (as measured at M_1 by the at least one first IED, and as calculated at V_2).

[0216] In accordance with some embodiments of this disclosure, the electrical system shown in Fig. 30H is mathematically and probabilistically indeterminate because there are too many unknown values from necessary inputs. Assumptions may be made regarding the occurrence of power quality events (e.g., voltage events) on the virtual devices (V_1 , V_2); however, the impact of the power quality events may impossible (or extremely hard) to define in this case. As is appreciated from discussions above and below, virtual metering data is derived from data taken from physical IEDs. In the embodiment shown in FIG. 30H, there are too few physical IEDs to derive the “virtual” data. FIG. 30H is shown to illustrate some constraints related to virtual IED derivations.

[0217] Referring to Fig. 30I, a further example electrical system includes at least four virtual meters (or IEDs) located (or derived) at respective “virtual” metering locations (V_1 , V_2 , V_3 , V_4) in the electrical system, and at least five IEDs installed at respective “physical” metering locations (M_1 , M_2 , M_3 , M_4 , M_5) in the electrical system. In particular, the electrical system includes at least one first “parent” virtual meter located at a first “virtual” metering location V_1 , at least one first “child” IED installed at a first “physical” metering location M_1 , and at least one second “child” IED installed at a second “physical” metering location M_2 (with the at least one first IED at metering location M_1 and the at least one second IED at metering location M_2 being children of the at least one first virtual meter at metering location/position V_1). The electrical system also includes at least one third “child” IED installed at a third “physical” metering location M_3 and at least one second “child” virtual meter located at a second “virtual” metering location V_2 (with the at least one third IED at metering location M_3 and the at least one second virtual meter at metering location V_2 being children of the at least one first IED at metering location M_1).

[0218] The electrical system further includes at least one fourth “child” IED installed at a fourth “physical” metering location M_4 and at least one third “child” virtual meter located at a third “virtual” metering location V_3 (with the at least one fourth IED at metering location M_4 and the at least one third virtual meter at metering location V_3 being children of the at least one second virtual meter at metering location V_2). The electrical system also includes at least one fifth “child” IED installed at a fifth “physical” metering location M_5 and at least one fourth “child” virtual meter located at a fourth “virtual” metering location V_4 (with the at least one fifth IED at metering location M_5 and the at least one fourth virtual meter at metering location V_4 being children of the at least one third virtual meter at metering location V_3). As illustrated, there are essentially five layers in the metering hierarchy from the first virtual metering location V_1 , to the fifth “physical” metering location M_5 and the fourth “virtual” metering location V_4 .

[0219] The electrical system shown in Fig. 30I illustrates a partially metered system, where only a subset of the total circuits is monitored by physical devices/IEDs. In accordance with various aspects of this disclosure, dynamic tolerance curves can be independently developed for each physically metered location (M_1, M_2, M_3, M_4, M_5) without any dependence or interdependence on external input(s) from other IEDs. The dynamic tolerance curves for the virtual metering locations V_1, V_2, V_3, V_4 may be derived from complementary and synchronous (or pseudo-synchronous) data (e.g., power, energy, voltage, current, harmonics, etc.) as measured by physical IEDs installed at the discretely metered locations M_1, M_2, M_3, M_4, M_5 . Additionally, electrical measurement data from energy-related signals captured by the at least one second IED installed at the second metering location M_2 may be used to generate a dynamic tolerance curve for the metering location M_2 without any input (or data) from the at least one first IED or the at least one third IED.

[0220] In particular, the electrical measurement data associated with the first virtual metering location V_1 may be determined (and used to help generate a dynamic tolerance curve for the first virtual metering location V_1) by calculating the summation of synchronous (or pseudo-

synchronous) data from the at least one first child IED installed at metering location M_1 and the at least one second child IED device installed at metering location M_2 (e.g., $V_1 = M_1 + M_2$, for synchronous or pseudo-synchronous data). Additionally, the electrical measurement data associated with the second metering location V_2 may be determined (and used to help generate a dynamic tolerance curve for the second virtual metering location V_2) by calculating the difference between synchronous (or pseudo-synchronous) data from the at least one first child IED installed at metering location M_1 and the at least one third child IED device installed at metering location M_3 (e.g., $V_2 = M_1 - M_3$, for synchronous or pseudo-synchronous data).

[0221] The electrical measurement data associated with the third virtual metering location V_3 may be determined (and used to help generate a dynamic tolerance curve for the third virtual metering location V_3) by first calculating the difference between synchronous (or pseudo-synchronous) data from the at least one first child IED installed at metering location M_1 and the at least one third child IED device installed at metering location M_3 , and then calculating the difference between the first calculated difference and synchronous (or pseudo-synchronous) data from the at least one fourth child IED installed at metering location M_4 (e.g., $V_3 = M_1 - M_3 - M_4$, for synchronous or pseudo-synchronous data).

[0222] Additionally, the electrical measurement data associated with the fourth virtual metering location V_4 may be determined (and used to help generate a dynamic tolerance curve for the fourth virtual metering location V_4) by first calculating the difference between synchronous (or pseudo-synchronous) data from the at least one first child IED installed at metering location M_1 and the at least one third child IED device installed at metering location M_3 , and then calculating the difference between the synchronous (or pseudo-synchronous) data from the at least one fourth child IED installed at metering location M_4 and the at least one fifth child IED installed at metering location M_5 . The difference between the first calculated difference and the calculated difference between the synchronous (or pseudo-synchronous) data from the at least one fourth child IED installed at metering location M_4 and the at least one fifth child IED installed at metering location M_5 may be used to determine the electrical

measurement data associated with the fourth virtual metering location V_4 (e.g., $V_4 = M_1 - M_3 - M_4 - M_5$, for synchronous or pseudo-synchronous data).

[0223] As will be further appreciated from discussions below, using event triggers or alarms from one or more of the physical IEDs (M_1, M_2, M_3, M_4, M_5), it is possible to use pre-event and post-event data from the physical IEDs to develop dynamic tolerance curves, determine event impacts, quantify recovery times, and assess other associated costs at the virtual meters (and metering locations V_1, V_2, V_3, V_4). Again, validity of the derived information for the virtual meter (V_1, V_2, V_3, V_4) is dependent on the veracity, accuracy, synchronicity, and availability of data from the physical IEDs (M_1, M_2, M_3, M_4, M_5). In this particular case, there are many interdependencies used to derive data for the virtual meters (and metering locations V_1, V_2, V_3, V_4), so it is understood that some deficiency may be experienced for one or more derivations.

[0224] It is understood that the above-described examples for determining, deriving, and/or generating dynamic tolerance curves for virtual meters in an electrical system may also apply to aggregation of zones and systems. In spirit of the concepts describing “operational impact,” “recovery time,” “recovery energy costs,” and so forth, it is understood that aggregation may only make sense when it is 1) directly useful to the customer/energy consumer, 2) and/or useful to be leveraged for additional customer and/or business-centered benefits (present or future). That is why the best approach to aggregation is typically to focus on the worst-case scenario (i.e., event impact, event recovery time, other associated event costs, etc.). If aggregation is performed and it does not reflect the customers experience in trying to resolve the event in question, then it is difficult to achieve any usefulness from the aggregation. In short, just because something is mathematically and/or statistically feasible does not necessarily make it useful.

III. Evaluating Load Impact and Recovery Time Using Hierarchy and Dynamic Tolerance Curve Data

[0225] In embodiments, when a load impacting voltage event occurs, it is important for the energy consumer (or the systems and methods disclosed herein) to prioritize the “what, when, why, where, who, how/how much/how soon, etc.” of the response. More specifically: 1) what happened, 2) when did it happen, 3) why did it happen, 4) where did it happen, 5) who’s responsible, 6) how do I resolve the issue, 7) how much is it going to cost, and 8) how soon can I get it resolved. Embodiments described herein assist energy consumers with answering these questions.

[0226] Understanding and quantifying the impact of voltage (and/or other) events from a IED, zone, and/or system perspective is extremely important for energy consumers to understand their electrical system and facility’s operation in its entirety, and to respond to electrical events accordingly. Because each load has unique operating characteristics, electrical characteristics and ratings, functions, and so forth, the impact of a voltage event may differ from one load to the next. This can result in unpredictable behavior, even with comparable loads connected to the same electrical system and located adjacent to each other. It is understood that some aspects of the embodiments described below may refer to or overlap with previously discussed ideas presented herein.

[0227] System (or hierarchical) perspectives show how an electrical system or metering system is interconnected. When a voltage event occurs, its impact is strongly influenced by the system impedance and sensitivity of a given load. For example, Fig. 31 illustrates a relatively simple fully-metered electrical system experiencing a voltage event (e.g., due to a fault). In general, the system impedance will dictate the magnitude of the fault, protective devices will dictate the duration of the fault (clearing time), and location of the fault will be an important factor in the scope of the fault’s impact to the electrical system. In Fig. 31, its possible (even likely) the shaded area will experience a significant voltage sag followed by an interruption (due to the operation of protective device(s)). In embodiments, the duration of the event’s impact will be from the onset time of the fault until the system is again operating normally (note: this example states a recovery time of 8 hours). The unshaded area of the electrical system in Fig.

31 may also experience a voltage event due to the fault; however, the recovery time for the unshaded area will likely be briefer than the shaded area.

[0228] In embodiments, both the shaded and unshaded areas of the electrical system shown in Fig. 31 may be impacted by the fault; however, both may exhibit different recovery time durations. If the processes served by both the shaded and unshaded areas are critical to the facility's operation, then the system recovery time will be equal to the greater of the two recovery times.

[0229] In embodiments, it is important to identify and prioritize IEDs, zones, and/or systems. Zones may be determined within the electrical system hierarchy based on: protection schemes (e.g., each breaker protects a zone, etc.), separately derived sources (e.g., transformers, generators, etc.), processes or sub-systems, load types, sub-billing groups or tenants, network communications schemes (e.g., IP addresses, etc.), or any other logical classification. Each zone is a subset of the metering system's hierarchy, and each zone may be prioritized by type and each zone may be assigned more than one priority if applicable (e.g., high priority load type with low priority process). For example, if a protective device also acts as a IED and is incorporated into the metering system, it and the devices below it could be considered a zone. If the protective devices are layered in a coordinated scheme, the zones would be similarly layered to correspond with the protective devices. In Fig. 32, another method to automatically determine zones involves leveraging hierarchical context to evaluate voltage, current, and/or power data (other parameters may also be used as necessary) to identify transformer locations. Fig. 32 indicates three zones: utility source, transformer 1, and transformer 2. Fig. 33 is an exemplary illustration of an energy consumer's custom zone configuration.

[0230] Once the zones are established, prioritizing each zone will help the energy consumer better respond to voltage events (or any other event) and their impact. While there are techniques to automatically prioritize zones (e.g., largest to smallest load, load types, recovery times, etc.), the most prudent approach would be for the energy consumer to rank the

priorities of each zone. It is certainly feasible (and expected) for two or more zones to have an equal ranking in priority. Once zone priorities are established, it is then possible to analyze the load impact and recovery time for voltage events from a zonal perspective. Again, all of this may be automated using the techniques described above for establishing zones, prioritizing based on the historical effects of voltage events within the electrical system, and providing the energy consumer with analyses summaries based on these classifications.

[0231] Zones are also useful for identifying practical and economical approaches to mitigate voltage events (or other PQ issues). Because mitigation solutions can range from system-wide to targeted schemes, it is beneficial to evaluate mitigation opportunities the same way. As shown in Fig. 21 above, for example, mitigation solutions for voltage events become more expensive as the proposed solution moves closer to the electrical main switchgear.

[0232] In embodiments, evaluating zones to identify mitigation opportunities of voltage events can produce a more balanced, economical solution. For example, one zone may be more susceptible to voltage events (e.g., perhaps due to a local motor starting) than another zone. It may be possible to provide electrical service to sensitive loads from another zone. Alternatively, it may be prudent to move the cause of the voltage events (e.g., the local motor) to another service point in another zone.

[0233] A further example benefit of evaluating zones is the ability to prioritize capital expenditure (CAPEX) investments for voltage event mitigation based on the prioritization of each respective zone. Assuming the zones have been properly prioritized/ranked, important metrics such as percent load impacted (relative), total load impacted (absolute), worst case severity, recovery time, etc. may be aggregated over time to indicate the best solution and location for mitigative equipment. Using aggregated zonal voltage tolerance data from IEDs within the zone may provide a “best-fit” solution for the entire zone or locate a targeted solution for one or more loads within a zone.

IV. Alarm Management of IEDs Using Dynamic Tolerance Curves and Associated Impact Data

[0234] As discussed above, each location within an electrical system/network generally has unique voltage event tolerance characteristics. Dynamically (continuously) generating the distinct voltage event tolerance characteristics for one or more metered points in the electrical system provides many benefits including a better understanding of an electrical system's behavior at the metered point, suitable and economical techniques for mitigating voltage anomalies, verification that installed mitigation equipment meets its design criteria, leveraging non-PQ IEDs to help characterize voltage event tolerances, and so forth.

[0235] Another example advantage of characterizing an IED point's voltage event tolerance is to customize alarms at the IED's point of installation. Using dynamic voltage event characterization to manage alarms provides several benefits including ensuring 1) relevant events are captured, 2) excessive alarms are prevented (better "alarm validity"), 3) appropriate alarms are configured, and 4) important alarms are prioritized.

[0236] Existing approaches to alarm configuration and management often include:

- Manual configuration by energy consumer based on standards, recommendations, or guessing.
- Some form of setpoint learning that necessitated a configuration "learning period" to determine what was normal. Unfortunately, if an event occurred during the learning period, it would be considered normal behavior unless the energy consumer caught it and omitted the data point.
- "Capture Everything" approach that requires the energy consumer to apply filters to distinguish which alarms are important and which are not.

[0237] In short, the energy consumer (who may not be an expert) could be required to actively discriminate which event alarms/thresholds are important, either before or after the event alarms are captured in a “live system.”

[0238] Currently, IED voltage event alarms have two important thresholds that are typically configured: 1) magnitude, and 2) duration (sometimes referred to as alarm hysteresis). Equipment/loads are designed to operate at a given optimal voltage magnitude (i.e., rated voltage) bounded by an acceptable range of voltage magnitudes. Additionally, it may be possible for a load to operate outside the acceptable voltage range, but only for short periods of time (i.e., duration).

[0239] For example, a power supply may have a rated voltage magnitude of 120 volts rms $\pm$ 10% (i.e., $\pm$ 12 volts rms). Therefore, the power supply manufacturer is specifying the power supply should not be operated continuously outside the range of 108-132 volts rms. More precisely, the manufacturer is making no promises regarding the power supply's performance or susceptibility to damage outside their prescribed voltage range. Less evident is how the power supply performs during momentary (or longer) voltage excursions/events outside the prescribed voltage range. Power supplies may provide some voltage ride-through due to their inherent ability to store energy. The length of voltage ride-through depends on a number of factors, primarily the amount/quantity of load connected to the power supply during the voltage excursion/event. The greater the load on the power supply, the shorter the power supply's ability to ride-through the voltage excursion/event. In summary, this substantiates the two parameters (voltage magnitude and duration during the voltage event), which also happen to be the same two parameters exemplified in basic voltage tolerance curves. It further validates load as an additional parameter that may be considered where a voltage event's impact and IED alarm thresholds are concerned.

[0240] In embodiments of this disclosure, a IED device's voltage magnitude alarm threshold may be initially configured with a reasonable setpoint value (e.g., the load's rated voltage $\pm$ 5%). The corresponding duration threshold may be initially configured to zero seconds (highest

duration sensitivity). Alternatively, the IED device's voltage magnitude alarm threshold may be configured for ANY voltage excursion above or below the load's rated voltage (highest magnitude sensitivity). Again, the corresponding duration threshold (alarm hysteresis) may be initially configured to zero seconds (highest sensitivity).

[0241] As the metered voltage deviates beyond the voltage alarm threshold (regardless of its configured setpoint), the IED device may alarm on a voltage disturbance event. The IED may capture characteristics related to the voltage event such as voltage magnitude, timestamp, event duration, relevant pre/during/post-event electrical parameters and characteristics, waveform and waveform characteristics, and/or any other monitoring system indication or parameter the IED is capable of capturing (e.g., I/O status positions, relevant time stamps, coincident data from other IEDs, etc.).

[0242] Voltage events may be evaluated to determine/verify whether a meaningful discrepancy exists between a pre-event electrical parameter's value (e.g., load, energy, phase imbalance, current, etc.) and its corresponding post-event value. If a discrepancy does not exist (pre-event vs. post-event), the voltage event may be considered to be "non-impactful" meaning there is no indication the energy consumer's operation and/or equipment was functionally affected by the voltage event. The voltage event data may still be retained in memory; however, it may be classified as non-impactful to the energy consumer's operation at the point where the IED captured the voltage event. The existing voltage alarm magnitude and duration threshold setpoints may then reconfigure to the magnitude and duration of the non-impactful event (i.e., reconfigured to less sensitive setpoints). Ultimately, in embodiments the more severe voltage event that does not indicate any operational and/or equipment functional impact at the IED point will become the new voltage magnitude and duration threshold for the voltage event alarms for that respective IED.

[0243] If a pre-event vs. post-event discrepancy does exist, the voltage event may be considered to be "impactful" meaning there is at least one indication the energy consumer's

operation and/or equipment was functionally affected by the voltage event. The voltage event data may be retained in memory, including all measured/calculated data and metrics related to the impactful event (e.g., % impacted, absolute impact, voltage magnitude, event duration, etc.). Moreover, additional relevant data associated with the voltage event may be appended to the voltage event data record/file at a later time (e.g., calculated recovery time from event, additional voltage event information from other IEDs, determined event source location, metadata, IED data, other electrical parameters, updated historical norms, statistical analysis, etc.). Because the voltage event is determined to be “impactful,” the voltage alarm magnitude and duration threshold setpoints are left unchanged to ensure less severe, yet still impactful, events continue to be captured by the IED at its respective installation point within the electrical system.

[0244] In embodiments, the final result of this process is the discrete IED device produces a custom voltage alarm template at the point of installation that indicates voltage events (and their respective characteristics) producing impactful events and/or differentiates impactful voltage events from non-impactful voltage events. As more voltage events occur, the custom voltage alarm template more accurately represents the true voltage event sensitivity at the IED’s point of installation. In embodiments, it is possible to capture any (or substantially any) voltage event that exceeds any standardized or custom threshold; however, the energy consumers may choose to prioritize impactful events as a distinctive category of alarms/indicators. This could be used, for example, to minimize the inundation of superfluous voltage alarms in the energy consumer’s monitoring system by annunciating only prioritized alarms considered to indicate an impactful had occurred.

[0245] As indicated above in connection with other embodiments of this disclosure, the tailored voltage tolerance curve built for customized voltage event alarm annunciation could also be used to recommend mitigation equipment to improve ride-through characteristics at the IED’s point of installation. Should the energy consumer install mitigation equipment, a manual or automatic indication can be provided/detected by the system so a new version of

the voltage tolerance template can be created based on the system modification (e.g., mitigation equipment installation). In embodiments, a practical approach may be a manual indication of supplemental mitigation equipment being added to the system; however, an automatic indication could also be provided based on “uncharacteristic changes” in the electrical system’s response to voltage events at the point of the IED’s installation, for example. These “uncharacteristic changes” could be established, for example, by statistically evaluating (e.g., via analytics algorithms) one or more electrical parameters (i.e., voltage, current, impedance, load, waveform distortion, and so forth). In embodiments, they may also be identified by any sudden change in voltage event ride through at the point of the IED’s installation. A query may be made of the energy consumer or electrical system manager to validate any additions, eliminations or changes to the electrical network. Feedback from the energy consumer could be used to better refine any statistical evaluations (e.g., analytics algorithms) related to voltage events (or other metering features). Historical information (including customized voltage tolerance curves) would be retained for numerous assessments such as verification of the effectiveness of mitigation techniques, impact of new equipment installation to voltage ride-through characteristics, and so forth.

[0246] As part of this embodiment, more than two event parameters may be used to configure thresholds to trigger alarms for voltage events. In the description above, the magnitude of voltage deviation and the duration of the voltage event are used configure and trigger voltage event alarms. In embodiments, it is also possible to include more dimensions such as load impact and/or recovery time to configure voltage event alarms. Just as it is possible to set voltage event setpoint thresholds to alarms only when any load is impacted, it is also possible to configure voltage event setpoint thresholds to allow some level of impact to the load. Through load identification, either manually or automatically (based on electrical parameter recognition), it is possible to alarm when only certain types of loads experience an impact due to a voltage event. For example, some loads have certain signatures such as elevated levels of specific harmonic frequencies. In embodiments, it would be possible to trigger a voltage event alarm if those specific harmonic frequencies are no longer evident.

[0247] It is possible to use other parameters to customize the alarm templates. For example, the energy consumer may only be interested in voltage events with a recovery times greater than 5 minutes. Voltage event characteristics that typically produce recovery times shorter than 5 minutes could be filtered by using historical event data to configure the alarm templates accordingly. Moreover, energy consumers may only be interested in voltage events that generate monetary losses greater than \$500. Again, voltage event characteristics that typically produce monetary losses less than \$500 could be filtered using historical data to configure the alarm templates accordingly. As is apparent, any other useful parameter derived from voltage event characteristics may be similarly used to tailor and provide practical alarm configurations. Multiple parameters may also be concurrently used (e.g., recovery times > 5 minutes AND monetary losses > \$500) to provide more complex alarm schemes and templates, and so forth.

[0248] In embodiments, as more voltage events occur, additional voltage pre/during/post-event attributes and parameters are captured at both the discrete and system level and integrated into typical historical characterizations (historical norms). This additional characterization of voltage events can be used, for example, to estimate/predict the expected recovery time from both a discrete and system level. Additionally, recommendations can be made to energy consumers on how to achieve a faster recovery time based on historical event data regarding the effective sequencing to reenergize loads.

[0249] In embodiments, customer alarm prioritization can be performed (for voltage events or any other event type) based on the level of load measured at one or more discrete metering/IED points within the electrical system. When some indication is received from a metered/virtual/IED point that a load or loads have changed (or are operating atypically), voltage event alarm setpoint thresholds may be reevaluated and modified based on the level of load measured at one or more discrete (or based on the load's atypical operation). For example, it may be advantageous to null, silence or deprioritize the voltage event alarm when one or more IEDs indicate the measure load is low (indicating the facility is off-line). Conversely,

raising the priority of the voltage event alarm would be prudent as one or more IEDs indicate additional loads being started.

[0250] As mentioned earlier in this section, in embodiments it is possible to use this feature to prioritize alarms (including voltage event alarms). The IED may be configured to capture data related to substantially any perceptible voltage variation from the nominal voltage (or load(s) rated voltage) at the point of installation, and take an action(s) including storing, processing, analyzing, displaying, controlling, aggregating, and so forth. Additionally, the same action(s) may be performed on substantially any alarms (including voltage event alarms) that exceed some pre-defined setpoint/threshold such as those defined by a dynamic voltage tolerance curve, standard(s), or other recommendations (as derived from any number or combination of electrical parameters, I/O, metadata, IED characteristics, etc.). In embodiments, any or all captured events (including voltage events) may then be analyzed to automatically prioritize the alarms at a discrete, zone and/or system level based on any number of parameters including: alarm type, alarm description, alarm time, alarm magnitude, affected phase(s), alarm duration, recovery time, waveform characteristics, load impact associated with an alarm, location, hierarchical aspects, metadata, IED characteristics, load type, customer type, economic aspects, relative importance to operation or load, and/or any other variable, parameter or combination thereof related to the event (including voltage events) and the energy consumer's operation. Prioritizing may be relevant for the inherent characteristics of discrete events or involve comparisons of more than one event (including voltage events), and may be performed as events originate, deferred to a later time, or dependent on the aforementioned parameters. In embodiments, prioritization may be interactive with the energy consumer, automated, or both with the goal being to facilitate the energy consumer's preferences.

[0251] In embodiments, parameters to be considered may include at least electrical data (from at least one phase), control data, time data, metadata, IED data, operational data, customer data, load data, configuration and installation data, energy consumer preferences,

historical data, statistical and analytical data, economic data, material data, any derived/developed data, and so forth.

[0252] For example, Fig. 34 illustrates a relatively simple voltage tolerance curve for an IED with voltage alarm thresholds set at $\pm 10\%$ of the nominal voltage for events arbitrarily ranging from 1usec to steady-state. In Fig. 35, a voltage sag event occurs on this IED that sags to 50% of the nominal voltage and lasts for 3 milliseconds in duration. Pre/during/post-event analysis of this event indicates no load was impacted. In embodiments, because no load was impacted, the alarm setpoint thresholds in the IED are reconfigured to indicate/prioritize the occurrence of a voltage event when (sometimes, only when) the magnitude and duration of a voltage event are more severe than the event described in Fig. 35. Fig. 36 illustrates changes made to the original voltage-tolerance curve. In short, voltage events occurring in the red area of the graph are expected to be non-impactful and voltage events occurring in the green area of the graph may or may not be impactful. In Fig. 37, another voltage event occurs and is captured by the same IED. In this second voltage event, a voltage interruption (to 0% of the nominal voltage) occurs and lasts for 1 millisecond in duration. Again, pre/during/post-event analysis of the second event indicates no load was impacted. And again, the alarm setpoint thresholds in the IED are reconfigured to indicate/prioritize the occurrence of a voltage event when (sometimes, only when) the magnitude and duration of the voltage event are more severe than the event described in Fig. 36. Fig. 38 illustrates changes made to the original voltage-tolerance curve.

[0253] In Fig. 39, a third voltage event occurs and is captured by the IED. In this third voltage event, the voltage sags to 30% of the nominal voltage and lasts for 2 milliseconds in duration. This time the pre/during/post-event analysis of the third event indicates 25% of the load was impacted (e.g., disconnected) at 30% of the nominal voltage. Subsequently, the alarms setpoint thresholds are left unchanged because of the 25% impact to the load (i.e., a load impact occurred where it was expected to occur). Fig. 40 illustrates the final settings of the voltage event alarm threshold after these three voltage events. Note that the third event is not shown on the graph because the purpose of this embodiment of the disclosure is to

reconfigure/modify voltage event setpoint thresholds. The energy consumer may be notified of the third event occurrence, and the voltage event data, calculations, derivation and any analyses may be stored for future reference/benefits.

V. Evaluating and Quantifying Voltage Event Impact on Energy and Demand

[0254] Establishing the losses incurred due to voltage events is often complicated; however, embodiments of this disclosure provide an interesting metric (or metrics) to help quantify the energy and demand contribution to the total losses. When a voltage event occurs, facility processes and/or equipment may trip off-line. The activity of restarting processes and/or equipment consumes energy and can (in some cases) produce a peak demand for the facility. Although these costs are frequently overlooked, they may be considerable over time while contributing little to the actual production and profitability of a facility's operation. There may be ways to recoup some of these costs through insurance policy coverage, tax write-offs in some jurisdictions, and even peak demand "forgiveness" from the utility. Perhaps most importantly, quantifying the financial impact of voltage events to utility bills can provide incentives to mitigate the voltage events leading to these unexpected and potentially impactful losses.

[0255] When a voltage event occurs, the analyses described above may be performed to determine the level of impact to the load or operation. If no evidence is found of an impact on a load, process, and/or system, this aspect of this embodiment of the disclosure may be disregarded. If the voltage event is found to have impacted a load, process, and/or system, the pre/during/post-event analyses of electrical parameters are performed. The recovery time clock starts and this embodiment of the disclosure categorizes the energy consumption, demand, power factor, and any other parameter related to the utility billing structure as associated with the recovery time interval. Evaluation and analyses may be performed on these parameters to determine discrete, zonal and/or system metrics (including aggregation), comparisons to historical event metrics, incremental energy/demand/power factor costs and so forth. These metrics may be evaluated against local utility rate structures to calculate the total

energy-related costs for recovery, discrete, zonal, and/or systems most susceptible and most costly during the recovery period for targeted mitigation, expectations based on historical voltage event data (e.g., number of events, recovery period of events, energy costs for events, etc.), opportunities to operationally/procedurally improve voltage event response time, and so forth.

[0256] In embodiments, the data and analyses collected before, during and/or after the recovery period may be filtered, truncated, summarized, etc. to help the energy consumer better understand the impact of the voltage event (or other event) on their electrical system, processes, operation, response time, procedures, costs, equipment, productivity or any other relevant aspect of their business's operation. It can also provide a useful summary (or detailed report) for discussions with utilities, management, engineering, maintenance, accounting/budgeting, or any other interested party.

VI. Disaggregation of Typical and Atypical Operational Data Using Recovery Time

[0257] It is important to recognize a facility's operation during a recovery period is often aberrant or atypical as compared to non-recovery times (i.e., normal operation). It is useful to identify, "tag" (i.e., denote), and/or differentiate aberrant or atypical operational data from normal operational data (i.e., non-recovery data) for performing calculations, metrics, analytics, statistical evaluations, and so forth. Metering/monitoring systems do not inherently differentiate aberrant operational data from normal operational data. Differentiating and tagging operational data as either aberrant (i.e., due to being in recovery mode) or normal provides several advantages including, but not limited to:

1. Analyses (such as the aforementioned) may assume operational uniformity throughout all the data; however, it is useful to disaggregate aberrant or atypical operational patterns from normal operational patterns to better evaluate and understand the significance of the data being analyzed. Data analysis is improved by providing two different categories of operations; normal and aberrant/abnormal/atypical. Each may

be analyzed automatically and independently to provide unique and/or more precise information regarding each operational mode within a facility or system. Differentiating normal operational data from atypical operational data (i.e., due to a voltage event) further bolsters decisions made based on the conclusions of analyses.

2. Differentiating normal and aberrant operational modes makes it possible to provide discrete baseline information for each operational mode. This provides the ability to better normalize operation data because atypical data can be excluded from analysis of system data. Additionally, aberrant operational modes may be analyzed to help understand, quantify and ultimately mitigate impacts associated with impactful voltage events. In the case of event mitigation, data analysis of aberrant operational periods will help identify possible more effective and/or economical approaches to reducing the impact of voltage events.
3. Losses incurred due to voltage events are generally difficult to establish; however, evaluations of data tagged (i.e., partitioned, denoted, etc.) as abnormal/aberrant/atypical may be used to identify energy consumption outliers associated with voltage events. This information may be used to help quantify the energy and demand contribution of events to the total losses. When a voltage event occurs, equipment may unintentionally trip off-line. The process of restarting equipment and processes consumes energy and can (in some cases) produce a new peak demand for the facility. Although these costs are frequently overlooked/missed, they may be considerable over time while contributing little to the actual production and profitability of the operation. There may be ways to recoup some of these costs through insurance policy coverage, tax write-offs in some jurisdictions, and even peak demand “forgiveness” from the utility. Perhaps most importantly, quantifying the financial impact of voltage events to utility bills can provide incentive to mitigate the voltage events leading to these unexpected and potentially impactful losses.

VII. Other Evaluations and Metrics Related to Voltage Event Impact and Recovery Time

[0258] As is known, voltage events including outages are a leading global cause of business interruption-related losses. The annual estimated economic loss for medium and large businesses is estimated to be between \$104 billion and \$164 billion based on a study by Allianz Global. In embodiments, by incorporating additional economic metadata, it is possible to evaluate individual voltage events to determine the monetary impact of these events. Additionally, in embodiments it is possible to totalize the voltage event impacts by aggregating data and information from individual events. Some example useful financial information to help quantify the economic impact of voltage events include: average material loss/event/hour, utility rate tariffs (as discussed above), average production loss cost/event/hour, estimated equipment loss/event/hour, average 3rd party costs/event/hour, or any other monetary metric related to the cost of downtime on a per event or daily/hourly/minutely basis. Using the recovery time from the calculations described above, metrics may be determined for substantially any loss that has been monetarily quantified. These metrics may be determined at a discrete IED, zone and/or system level accordingly.

[0259] A number of new voltage event-related indices are set forth herein as useful metrics for qualifying and quantifying voltage events and anomalies. While these new indices focus on voltage sags, in embodiments they may also be considered for any other voltage event or category of power quality event. Example indices include:

- Mean Time Between Events (MTBE). As used herein, the term “MTBE” is used to describe the average or expected time a system or portion of a system is operational between events and their subsequent recovery time. This includes both impactful and non-impactful events, so there may or may not be a quantity of recovery time associated with each event.
- Mean Time Between Impactful Events (MTBIE). As used herein, the term “MTBIE” is used to describe the average or expected time a system or portion of a system is operational between events and their subsequent recovery time. In embodiment,

this metric is limited to only impactful events and will likely have some quantity of recovery time associated with each event.

- Mean Time to Restart (MTTR). As used herein, the term “MTTR” is used to describe the average time it takes to restart production at a system or portion of a system (e.g., load, zone, etc.) level. This “average time” includes all (or substantially all) factors involved in restarting production including (but not limited to): repairs, reconfigurations, resets, reinitializations, reviews, retests, recalibrations, restarts, replacing, retraining, relocating, revalidations, and any other aspect/function/work effecting the recovery time of an operation.
- Sag rate. As used herein, the term “sag rate” is used to describe the average number of voltage sag-events of a system or portion of a system over a given time period such as hours, months, years (or other time period).
- Production Availability. As used herein, the term “production availability” generally refers to the immediate readiness for production, and is defined as the ability of a facility to perform its required operation at a given time or period. This metric focuses on event-driven parameter(s) and may be determined by:

$$PA_i = \frac{MTBIE}{MTBIE + MTTR}$$

[0260] In embodiments, systems, zones, and/or discrete IED points may be characterized by their “Number of 9’s Production Up-Time,” which is an indication of the production availability exclusive of the recovery time duration. Similar to the number of 9’s in the usual connotation, this metric may be determined annually (or normalized to an annual value) to provide an indication or metric of the impact of voltage events (or other events) on an operation’s productivity. This metric may be useful to help identify mitigation investment opportunities and to prioritize those opportunities accordingly.

[0261] In embodiments, it is possible to use the metrics set forth above to estimate/predict recovery time based on historical recovery time information. A voltage event’s magnitude,

duration, location, metadata, IED characterization, or other calculated/derived data and information, for example, may be used to facilitate these estimations and predictions. This measure may be performed and provided to energy consumers at the discrete IED point, zone, and/or system level as one or more reports, texts, emails, audible indications, screens/displays, or through any other interactive means.

[0262] A few examples of supplementary metrics that may be unique to an energy consumer's operation and assist in prioritizing mitigation equipment considerations for placement, investment, etc. include:

- Average Zonal Interruption Frequency Index (AZIFI). AZIFI is an example metric that can be used to quantify zones experiencing "the most" interruptions in an electrical system. As used herein, AZIFI is defined as:

$$AZIFI = \frac{\text{number of zone impacts within facility}}{\text{total number of zones in the system}}$$

- Zonal Impact Average Interruption Frequency Index (ZIAIFI). ZIAIFI is an example metric that can be used to show trends in zone interruptions along with number of zones affected in electrical system. As used herein, ZIAIFI is defined as:

$$ZIAIFI = \frac{\text{number of zone impacts}}{\text{number of zones that had at least one impact}}$$

- Average Zonal Interruption Duration Index (AZIDI). AZIDI is an example metric that can be used to indicate an overall reliability of the system based on an average of zone impacts. As used herein, AZIDI is defined as:

$$AZIDI = \frac{\text{sum of the recovery time durations of all impacted zones}}{\text{total number of zones in the system}}$$

- Zonal Total Average Interruption Duration Index (ZTAIDI). ZTAIDI is an example metric that can be used to provide an indication of the average recovery period for zones that experienced at least one impactful voltage event. As used herein, ZTAIDI is defined as:

$$ZTAIDI = \frac{\text{sum of the durations of all zone impacts}}{\text{number of zones that experienced at least one impact}}$$

[0263] While the foregoing metrics focus on zone-related impacts, in embodiments some or all concepts may be reused for discrete IED points or (in some cases) system impact metrics. It is understood that the purpose here is to document examples of the ability to create useful metrics for energy consumers and their operations; not to define every possible metric or combination thereof.

[0264] It is also understood that each of the metrics discussed above may be further determined and partitioned for upstream, downstream, internal (e.g., facility), and external (e.g., utility) voltage event sources as appropriate. The latter two mentioned (internal/external) may require some level of hierarchical classification of the IED and/or electrical system. Other classifications of hierarchies (e.g., protection layout schemes, separately derived sources, processes or sub-systems, load types, sub-billing groups or tenants, network communications schemes, etc.) may be used to create/derive additional useful metrics as needed to better evaluate the impact of voltage events on a facility's operation, for example. Outputs from embodiments of this disclosure may be provided by one or more reports, texts, emails, audible indications, screens/displays, or through any other interactive means. Indications may be provided at the IED, on-site software, cloud, gateway, or other monitoring system component and/or accessory. In embodiments, the outputs and indications may be generated by circuitry and systems according to the disclosure in response to the circuitry and systems receiving and processing respective inputs.

VIII. Voltage Event Recovery Status Tracking

[0265] An example method according to the disclosure for reducing recovery time periods includes providing a method of tracking the recovery as it progresses. By identifying and monitoring the recovery periods through discrete IEDs, zones, hierarchies, and/or the system in real-time, the energy consumer (and the systems and methods disclosure herein) is/are better able to identify, manage, and expedite the recovery process for an event throughout their facility. Event recovery tracking allows energy consumers to understand the status of the

recovery and make better and quicker decisions to facilitate its recovery. This embodiment would also allow the energy consumer to review historical data to make recovery improvements, produce and/or update recovery procedures, identify zonal recovery constrictions, troublesome equipment, and so forth to improve future event recovery situations (and thus, increase system uptime and availability). Alarming capabilities may be incorporated into recovery situations to provide indications of constraining locations within zones or the facility. Historical recovery metrics or some other configured setpoints may be used to determine recovery alarm threshold settings for IEDs, system software, and/or cloud, and outputs from embodiments of this disclosure may be provided by one or more reports, texts, emails, audible indications, screens/displays, or through any other interactive means.

IX. Developing Various Baselines Related to Voltage Events

[0266] Another example method for determining expected recovery times uses factors such as market segments and/or customer types, processes-based evaluations, and/or load and equipment types to determine the expected recovery times. By defining recovery times based on these and other factors, for example, a recovery time baseline or reference can be developed with respect to a voltage event's magnitude, duration, percent load impacted, and/or any other electrical parameter, metadata, or IED specification. The baselines/references may be used to set recovery alarm thresholds, assess recovery time performance and identify opportunities for improvement, estimate actual vs. expected recovery time and costs, improve accuracy of estimates for impactful voltage events, and so forth. Actual historical voltage event impact and recovery time data may be used to produce relevant models through various means including statistical analyses (and/or analytics) and evaluations, simple interpolation/extrapolation, and/or any other method that produces a reasonable typical value(s). Baseline/reference models may range from simple to complex, and may be created or determined for discrete IED locations, zones, or entire systems, and outputs from embodiments of this disclosure may be provided by one or more reports, texts, emails, audible indications, screens/displays, or through any other interactive means.

X. Evaluating Voltage Event for Similarities to Identify Repetitive Behavior

[0267] In embodiments, evaluating voltage events across an electrical system to examine event similarity may be useful for energy consumers. Similarities may be in event time of occurrence, seasonality, recovery time characteristics, behavior of electrical parameters, behavior of zonal characteristics, behavior of operational processes, and/or any other notable behaviors or commonalities. Identifying repetitive behaviors and/or commonalities may be an important tactic for prioritizing and resolving voltage event effects. Moreover, analysis/analytics of historical data may provide the ability to predict the system impact and recovery time due to a voltage event after the initial onset of said voltage event.

XI. Voltage Event Forecasting

[0268] As mentioned in previous embodiments of the disclosure, it is important to be able to identify beneficial opportunities for energy consumers to mitigate voltage events. Another metric that may be considered is forecasting an estimated number of interruptions, estimated impact, and total recovery time (and associated costs). In embodiments, this metric may be extremely useful for planning purposes, support of capital investment opportunities in voltage event mitigation equipment, and even to forecast expected savings for installing said mitigation equipment. These forecasts may be evaluated at a later point in time to ascertain their accuracy and to fine-tune forecasts and expectations going forward.

XII. Other Graphs and Diagrams Related to Voltage Event Impact and Recovery Time

[0269] Aside from the various plots (or graphs) discussed in connection with the embodiments described above, there are other additional useful methods to display data related to voltage events. The graphs described below in connection with Figs. 41-44, for example, are only a few examples of displaying data in a useful format; there may be many other methods to present voltage event data in a meaningful way that can benefit energy consumers. Graphs, charts, tables, diagrams, and/or other illustrative techniques, for example, may be used to summarize, compare, contrast, validate, order, trend, demonstrate relationships, explain, and so forth.

These data types may be real-time, historical, modeled, projected, baseline, measured, calculated, statistical, derived, summarized, and/or estimated. Graphs may also be any dimension (e.g., 2-D, 3-D, etc.), color, shade, shape (e.g., line, bar, etc.), etc. to provide a unique and useful perspective.

[0270] Fig. 41 illustrates an example of the load impact versus recovery time for a single event. The green area is indicative of normal or expected range of operational parameters, the shaded orange area is highlighting the recovery time period, and the black line is the load as a function of time. Fig. 42 illustrates an example of a series of impactful events versus their recovery time from a single IED (multiple IEDs could also be used here). In this example, the green area is indicative of normal or expected operational parameters, and the shaded orange highlights the periods when the system has experienced an impactful event and experienced a recovery period. Fig. 43 illustrates an example of additional data being integrated with the data shown in Fig. 41. In this example, the green area is indicative of normal or expected range of operational parameters, the shaded orange is highlighting the recovery time period, the black line is showing the load as a function of time, the dashed pink line is showing the expected load as a function of time, and the dashed blue line shows a typical pre-event profile. As a rule of thumb, the behavior of upstream events may be more unpredictable than downstream events over time. Fig. 44 illustrates an example of pre/during/post-event percent of load impact versus recovery time for a voltage event. Again, different variables, metrics parameters, characteristics, etc. may be graphed, illustrated, etc. shown as needed or useful.

XIII. Aggregation/consolidation of Voltage Event Impact and Recovery Time Data

[0271] As is known, voltage events are often extensive, impacting multiple loads, processes, and even the entire system concurrently. In embodiments, metering systems according to the disclosure may exhibit multiple alarms from different IEDs located across the facility. Source events generally impact the entire system, for example, resulting in every (or substantially every) capable IEDs indicating an event has occurred.

[0272] In embodiments, aggregating/consolidating the multitude of voltage event data, alarms and impacts across a system is important for several reasons. First, many energy consumers have a tendency to ignore “alarm avalanches” from monitoring systems, so aggregating/consolidating voltage event data decreases the number alarms the energy consumer has to review and acknowledge. Second, the data from a flurry of alarms is often the result of one voltage event coming from the same root cause. In this case, it is much more efficient to reconcile all coincident voltage events captured by multiple IEDs into a single event for reconciliation. Third, bundled voltage events are much easier to analyze than independent voltage events as most of the relevant data and information is available in one place. For the sake of brevity, there are many other reasons to aggregate/consolidate voltage events not listed here.

[0273] The ability to aggregate/consolidate the impact of voltage events and their often-accompanying recovery times is important because it helps avoid redundancy of event data. Redundant event data can skew metrics and exaggerate conclusions, which may result in flawed decisions. This disclosure focuses on three layers of aggregation/consolidation within electrical systems: IED, zonal and system.

[0274] In embodiments, the first layer (IED) requires minimal aggregation/consolidation because data is acquired from a single point/device and (hopefully) the device shouldn't be producing redundant information within itself from voltage events. In some cases, there may be somewhat superfluous alarm information from a single device. For example, a three-phase voltage event may provide one alarm for each of the three phases experiencing the voltage event. Moreover, an alarm may be triggered for both the event pickup and dropout, resulting in six total voltage event alarms (a pickup and dropout alarm for each of the three phases). While this example of alarm abundance may be bothersome and confusing, many devices and monitoring systems already aggregate/consolidate multiple event alarms as just described into a single event alarm. In some embodiments, a single voltage event alarm may be provided from each IED for each voltage event that occurs in the electrical system.

[0275] It was mentioned above that a voltage event often impacts multiple IEDs within a monitoring system; specifically, those that are capable of capturing anomalous voltage conditions. Since zones and systems typically consist of multiple IEDs, the need to aggregate/consolidate the impact and subsequent repercussions of voltage events lies with these two (zones and systems). Although a zone may encompass an entire system, zones are configured as a subset/sub-system of the electrical and/or metering system. However, because zones and systems both generally consist of multiple devices, they will be treated similarly.

[0276] In embodiments, there are different methods/techniques to aggregate/consolidate zones. A first example method includes evaluating the voltage event impact and recovery time from all IEDs within a particular zone and attributing the most severe impact and recovery time from any single IED within that zone to the entire zone. Because the event impact and recovery time are independent variables, and therefore may be derived from different IEDs, these two variables should be treated independently from each other. Of course, it would be important to track which zonal device was considered/recognized as having experienced the most severe impact and which zonal device experienced the longest recovery time. This same approach could be used for systems by leveraging the conclusions generated from the zone evaluations. Ultimately, the recovery time for a system is not completed until all relevant IEDs indicate that is the case.

[0277] A second example method includes assessing a voltage event within a zone by using statistical evaluations (e.g., average, impact and average recovery time, etc.) from all IEDs with a particular zone. In this case, the severity of a voltage event may be determined for the entire zone by statistically appraising data from all IEDs and providing results to represent the entire zone for each particular voltage event. Statistical determinations including means, standard deviations, correlations, confidence, error, accuracy, precision, bias, coefficients of variation, and any other statistical methods and/or techniques may be employed to aggregate/consolidate the data from multiple IEDs to a representative value or values for the zone. The same statistical approach may be used to combine zones into representative

metrics/values for system impact and recovery time. Again, the recovery time for a system will be contingent on each relevant IED indicating that is the case.

[0278] Another example method to evaluate voltage events is by load-type. In embodiments, the energy consumer (or systems and method disclosed herein) may choose to categorize and aggregate/consolidate loads by similarity (e.g., motors, lighting, etc.) regardless of their location within the facility's electrical system, and evaluate the impact and recovery time of those loads accordingly. It would also be possible to evaluate voltage events by their respective processes. By aggregating/consolidating loads (regardless of type, location, etc.) associated with the same process, the impact and recovery time could be quantified for said process. Another method to aggregate/consolidate voltage events is by sources and/or separately derived sources. This approach would help quantify the impact and recovery time of a voltage event as it related to the energy source within the facility (or out on the utility network). Other useful and logical methods to aggregate/consolidate voltage event information from two or more IEDs may be considered as well (e.g., by building, by product, by cost, by maintenance, and so forth).

[0279] In embodiments, a fundamental purpose of aggregating/consolidating voltage event data is to identify opportunities to decrease these events' overall impact on the energy consumer's business to reduce downtime and make it more profitable. One or more of the methods (or combinations of methods) described herein may be used to meet this objective. It may be useful or even required to have one or more of these methods configured by the energy consumer (or surrogate), or the system and methods disclosed herein. The ability to consider the voltage event impact and recovery time at discrete IEDs is not mutually exclusive from any approach to consider and evaluate aggregated/consolidated voltage event impact and recovery time.

[0280] Another interesting prospect would be evaluating the performance of the energy consumer's operation after the initial voltage event occurs. For example, a voltage event may result in one load tripping off-line. Shortly after, another related load may also trip off-line as a

result of the first load tripping; not due to another voltage event. The extent of this chain reaction/propagation would be of interest when determining consequences of providing ride-through mitigation for the first load. In this example, providing a timeline of load reactions over the recovery period due to the original voltage event may be prudent to help minimize the overall impact of voltage events on the energy consumer's operation.

[0281] In embodiments, outcomes from analyses of the voltage and current data apply to the point in the network where the IED capturing the data is connected. Each IED in the network may typically yield distinct analyses of the event, assuming each IED is uniquely placed. As used herein, the term "uniquely placed" generally refers to the location of the installation within the electrical system, which impacts impedance, metered/connected loads, voltage levels, and so forth. In some cases, it may be possible to interpolate or extrapolate voltage event data on a case-by-case basis.

[0282] In embodiments, in order to accurately characterize power quality events (e.g., voltage sags) and their subsequent network impact(s), it is important to measure the voltage and current signals associated with the event. Voltage signals can be used to characterize the event, current signals can be used to quantify the event's impact, and both voltage and current can be used to derive other relevant electrical parameters related to this disclosure. Although outcomes from analyses of the voltage and current data apply to the point in the network where the IED capturing the data is connected, it may be possible to interpolate and/or extrapolate voltage event data on a case-by-case basis. Each IED in the network typically yields distinct analyses of the event, assuming each IED is uniquely placed.

[0283] In embodiments, there are multiple factors that can influence the impact (or non-impact) of a voltage sag. The impedance of the energy consumer's electrical system may cause voltage events to produce more severe voltage sags deeper into the system hierarchy (assuming a radial-fed topology). Voltage event magnitudes, durations, fault types, operational parameters, event timing, phase angles, load types, and a variety of other factors related to

functional, electrical, and even maintenance parameters can influence the effects of voltage sag events.

[0284] It is understood that any relevant information and/or data derived from IEDs, customer types, market segment types, load types, IED capabilities, and any other metadata may be stored, analyzed, displayed, and/or processed in the cloud, on-site (software and/or gateways), or in an IED in some embodiments.

[0285] Referring to Figs. 45-48, several flowcharts (or flow diagrams) are shown to illustrate various methods of the disclosure. Rectangular elements (typified by element 4505 in Fig. 45), as may be referred to herein as “processing blocks,” may represent computer software and/or IED algorithm instructions or groups of instructions. Diamond shaped elements (typified by element 4525 in Fig. 45), as may be referred to herein as “decision blocks,” represent computer software and/or IED algorithm instructions, or groups of instructions, which affect the execution of the computer software and/or IED algorithm instructions represented by the processing blocks. The processing blocks and decision blocks can represent steps performed by functionally equivalent circuits such as a digital signal processor circuit or an application specific integrated circuit (ASIC).

[0286] The flowcharts do not depict the syntax of any particular programming language. Rather, the flowcharts illustrate the functional information one of ordinary skill in the art requires to fabricate circuits or to generate computer software to perform the processing required of the particular apparatus. It should be noted that many routine program elements, such as initialization of loops and variables and the use of temporary variables are not shown. It will be appreciated by those of ordinary skill in the art that unless otherwise indicated herein, the particular sequence of blocks described is illustrative only and can be varied. Thus, unless otherwise stated, the blocks described below are unordered; meaning that, when possible, the blocks can be performed in any convenient or desirable order including that sequential blocks can be performed simultaneously and vice versa. It will also be understood that various

features from the flowcharts described below may be combined in some embodiments. Thus, unless otherwise stated, features from one of the flowcharts described below may be combined with features of other ones of the flowcharts described below, for example, to capture the various advantages and aspects of systems and methods associated with dynamic tolerance curves sought to be protected by this disclosure.

[0287] Referring to Fig. 45, a flowchart illustrates an example method 4500 for managing power quality events (or disturbances) in an electrical system that can be implemented, for example, on a processor of an IED (e.g., 121, shown in Fig. 1A) and/or a processor of a control system associated with the electrical system. Method 4500 may also be implemented remote from the IED and/or control system in a gateway, cloud, on-site software, etc.

[0288] As illustrated in Fig. 45, the method 4500 begins at block 4505, where energy-related signals (or waveforms) associated with one or more loads (e.g., 111, shown in Fig. 1A) in an electrical system are measured and data is captured, collected, stored, etc. by an IED (and/or control system) coupled to the loads.

[0289] At block 4510, electrical measurement data from the energy-related signals (e.g., voltage and/or current signals) is processed to identify at least one power quality event associated with one or more of the loads. In some embodiments, identifying the at least one power quality event may include identifying: (a) a power quality event type of the at least one power quality event, (b) a magnitude of the at least one power quality event, (c) a duration of the at least one power quality event, and/or (d) a location of the at least one power quality event in the electrical system, for example. In embodiments, the power quality event type may include one of a voltage sag, a voltage swell, and a voltage transient.

[0290] At block 4515, an impact of the at least one identified power quality event on one or more of the loads is determined. In some embodiments, determining the impact of the at least one identified power quality event includes measuring one or more first parameters (e.g., “pre-

event” parameters) associated with the loads at a first time (e.g., a time prior to the event), measuring one or more second parameters (e.g., “post-event” parameters) associated with the loads at a second time (e.g., a time after the event), and comparing the first parameters to the second parameters to determine the impact of the at least one identified power quality event on the loads. In embodiments, the power quality event(s) may be characterized as an impactful event or a non-impactful event based, at least in part, on the determined impact of the event(s). An impactful event may, for example, correspond to an event that interrupts operation (or effectiveness) of the loads and/or the electrical system including the loads. This, in turn, may impact an output of the system, for example, the production, quality, rate, etc. of a product generated by the system. In some embodiments, the product may be a physical/tangible object (e.g., a widget). Additionally, in some embodiments the product may be a non-physical object (e.g., data or information). A non-impactful event, by contrast, may correspond to an event that does not interrupt (or minimally interrupts) operation (or effectiveness) of the loads and/or the electrical system including the loads.

[0291] At block 4520, the at least one identified power quality event and the determined impact of the at least one identified power quality event are used to generate or update an existing tolerance curve associated with the one or more of the loads. In embodiments, the tolerance curve characterizes a tolerance level of the loads to certain power quality events. For example, the tolerance curve (e.g., as shown in FIG. 4) may be generated to indicate a “prohibited region”, a “no damage region” and a “no interruption in function region” associated with the loads (and/or electrical system), with the respective regions corresponds to various tolerance levels of the loads to certain power quality events. The tolerance curve may be displayed on a graphical user interface (GUI) (e.g., 230, shown in FIG. 1B) of the IED and/or or GUI of the control system, for example. In embodiments where a tolerance curve has already been generated prior to block 4520, for example, due to there being an existing tolerance curve, the existing tolerance curve may be updated to include information derived from the at least one identified power quality event and the determined impact of the at least one identified power quality event. An existing tolerance curve may exist, for example, in

embodiments in which a baseline tolerance curve exists or in embodiments in which a tolerance curve has already been generated using method 4500 (e.g., an initial tolerance curve generated in response to a first or initial power quality event). In other words, in embodiments a new tolerance curve is typically not generated after each identified power quality event, but rather each identified power quality event may result in updates being made to an existing tolerance curve.

[0292] At block 4525, which is optional in some embodiments, it is determined if the impact of the at least one identified power quality event exceeds a threshold or falls outside of a range or region (e.g., “no interruption in function region”) indicated in the tolerance curve. If it is determined that the impact of the at least one identified power quality event falls outside of the range indicated in the tolerance curve (e.g., the event results in an interruption to the function of a load as measured by an electrical parameter or indicated by some external input), the method may proceed to block 4530. Alternatively, if it is determined that the impact of the at least one identified power quality event does not fall outside of a range indicated in the tolerance curve (e.g., the event does not result in an interruption in a function of a load), the method may end in some embodiments. In other embodiments, the method may return to block 4505 and repeat again. For example, in embodiments in which it is desirable to continuously (or semi-continuously) capture energy-related signals and to dynamically update the tolerance curve in response to power quality events identified in these captured energy-related signals, the method may return to block 4505. Alternatively, in embodiments in which it is desirable to characterize power quality events identified in a single set of captured energy-related signals, the method may end.

[0293] Further, in embodiments the event information may be used to adjust (e.g., expand) the “no interruption in function” region, for example, to generate a custom tolerance curve for the specific IED location (similar to FIG. 2). It is to be appreciated that characterizing the electrical system at certain points is extremely useful to users because they can better understand the behavior of their system.

[0294] In some embodiments, the range indicated in the tolerance curve is a predetermined range, for example, a user configured range. In other embodiments, the range is not predetermined. For example, I may choose to have no “no interruption in function” region and say anything deviating from a nominal voltage needs to be evaluated. In this case, the voltage may range all over the place and I may have dozens of power quality events; however, my load may not experience any interruptions. Thus, these events are not considered impactful. In this case, I widen/expand my “no interruption” region from basically the nominal voltage outwards to the point where these events do start to perturbate my loads (based on measured load impact pre-event vs. post event).

[0295] In other words, the invention is not limited to the ITIC curve (or any other predetermined range or curve(s)). Rather, embodiments of the invention call for “creating” a custom voltage tolerance curve for a specific location (i.e., where the IED is located) within the electrical system or network. The curve may be based on the ITIC curve, the SEMI curve, or any number of other curves. Additionally, the curve may be a custom curve (i.e., may not be based on a known curve, but rather may be developed without an initial reference or baseline). It is understood that a predetermined tolerance curve is not required for this invention, rather it just used to explain the invention (in connection with this figure, and in connection with figures described above and below).

[0296] At block 4530, which is optional in some embodiments, an action affecting at least one component of the electrical system may be automatically performed in response to the determined impact of the at least one identified power quality event being outside of the range indicated in the tolerance curve. For example, in some embodiments a control signal may be generated in response to the determined impact of the at least one identified power quality event being outside of the range, and the control signal may be used to affect the at least one component of the electrical system. In some embodiments, the at least one component of the electrical system corresponds to at least one of the loads monitored by the IED. The control signal may be generated by the IED, a control system, or another device or system associated

with the electrical system. As discussed in figures above, in some embodiments the IED may include or correspond to the control system. Additionally, in some embodiments the control system may include the IED.

[0297] As another example, an action that may be affected at block 4530 is starting and stopping a timer to quantify a length (or duration) of the impact to production, for example, in a facility with which the impact is associated. This will help a user make better decisions regarding operation of the facility during atypical conditions.

[0298] Subsequent to block 4530, the method may end in some embodiments. In other embodiments, the method may return to block 4505 and repeat again (for substantially the same reasons discussed above in connection with block 4525). In some embodiments in which the method ends after block 4530, the method may be initiated again in response to user input and/or a control signal, for example.

[0299] Referring to Fig. 46, a flowchart illustrates an example method 4600 for quantifying power quality events (or disturbances) in an electrical system that can be implemented, for example, on a processor of an IED (e.g., 121, shown in Fig. 1A) and/or a processor of a control system. Method 4600 may also be implemented remote from the IED in a gateway, cloud, on-site software, etc. This method 4600 evaluates energy-related signals (e.g., voltage and/or current signals) measured and captured by the IED to determine whether the electrical system was impacted (e.g., at the IED(s) level) using pre-event/post-event power characteristics. In embodiments, it is possible to determine a recovery time using a threshold (e.g., the post-event power is 90% of the pre-event power). This allows us to quantify the impact of a power quality disturbance to a load(s), process(es), system(s), facility(ies), etc.

[0300] As illustrated in Fig. 46, the method 4600 begins at block 4605, where energy-related signals (or waveforms) are measured and captured by an IED.

[0301] At block 4610, the energy-related signals are processed to identify a power quality event associated with one or more loads (e.g., 111, shown in Fig. 1A) monitored by the IED. In some embodiments, pre-event, event and post-event logged data may also be used to identify the power quality event. The pre-event, event and post-event logged data may, for example, be stored on a memory device associated with the IED and/or gateway, cloud and/or on-site software application.

[0302] At block 4615, pre-event parameters are determined from the energy-related signals. In embodiments, the pre-event parameters correspond to substantially any parameters that can be directly measured and/or derived from voltage and current including, but not limited to, power, energy, harmonics, power factor, frequency, event parameters (e.g., time of disturbance, magnitude of disturbance, etc.), etc. In embodiments, pre-event data can also be derived from “statistical norms.” Metadata may also be used to help derive additional parameters accordingly.

[0303] At block 4620, an impact of the power quality event is determined, measured or calculated. In embodiments, the event impact is calculated based on pre-event vs. post-event parameters. In embodiments, this includes both the characteristics of the event (i.e., magnitude, duration, disturbance type, etc.) and its impact to load(s), process(es), system(s), facility(ies), etc. at the metered point in the system.

[0304] At block 4625, recovery thresholds (or conditions) are compared to real-time parameters. In embodiments, the recovery thresholds may correspond to a percent of pre-event conditions to be considered as a system, sub-system, process, and/or load recovery condition. In embodiments, industry standards, market segment recommendations, historical analysis, independently determined variables, and/or load characteristics may be used to provide the recovery thresholds. Additionally, statistical norms may be used to provide the recovery thresholds. In embodiments, the recovery thresholds are configured (e.g., pre-configured) recovery thresholds that are stored on a memory device associated with the IED.

An alternative approach is to pass all voltage event information to the cloud or on-site software and then filter it there using recovery thresholds. In this case, the recovery thresholds would be stored in the cloud or on-site and not in the IED.

[0305] At block 4630, the IED determines if the real-time parameters meet the recovery thresholds (or conditions). If the IED determines that the real-time parameters meet the recovery thresholds, the method proceeds to block 4635. Alternatively, if the IED determines that the real-time parameters do not meet the recovery thresholds, the method may return to block 4625, and block 4625 may be repeated again. In embodiments, the output here is to determine the recovery time; therefore, it may stay in the loop until the post-event levels meet a predetermined threshold.

[0306] At block 4635, the IED calculates a recovery time from the power quality event. In embodiments, the recovery time is calculated from a time associated with the power quality event (e.g., an initial occurrence of the power quality event) until a time the recovery thresholds are met.

[0307] At block 4640, an indication of the power quality disturbance (or event) is provided at an output of the IED. In embodiments, the indication may include one or more reports and/or one or more control signals. The report may be generated to include information from any discrete IED of the electrical system including: recovery time, impact on power, costs associated with the event impact, I/O status changes, time of event/time of recovery, changes in voltages/currents, imbalance changes, areas impacted, etc. In embodiments, recovery time and impact may be based on data from one or more IEDs. The reports may be provided to customer, sales teams, offer management, engineering teams, and/or any other interested party, etc. The control signals may be generated to control one or more parameters or characteristics associated with the electrical system. As one example, the control signals may be used to adjust one or more parameters associated with load(s) which the IED is configured to monitor.

[0308] At block 4640, the indication of the power quality disturbance (and other data associated with method 4600) may also be stored. In some embodiments, the indication may be stored locally, for example, on a same site as the IED (or on the IED device itself). Additionally, in some embodiments the indication may be stored remotely, for example, in the cloud and/or on-site software. After block 4640, the method 4600 may end.

[0309] Referring to Fig. 47, a flowchart illustrates an example method 4700 for expanded qualified lead generation for power quality. Similar to method 4600 described above in connection with Fig. 46, for example, in embodiments method 4700 can be implemented on a processor of an IED and/or a processor of a control system. Method 4700 may also be implemented remote from the IED in a gateway, cloud, on-site software, etc. In embodiments, by evaluating pre-event/post-event power characteristics of power quality events, it is possible to quantify the susceptibility of the electrical system at metered points to power quality disturbances. This information could be used to identify product offerings for mitigative solutions and provide better qualified leads to organizations marketing those solutions. In embodiments, method 4700 may also be used for energy savings opportunities (e.g., power factor correction, increased equipment efficiency, etc.) when a power quality event occurs.

[0310] As illustrated in Fig. 47, the method 4700 begins at block 4705, where energy-related signals (or waveforms) are measured and captured by an IED.

[0311] At block 4710, the energy-related signals (e.g., voltage and/or current signals) are processed to identify a power quality event associated with one or more loads monitored by the IED. In some embodiments, pre-event, event and post-event logged data may also be used to identify the power quality event. The pre-event, event and post-event logged data may, for example, be stored on a memory device associated with the IED and/or gateway, cloud and/or on-site software application.

[0312] At block 4715, pre-event parameters are determined from the energy-related signals. In embodiments, the pre-event parameters correspond to substantially any parameters that can be directly measured and/or derived from voltage and current including, but not limited to, power, energy, harmonics, power factor, frequency, event parameters (e.g., time of disturbance, magnitude of disturbance, etc.), etc. In embodiments, pre-event data can also be derived from “statistical norms.” Metadata may also be used to help derive additional parameters accordingly.

[0313] At block 4720, an impact of the power quality event is calculated. In embodiments, the event impact is calculated based on pre-event vs. post-event parameters. In embodiments, this includes both the characteristics of the event (i.e., magnitude, duration, disturbance type, etc.) and its impact to load(s), process(es), system(s), facility(ies), etc. at the metered point in the system.

[0314] At block 4725, event characteristics are compared to mitigative solutions (e.g., product solutions). In embodiments, there may be a library of design and applications criteria for solutions to mitigate issues associated with a power quality event or disturbance. The library of design and applications criteria for solutions may be stored on a memory device associated with the IED, or accessed by the IED (e.g., remotely, via the cloud). In some embodiments, block 4725 may be performed in the cloud or on-site software. That way the energy consumer is able to see everything from a system level.

[0315] At block 4730, the IED determines if a particular entity (e.g., Schneider Electric) provides a mitigative solution for specific event. If the IED determines that the particular entity provides a mitigative solution for the specific event, the method proceeds to a block 4635. Alternatively, if the IED determines that the particular entity does not provide a mitigative solution for the specific event, the method proceeds to a block 4750. In some embodiments, the “IED” may be defined as being in the cloud or on-site (yet remote from the meter). In embodiments, it may be prudent to put the solutions and much of the analysis in the cloud or

on-site software because it's easier to update, the energy consumer has easier access to it, and it provides an aggregate system view.

[0316] At block 4735, a list of solutions provided by the particular entity is built for the specific event or issue (or type of event or issue). At block 4740, a report is generated and provided to customers, sales teams associated with the particular entity or other appropriate representatives of the entity. In embodiments, the report may include information from any discrete metering device (or as a system) including: recovery time, impact on power, I/O status changes, time of event/time of recovery, changes in voltages/currents, changes in phase balance, processes and/or areas impacted, etc. Report may include information on SE solution (e.g., customer facing literature, features and benefits, technical specifications, cost, etc.), approximate solution size required for given event (or event type), comparisons to external standards, placement, etc. Electrical and/or metering system hierarchy and/or other metadata (e.g., load characteristics, etc.) may be used to assist evaluation.

[0317] At block 4745, the report (and other information associated with the method 4700) may be stored. In some embodiments, the report may be stored locally, for example, on a same site as the IED (or on the IED device itself). Additionally, in some embodiments the report may be stored remotely, for example, in the cloud. In embodiment, blocks 4740 and 4745 may be performed substantially simultaneously.

[0318] Returning now to block 4730, if it is determined that the particular entity does not provide a mitigative solution for the specified event, the method proceeds to a block 4750. At block 4750, event parameters and/or characteristics (and other information associated with the method 4700) may be stored (e.g., locally and/or in the cloud). At block 4755, a report is generated based, at least in part, on select information stored at block 4750. In embodiments, the report may include an evaluation of energy consumer impacts and needs for potential future solution development, third-party solutions, etc. After block 4755 (or blocks 4740/4745), the method 4700 may end.

[0319] Referring to Fig. 48, a flowchart illustrates an example method 4800 for dynamic tolerance curve generation for power quality. Similar to methods 4500, 4600 and 4700 described above, in embodiments method 4800 can be implemented on a processor of an IED and/or a processor of a control system. Method 4800 may also be implemented remote from the IED in a gateway, cloud, on-site software, etc. In embodiments, by evaluating pre-event/event/post-event power characteristics of power quality events, it is possible (over time) to automatically develop a custom event tolerance curve for substantially any given energy consumer. This is extremely useful to help energy consumers identify, characterize, analyze and/or desensitize their system to power quality events.

[0320] As illustrated in FIG. 48, the method 4800 begins at block 4805, where energy-related signals (or waveforms) are measured and captured by an IED.

[0321] At block 4810, the energy-related signals (e.g., voltage and/or current signals) are processed to identify a power quality event associated with one or more loads monitored by the IED. In some embodiments, pre-event, event and post-event logged data may also be used to identify the power quality event. The pre-event, event and post-event logged data may, for example, be stored on a memory device associated with the IED and/or gateway, cloud and/or on-site software application.

[0322] At block 4815, pre-event parameters are determined from the energy-related. In embodiments, the pre-event parameters correspond to substantially any parameters that can be directly measured and/or derived from voltage and current including, but not limited to, power, energy, harmonics, power factor, frequency, event parameters (e.g., time of disturbance, magnitude of disturbance, etc.), etc. In embodiments, pre-event data can also be derived from “statistical norms.” Metadata may also be used to help derive additional parameters accordingly.

[0323] At block 4820, an impact of the power quality event is determined. In embodiments, the event impact is calculated based on pre-event vs. post-event parameters. In embodiments, this includes both the characteristics of the event (i.e., magnitude, duration, disturbance type, etc.) and its impact to load(s), process(es), system(s), facility(ies), etc. at the metered point in the system.

[0324] At block 4825, disturbance thresholds (or conditions) are compared to the determined impact of the event. In embodiments, the disturbance thresholds may correspond to a percent change between pre-event and post-event conditions to be considered a “significant” system, sub-system, process, and/or load disturbance. For example, a 5% reduction in load due to an electrical (or other) event may be considered “significant.” In embodiments, the disturbance thresholds are configured (e.g., pre-configured) disturbance thresholds that are stored on a memory device associated with the IED and/or gateway, cloud and/or on-site software application.

[0325] At block 4830, the IED determines if the system, sub-system, process, facility and/or load experienced (or is experiencing) a “significant” disturbance (e.g., based on the comparison at block 4825). If the IED determines that the system, sub-system, process, facility and/or load(s) experienced a “significant” disturbance, the method proceeds to a block 4835. Alternatively, if the IED determines that the system, sub-system, process, facility and/or load(s) has not experienced a “significant” disturbance, the method proceeds to a block 4840.

[0326] At block 4835, a disturbance point is generated and plotted as perturbative (e.g., impacting the system, sub-system, process, facility and/or load(s), for example). At block 4845, a baseline tolerance curve (e.g., SEMI-F47, ITIC, CBEMA, etc.) is modified, changed and/or customized) based on characteristics associated with the specific recorded disturbance (here, at block 4835).

[0327] Alternatively, at block 4840, in response to the IED determining that the system, sub-system, process, facility and/or load has not experienced a “significant” disturbance, a disturbance point is generated and plotted as non-perturbative (e.g., not impacting the system, sub-system, process, facility and/or load(s), for example). At block 4845, the baseline tolerance curve is modified, changed and/or customized based on the characteristics associated with specific recorded disturbance (here, at block 4840). For example, lines in the curve may be moved between “no interruption region” and “no damage/prohibited region.” Alternatively, the lines in the curve may not be moved at all.

[0328] At block 4850, a report is generated. In embodiments, the report may include information from substantially any discrete IED (or as a system) including: recovery time, impact on power, I/O status changes, time of event/time of recovery, changes in voltages/currents, imbalance changes, areas and loads impacted, etc. The report may include updated graphs of tolerance curve(s), highlighted changes in curve(s), recommended mitigation solution(s), etc.

[0329] At block 4855, which is optional in some embodiments, at least one alarm setting may be updated at discrete metering point(s) to match the new tolerance curve (e.g., generated at block 4845). At block 4860, the new tolerance curve (and other information associated with the method 4800) may be stored (e.g., locally, in a gateway, on-site software, and/or in the cloud). In some embodiments, two or more of blocks 4850, 4855 and 4860 may be performed substantially simultaneously. After blocks 4850, 4855, and 4860, the method 4800 may end.

[0330] In general, equipment (e.g., a load or other electrical infrastructure) is designed to have a rated voltage and recommended operational range, as illustrated in Figs. 49 and 50. The rated voltage is the desired voltage magnitude/level for optimal equipment operation. Additionally, the recommended operational range is the area surrounding the rated voltage (above and below the rated voltage) where the equipment may still successfully operate continuously, although not necessarily optimally (e.g., lower efficiency, additional heating,

higher currents, etc.). IED voltage event alarm thresholds (also referred to herein as “alarm thresholds” for simplicity) are typically configured (but not always) to align with the recommended operational range so that excursions beyond the recommended operational range may be measured, captured and stored. This is because a strong correlation exists with excessive voltage excursions and temporary or permanent damage to the equipment experiencing these excursions. Additionally, voltage excursions may lead to operational issues, interruptions, loss of data, and/or any other number of impacts to equipment, processes, and/or operations.

[0331] While the “recommended operational range” of loads, processes, and/or systems is typically associated with a voltage magnitude, the duration of these excursions is also an important consideration. For example, a 1-millisecond voltage excursion of +10% outside of the recommended operational range may not adversely impact the operation of a load, process, and/or system, nor impact its expected operational life. Alternatively, a 20-millisecond voltage excursion of +10% outside of the recommended operational range may cause the same load, process, and/or system to experience an interruption and/or reduce its life expectancy (by some extent).

[0332] Figs. 49 and 50 illustrate two representations of the same concept. Namely, Fig. 49 shows a rms waveform and Fig. 50 shows an instantaneous waveform. The rms waveform shown in Fig. 49 is derived from the instantaneous waveform data shown in Fig. 50 using a well-known equation (root-mean-square) calculation. Both waveform representations are useful for analyzing power and energy-related issues and troubleshooting power quality problems. Each respective graphic illustrates an exemplary voltage rating, upper alarm threshold, and lower alarm threshold for a theoretical load, process and/or system. In this case, the recommended operational range (shaded area) is assumed to align with the bounds of the upper and lower alarm thresholds, respectively.

[0333] Referring to Fig. 51, a flowchart illustrates an example method 5100 for characterizing power quality events in an electrical system that can be implemented, for example, on a processor of at least one IED (e.g., 121, shown in Fig. 1A). Method 5100 may also be implemented remote from the at least one IED in a gateway, cloud-based system, on-site software, or another head-end system in some embodiments.

[0334] As illustrated in Fig. 51, the method 5100 begins at block 5105, where energy-related signals are measured and data is captured, collected, stored, etc. by at least one first IED of a plurality of IEDs in an electrical system. The at least one first IED is installed at a first metering point (e.g., a physical metering point) in the electrical system (e.g., metering point M₁, shown in Fig. 30F).

[0335] At block 5110, energy-related signals are measured and data is captured, collected, stored, etc. by at least one second IED of the plurality of IEDs in the electrical system. The at least one second IED is installed at a second metering point (e.g., a physical metering point) in the electrical system (e.g., metering point M₂, shown in Fig. 30F).

[0336] In some embodiments, the energy-related signals captured by the at least one first IED and the energy-related signals captured by the at least one second IED include at least one of: voltage, current, energy, active power, apparent power, reactive power, harmonic voltages, harmonic currents, total voltage harmonic distortion, total current harmonic distortion, harmonic power, individual phase currents, three-phase currents, phase voltages, and line voltages.

[0337] At block 5115, electrical measurement data for at least one first virtual meter in the electrical system is derived from (a) electrical measurement data from or derived from the energy-related signals captured by the at least one first IED, and (b) electrical measurement data from or derived from the energy-related signals captured by the at least one second IED. In embodiments, the at least one first virtual meter is derived or located at a third metering

point in the electrical system (e.g., metering point V_1 , shown in Fig. 30F). In embodiments, the third metering point (e.g., a virtual metering point) is different from both the first metering point and the second metering point.

[0338] In some embodiments, the electrical measurement data for the at least one first virtual meter may be derived based on a known location of the at least one first virtual meter with respect to the at least one first IED and the at least one second IED. For example, as described above in connection with Figs. 30B-30I, the electrical measurement data for a virtual meter (e.g., the at least one first virtual meter) may be derived based on known locations of, and parent-child relationship(s) between, the virtual meter and other meters (e.g., IEDs) in the electrical system.

[0339] At block 5120, the derived electrical measurement data for the at least one first virtual meter is used to generate or update a dynamic tolerance curve associated with the third metering point or location. As discussed in connection with figures above, a dynamic tolerance curve may characterize an impact of a power quality event (or power quality events) in an electrical system. As also discussed in connection with figures above, in some embodiments at least one means for mitigating the impact of the power quality event (or power quality events) may be selected and applied in response to an analysis of the dynamic tolerance curve.

[0340] Subsequent to block 5120, the method 5100 may end in some embodiments. In other embodiments, the method 5100 may repeat again, for example, in response to a control signal or user input, or automatically to ensure that the dynamic tolerance curve associated with the third metering point or location is up-to-date.

[0341] In some embodiments, the electrical measurement data from or derived from energy-related signals captured by the at least one first IED may also be used to generate or update a dynamic tolerance curve associated with the first metering point. Additionally, in some embodiments the electrical measurement data from or derived from energy-related signals

captured by the at least one second IED may also be used to generate or update a dynamic tolerance curve associated with the second metering point.

[0342] For example, in some embodiments the electrical measurement data from or derived from the energy-related signals captured by the at least one first IED in the electrical system may be processed to identify a power quality event at the first metering point, and to determine an impact of the identified power quality event at the first metering point. The identified power quality event and the determined impact of the identified power quality event at the first metering point may be used to generate or update the first dynamic tolerance curve associated with the first metering point. In some embodiments, the first dynamic tolerance curve characterizes at least an impact of power quality event(s) on the first metering point.

[0343] The at least one first IED may be configured to monitor one or more loads in the electrical system in some embodiments. In these embodiments, the first dynamic tolerance curve may further characterize a response of the one or more loads to the power quality events.

[0344] In some embodiments, the at least one second IED may not be configured to capture the power quality event, or the at least one second IED may be incapable of capturing the power quality event. In these embodiments, for example, an impact of the identified power quality event at the second metering point may be determined based on an evaluation of the electrical measurement data from or derived from the energy-related signals captured by the at least one second IED proximate to a time of occurrence of a power quality event identified at the first metering point. The time of occurrence of the identified power quality event at the first metering point may be determined, for example, by processing the electrical measurement data from or derived from the energy-related signals captured by the at least one first IED.

[0345] In some embodiments, the identified power quality event and the determined impact of the identified power quality event at the second metering point may be used to generate or

update the second dynamic tolerance curve associated with the second metering point. In some embodiments, the second dynamic tolerance curve characterizes at least an impact of power quality event(s) on the second metering point.

[0346] The at least one second IED may be configured to monitor one or more loads in the electrical system in some embodiments. In these embodiments, the second dynamic tolerance curve may further characterize a response of the one or more loads to the power quality events.

[0347] In the above-described embodiments in which the at least one second IED may not be configured to capture the power quality event, or the at least one second IED may be incapable of capturing the power quality event, at least the determined time of occurrence of the identified power quality event at the first metering point may be communicated from the at least one first IED to at least one of: a cloud-based system, on-site software, a gateway, and another head-end system. The impact of the identified power quality event at the second metering point may be determined on the at least one of: the cloud-based system, the on-site software, the gateway, and the other head-end system in some embodiments.

[0348] In some embodiments, communicating the determined time of occurrence from the at least one first IED to the at least one of: the cloud-based system, the on-site software, the gateway, and the other head-end system, includes: producing at least one of a timestamp, alarm, and a trigger indicative of the determined time of occurrence on the at least one first IED; and communicating the at least one of the timestamp, the alarm, and the trigger to the at least one of: the cloud-based system, the on-site software, the gateway, and the other head-end system.

[0349] Referring to Fig. 52, a flowchart illustrates an example method 5200 for characterizing an impact of a power quality event on an electric system. The method 5200 may be implemented, for example, on a processor of at least one IED (e.g., 121, shown in Fig. 1A)

and/or remote from the at least one IED in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0350] As illustrated in Fig. 52, the method 5200 begins at block 5205, where energy-related signals (or waveforms) are measured and data is captured, collected, stored, etc. by at least one metering device in an electrical system. In some embodiments, the at least one metering device includes at least one of an IED and/or a virtual meter. Additionally, in some embodiments the energy-related signals include at least one of: voltage, current, energy, active power, apparent power, reactive power, harmonic voltages, harmonic currents, total voltage harmonic distortion, total current harmonic distortion, harmonic power, individual phase currents, three-phase currents, phase voltages, and line voltages.

[0351] At block 5210, electrical measurement data from or derived from the energy-related signals captured by the at least one metering device at block 5205, is processed to identify a power quality event associated with at least one load (e.g., 111, shown in Fig. 1A) monitored by the at least one metering device. The at least one metering device and the at least one load are installed at respective locations in the electrical system.

[0352] At block 5215, it is determined if the identified power quality event has an impact on the at least one load or on the electrical system. If it is determined the identified power quality event has an impact on the at least one load or on the electrical system, the method proceeds to block 5220.

[0353] At block 5220, a recovery time for the at least one load or the electrical system to recover from the identified power quality event is determined. Additionally, at block 5225, the data captured, collected, and/or stored during the recovery time is tagged (or otherwise indicated) as atypical or abnormal based on the determined recovery time. In some embodiments, the recovery time is tagged (or otherwise indicated) in a dynamic tolerance curve associated with the at least one load or the electrical system.

[0354] Returning briefly now to block 5215, if it is determined the identified power quality event does not have an impact on the at least one load or on the electrical system, the dynamic tolerance curve may be updated and the method may end in some embodiments. Subsequent to block 5225, the method may also end in some embodiments.

[0355] In other embodiments, the method may include one or more additional steps. For example, in some embodiments in response to determining that the identified power quality event has an impact on the at least one load or on the electrical system, one or more metrics associated with the electrical measurement data may be compared against local utility rate structures to calculate a total energy-related cost of the identified power quality event, and to identify opportunities for reducing the total energy-related cost. It is understood that in some embodiments the total energy-related cost of the identified power quality event, and the identified opportunities for reducing the total energy-related cost are based on the tagged recovery time data.

[0356] Additionally, in some embodiments an economic impact of the identified power quality event may be determined based, at least in part, on one or more metrics associated with the determined recovery time. Example metrics are discussed throughout this disclosure.

[0357] Referring to Fig. 53, a flowchart illustrates an example method 5300 for reducing recovery time from a power quality event in an electrical system, for example, by tracking a response characteristic of the electrical system. The method 5300 may be implemented, for example, on a processor of at least one IED (e.g., 121, shown in Fig. 1A) and/or remote from the at least one IED in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0358] As illustrated in Fig. 53, the method 5300 begins at block 5305, where energy-related signals (or waveforms) are measured and data is captured, collected, stored, etc. by at least one IED in an electrical system. In some embodiments, the energy-related signals include at least

one of: voltage, current, energy, active power, apparent power, reactive power, harmonic voltages, harmonic currents, total voltage harmonic distortion, total current harmonic distortion, harmonic power, individual phase currents, three-phase currents, phase voltages, and line voltages.

[0359] At block 5310, electrical measurement data from or derived from the energy-related signals captured by the at least one IED at block 5305, is processed to identify a power quality event associated with one or more portions of the electrical system.

[0360] At block 5315, at least one means for recovering from the identified power quality event is determined. Additionally, at block 5320 a selected one of the at least one means for recovering from the identified power quality event is applied.

[0361] At block 5325, a response characteristic of the electrical system is tracked in response to the selected one of the at least one means for recovering from the identified power quality event being applied. In some embodiments, the response characteristic of the electrical system is tracked with respect to a baseline response of the electrical system. In some embodiments, tracking the response characteristic includes identifying recurring event data. The identified recurring event data may be used, for example, to forecast power quality events in the electrical system.

[0362] As discussed above in connection with section VI of this disclosure, entitled “Disaggregation of Typical and Atypical Operational Data Using Recovery Time,” it is important to recognize a facility’s operation during a recovery period is often aberrant or atypical as compared to non-recovery times (i.e., normal operation). Additionally, it is useful to identify and “tag” (i.e., denote) and differentiate aberrant or atypical operational data from normal operational data (i.e., non-recovery data) for performing calculations, metrics, analytics, statistical evaluations, and so forth. Metering/monitoring systems do not inherently differentiate aberrant operational data from normal operational data. Differentiating and

tagging operational data as either aberrant (i.e., due to being in recovery mode) or normal provides several advantages, examples of which are provided in section VI of this disclosure.

[0363] At block 5330, the response characteristic of the electrical system is evaluated to determine effectiveness of the selected one of the at least one means for recovering from the identified power quality event. If it is determined that the selected one of the at least one means for recovering from the identified power quality event is not effective, the method may return to block 5315 in some embodiments. Upon returning to block 5315, at least one other means for recovering from the identified power quality event may be determined. Additionally, at block 5320 a selected one of the at least one other means for recovering from the identified power quality event may be applied.

[0364] Returning now to block 5330, if it is alternatively determined that the selected one of the at least one means for recovering from the identified power quality event is effective, the method may end in some embodiments. Alternatively, information about the issue and its resolution may be included in and/or appended to a history file, for example. In other embodiments, the method may return to block 5325 (e.g., such that the response characteristic of the electrical system may be further tracked).

[0365] As discussed in connection with figures above, an electrical system may include a plurality of metering points or locations, for example, metering points M_1 , M_2 , etc. shown in Figs. 29, 30A, 30B, and 30F-33. In some embodiments, it may be desirable to generate, update or derive a dynamic tolerance curve for each metering point of the plurality of metering points. Additionally, in some embodiments it may be desirable to analyze power quality events in the electrical system, for example, based on analysis of data aggregated, extracted and/or derived from the dynamic tolerance curves.

[0366] Referring to Fig. 54, a flowchart illustrates an example method 5400 for analyzing power quality events in an electrical system. The method 5400 may be implemented, for

example, on a processor of at least one metering device (e.g., 121, shown in Fig. 1A) and/or remote from the at least one metering device in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system. In some embodiments, the at least one metering device may be located at a respective metering location of a plurality metering locations in the electrical system (e.g., M_1 , shown in Fig. 29).

[0367] As illustrated in Fig. 54, the method 5400 begins at block 5405, where energy-related signals (or waveforms) are measured and data is captured, collected, stored, etc. by at least one of a plurality of metering devices in an electrical system. The at least one of a plurality of metering devices may each be associated with a respective metering location of a plurality of metering locations in the electrical system. For example, a first one of the plurality of metering devices may be associated with a first metering location in the electrical system (e.g., M_1 , shown in Fig. 29), a second one of the plurality of metering devices may be associated with a second metering location in the electrical system (e.g., M_2 , shown in Fig. 29), and a third one of the plurality of metering devices may be associated with a third metering location in the electrical system (e.g., M_3 , shown in Fig. 29).

[0368] In some embodiments, the plurality of metering devices include at least one IED (e.g., 121, shown in Fig. 1A). Additionally, in some embodiments the energy-related signals measured by the plurality of metering devices include at least one of: voltage, current, energy, active power, apparent power, reactive power, harmonic voltages, harmonic currents, total voltage harmonic distortion, total current harmonic distortion, harmonic power, individual phase currents, three-phase currents, phase voltages, and line voltages.

[0369] At block 5410, electrical measurement data from or derived from the energy-related signals captured by the plurality of metering devices at block 5405, is processed to generate, update and/or derive at least one of a plurality of dynamic tolerance curves using one or more of the techniques disclosed herein, e.g., in connection with Figs. 45 and 51. In some embodiments, the at least one of a plurality of dynamic tolerance curves are generated,

updated and/or derived for each of the plurality of metering locations in the electrical system. The plurality of metering locations include at least one physical metering point (e.g., M_1 and M_2 , shown in Fig. 30F). In some embodiments, the plurality of metering locations may also include at least one virtual metering point (e.g., V_1 , shown in Fig. 30F).

[0370] Similar to the dynamic tolerance curves discussed throughout this disclosure, each of the plurality of dynamic tolerance curves generated, updated and/or derived at block 5410 may characterize and/or depict a response characteristic of the electrical system. More particularly, each of the plurality of dynamic tolerance curves may characterize and/or depict a response characteristic of the electrical system at a respective metering point of the plurality of metering points in the electrical system (e.g., M_1 , M_2 , etc., shown in Fig. 29). In embodiments in which the plurality of metering points include at least one virtual metering point, the dynamic tolerance curve for the at least one virtual metering point may be derived from the dynamic tolerance curve data for at least one physical metering point, for example, as discussed above in connection with Fig. 30F and other figures herein.

[0371] In some embodiments, one or more of the plurality of dynamic tolerance curves may have associated thresholds or setpoints, for example, for generating alarms in the electrical system. The thresholds or setpoints may include one or more upper alarm thresholds and/or one or more lower alarm thresholds in some embodiments, several examples of which are described above in connection with Figs. 49 and 50, for example. In accordance with various aspects of this disclosure, an alarm may be triggered in response to a power quality event being above one or more upper alarm thresholds or below or below one or more lower alarm thresholds. Additionally, in accordance with various aspects of this disclosure, an action (or actions) may be taken in response to the alarm (or alarms) being triggered.

[0372] Example actions that may be performed in response to the alarm being triggered, e.g., due to an anomalous voltage condition, may include, for example, reporting an anomalous voltage condition (e.g., through a voltage event alarm generated by at least one IED) and/or

automatically performing an action (or actions) affecting at least one component of the electrical system, e.g., starting a diesel generator, operating a throw-over or static switch, etc. Similar to method 4500 described above in connection with Fig. 45, in some embodiments a control signal may be generated in response to the anomalous voltage condition, and the control signal may be used to affect the at least one component of the electrical system (e.g., a load monitored by the at least one IED, or a mitigative device such as a diesel generator, throw-over or static switch, etc.). The control signal may be generated by the at least one IED, a control system, or another device, software or system associated with the electrical system. As discussed in figures above, in some embodiments the at least one IED may include or correspond to the control system. Additionally, in some embodiments the control system may include the at least one IED.

[0373] Further example actions that may be performed in response to the alarm being triggered, e.g., to prevent a potential tripping due to a voltage sag duration or magnitude, may include, for example, turning “off” some running process steps which are identified as potential “sag exacerbators” such as postponing (if possible) a motor start during an existing voltage sag. Additionally, in some embodiments a user alarm (e.g., sent to a mobile phone application or other device application) may be triggered in response to the alarm (i.e., a system alarm) being triggered. Further, in some embodiments the alarm may be used as input to a manufacturing SCADA system, for example, to change or delay another process. The alarm may also be remedial, for example, by providing the maintenance team with a precise localization of an issue and a priority list of what issue(s) is/are most critical, which issue(s) to address first, second, etc. In some embodiments, the system may also provide a recommended response (or responses) to the issues, e.g., for correcting the issues. One example recommended response may be to disconnect and/or reconfigure a load causing the issues, with the disconnecting and/or reconfiguring being manually performed by the user and/or automatically performed by the system. As illustrated above, the types of actions that can be performed in response to alarms can take a variety of forms.

[0374] The above-discussed thresholds or setpoints (i.e., thresholds for generating alarms) may be generated during a so-called “learning period” in some embodiments, for example.

[0375] In accordance with some aspects of this disclosure, the dynamic tolerance curves generated, updated and/or derived at 5410 can be prepared by deducing relevant signal characteristics from the above-discussed electrical measurement data. Examples of relevant signal characteristics (and information) may include severity (magnitude), duration, power quality type (e.g., sag, swell, interruption, oscillatory transient, impulsive transient, etc.), time of occurrence, process(es) involved, location, devices impacted, relative or absolute impact, recovery time, periodicity of events or event types, etc. Additional examples of relevant signal characteristics may include identified changes in current, phase shifts, etc., which result in an interpretation (or interpretations) such as “inductive or capacitive load type added or removed from system,” “percentage of pre-event loads added or dropped from system” during an event, etc. In some embodiments, these relevant signal characteristics are determined from portions of the electrical measurement data from prior to a start time of power quality events, and from portions of the electrical measurement data from after an end time of power quality events. Additionally, in some embodiments these relevant signal characteristics are determined from portions of the electrical measurement data from during the power quality events (such as magnitude, duration, phases impacted, etc.).

[0376] In some embodiments, at least one of the plurality of dynamic tolerance curves may be displayed on a graphical user interface (GUI) (e.g., 230, shown in FIG. 1B) of at least one metering device, and/or or a GUI of a control system associated with the electrical system, for example. In some embodiments, the at least one of the plurality of dynamic tolerance curves is displayed in response to user input. The control system may correspond to or include a power or industrial/manufacturing SCADA system, a building management system, and a power monitoring system, as a few examples.

[0377] In some embodiments, the method may proceed to block 5415 after block 5410. In other embodiments, the method may return to block 5405 and blocks 5405 and 5410 may be repeated, for example, for capturing additional energy-related signals and updating the plurality of dynamic tolerance curves generated at block 5410. In doing so, the plurality of dynamic tolerance curves may be automatically/dynamically maintained at their optimal level. It is understood that optimal may mean different things due to the nature of the loads, segments, processes, and/or other inputs. This may result in a multitude of different curves, each or all relevant to different usages (applications). According to some aspects of this disclosure, “dynamic” of the dynamic tolerance curve means that there are changes which may occur over time. Thus, time may be an important factor to model, or an important factor to include in any model or curve. This is core to the innovation at each meter, and then at the global system level analysis, aggregation, action recommendation or any related automation changes or commands (non-exhaustive list). Thus, a model can be built of the evolution over time. To simplify the understanding, this may be represented by two (or more) different linked graphs, for example. A trend of each change point’s optimal values (what is the value of the “initial impact” point). Additionally, the relative impact on loads or critical loads, such as the percentages of loads dropping off at an initial impact point, over time.

[0378] At block 5415, power quality data from the plurality of dynamic tolerance curves is selectively aggregated. In some embodiments, the power quality data is selectively aggregated based on locations of the plurality of metering points in the electrical system. For example, power quality data from dynamic tolerance curves associated with metering points in a same or similar portion of the electrical system may be aggregated.

[0379] Additionally, in some embodiments the power quality data is selectively aggregated based on criticality or sensitivity of the plurality of metering points to power quality events. For example, power quality data from dynamic tolerance curves associated with highly critical or sensitive metering points may be aggregated. In some embodiments, the criticality of the metering points is based on the load type(s) at the metering points, and the importance of the

loads to operation of a process (or processes) associated with the electrical system. Additionally, in some embodiments the sensitivity of the metering points is based on the sensitivity of the loads to power quality events.

[0380] In accordance with some aspects of this disclosure, degradations or improvements in the loads or the electrical system's sensitivity or resilience to power quality events may be identified at each respective metering point in the electrical system. The degradations or improvements in the electrical system's sensitivity or resilience to power quality events may be identified, for example, based identified changes in the dynamic tolerance curves for each respective metering point. In some embodiments, the identified degradations or improvements in the loads or the electrical system's sensitivity or resilience to power quality events may be reported. For example, the identified degradations or improvements in the loads or the electrical system's sensitivity or resilience to power quality events may be reported by generating and/or initiating a warning (e.g., a key performance indicator) indicating the identified degradations or improvements in the electrical system's sensitivity or resilience to power quality events. The warning may be communicated via at least one of: a report, a text, an email, audibly, and an interface of a screen/display, for example. In some embodiments, the screen/display may correspond to a screen/display on which the dynamic tolerance curve(s) is/are presented. The communicated warning may provide actionable recommendations for responding to the identified degradations or improvements in the electrical system's sensitivity or resilience to power quality events.

[0381] In accordance with further aspects of this disclosure, power quality data from the plurality of dynamic tolerance curves may be selectively aggregated to generate one or more aggregate dynamic tolerance curves.

[0382] In some embodiments, the plurality of dynamic tolerance curves may be aggregated by graphing the plurality of dynamic tolerance curves in a composite plot (or plots). For example, the response characteristic of the electrical system at each metering point, e.g., as indicated in

the plurality of tolerance curves, may be presented as a sub-graph in the composite plot (or plots). In some embodiments, the plurality of tolerance curves may be presented in the composite plot (or plots), e.g., in order of appearance in the plot (or plots), based on a criticality or sensitivity ranking (1st to last) of the metering points. It is understood that other groupings may be overlaid, for example, to reflect an analysis by location. One may first group by location such as one graph per location, then sort the meters in decreasing order of sensitivity or criticality.

[0383] In accordance with some aspects, it is possible to overlay common impact model(s) and highlight key specificities of each meter by color-coding, for example. A dynamic tolerance curve generated for a most sensitive high-criticality (e.g., on magnitude initial start) meter in an electrical system may, for example, serve as a reference curve for each and all the other meters. Then it is possible to play on other graphical components to highlight the criticality of a load/process if tagged for each or certain meters (for example by using the line thickness, shading, or coloring the curve line in red, green or blue, for example, for “highly-critical”, “somewhat-critical”, “not-critical”, etc.).

[0384] Additionally, in accordance with some aspects, dynamic tolerance curves associated with each relevant group of meters may be presented as a sub-graph in the composite plot (or plots). The relevance of a group may depend, for example, on the goal (or goals) of the composite plot (or plots). It is understood that many different relevant groupings may be used in different contexts. For example, the curves/meters may be grouped for location (e.g., meter location) based analysis. Additionally, the curves/meters may be grouped by criticality. For example, highly critical meters may be grouped vs. the other categories of meters. Additionally, all the individual highly-critical meters may be plotted against an aggregated curve of less critical meters. The curves/meters may also be grouped by impact, e.g., group meters by similar percentages at a given magnitude of a voltage sag and duration level. Additionally, the meters may be grouped by sensitivity curve or range, e.g., distance between initial and final impact.

[0385] It is understood that the above criteria may be combined. For example, a filter may be applied per location, so a grouping by location. Then the typical location may be plotted where all meters at this location are used to calculate the mean thresholds and change points.

Aggregated typical graphs of highly critical meters may then be compared with the minimal “initial impact values” curve from the typical (mean) “initial impact values” curve. This would indicate whether there is one or a few IEDs creating the “weak points” of the system that may need to be made more robust (e.g., SagFigher® solution to be analyzed).

[0386] The ranking (first to last) in order of appearance of each meter may be based on the criticality or the sensitivity of the electrical system and/or the load (or loads) at the metering point(s) associated with the meter, for example. However, other groupings may be overlaid. For example, to reflect an analysis by location, one may first group the meters by location, then sort the meters in decreasing order of sensitivity or criticality.

[0387] Subsequent to block 5415, the method may proceed to block 5420. At block 5420, power quality events in the electrical system are analyzed based on the selectively aggregated power quality data. For example, the selectively aggregated power quality data may be processed or analyzed to determine a relative criticality score of each of the power quality events to a process or an application associated with the electrical system. The relative criticality score may be based on an impact of the power quality events to the process or the application, for example. For example, a rooftop HVAC unit or system dropping off for three hours for an office building may be considered less critical than for a data center. Additionally, a motor in a steel production line may be considered more critical than a lighting rail or fixture above the steel production line. In some embodiments, the relative criticality score may be used as an input for supervised learning. Supervised learning means that some variable(s) may be used to teach the calculation engine which issues have more value than others.

[0388] In some embodiments, the impact of the power quality events is related to tangible or intangible costs associated with the power quality events to the process or the application.

Additionally, in some embodiments the impact of the power quality events is related to relative impact on loads in the electrical system. In some embodiments, there may be an absolute threshold or non-acceptable trip off-line of a load (or loads) related to the process or the application. For example, in the above example of a data center, a cooling pump of the HVAC system may be considered a critical component, which should never be trip off-line.

Additionally, in the above example of a steel production line, there may be a path in the production line where there is no redundancy of motor on the conveyor belt. This may be the component or process which should never misoperate, trip off-line, and/or malfunction.

[0389] In some embodiments, the determined relative criticality score, e.g., at block 5420, may be used to prioritize responding to (or a response to) the power quality events. For example, the determined relative criticality score (e.g., a criticality score using a historical analysis of the voltage event impacts) may be used to determine how significant load loss effects the system operation. The more significant the impact, the worse the relative criticality score as related to other IEDs in the system. This could also be performed based on discrete locations of said IEDs (i.e., some locations are more significantly impacted by voltage events than other locations). Some locations may inherently have worse criticality scores than others due to their processes, functions, and/or loads.

[0390] The relative criticality score may also be used, for example, as an input to drive a manufacturing SCADA to determine if an alternative process should be triggered or terminated. For example, voltage sags may result in poorer product quality or product defects such as fluctuations in the heat and pressure conditions producing an increase in the quantity of air bubbles in rubber products. A higher criticality score may reflect these portions of the production process. In this case, an alternative/corrective process may be triggered to complement the current process step or scrap the product.

[0391] In embodiments in which the power quality data from the plurality of dynamic tolerance curves has been selectively aggregated to generate one or more aggregate dynamic

tolerance curves at block 5415, the aggregate dynamic tolerance curves may be analyzed or otherwise evaluated to analyze power quality events in the electrical system.

[0392] The power quality events analyzed at block 5420 may include, for example, at least one of: a voltage sag, a voltage swell, a voltage transient, a momentary interruption, a temporary interruption, and a long-duration root-mean-square (rms) variation.

[0393] In some embodiments, at block 5420 it may also be determined if any discrepancies exist between the selectively aggregated power quality data. For example, the discrepancies may include inconsistent naming conventions in the selectively aggregated data. As one example, the naming conventions for power quality data in a dynamic tolerance curve associated with a first metering point in the electrical system may be different from the naming conventions for power quality data in a dynamic tolerance curve associated with a second metering point in the electrical system. In embodiments in which discrepancies are identified, additional information may be requested (e.g., from a system user) to reconcile the discrepancies. Recommendations may be made.

[0394] After block 5420, the method may end in some embodiments. In other embodiments, the method may return to block 5405 and repeat again (e.g., for capturing additional energy-related signals, updating the dynamic tolerance curves associated with the metering points in the electrical system, and selectively aggregating power quality data from the updated dynamic tolerance curves to analyze power quality events).

[0395] It is understood that method 5400 may include one or more additional blocks in some embodiments. For example, the method 5400 may include tagging power quality events in one or more of the plurality of dynamic tolerance curves with relevant and characterizing information, for example, based on information extracted about the power quality events. In some embodiments, the relevant and characterizing information includes at least one of: a severity score, recovery time, percentage of loads added or lost during event, inductive or

capacitive load(s) added or dropped during event, location within a system, type of load or loads downstream from the IED providing the information, impact to a facility's operation, etc. Additionally, in some embodiments the information about the power quality events may be extracted from portions of electrical measurement data from energy-related signals captured prior to a start time of the power quality events. In some embodiments, the information about the power quality events may be extracted from portions of electrical measurement data from energy-related signals captured after an end time of the power quality events. Information may also be extracted from portions of electrical measurement data from energy-related signal captured during the power quality events.

[0396] In accordance with some aspects of this disclosure, tagging and data enriching can be performed at substantially any time. For example, tagging and data enriching may be performed before or during the site commissioning based on the loads which will be running, and based on calculations and process planning (times of preparation and of calculations) as a few examples. During normal operations, events may be tagged on the fly (times of normal running operations). Additionally, events may be tagged during re-commissioning or extensions, or maintenance (e.g., times of changes).

[0397] As discussed in connection with figures above, a dynamic tolerance curve may characterize an impact of a power quality event (or power quality events) in an electrical system. As also discussed in connection with figures above, in some embodiments at least one means for mitigating the impact of the power quality event (or power quality events) may be selected and applied in response to an analysis of the dynamic tolerance curve. For example, in accordance with some aspects of this disclosure, the dynamic tolerance curve may be used to prevent tripping of more critical loads by driving counter measures, including system level process optimization. For illustration purposes, if a user specifies absolute thresholds, the system (e.g., control system) may calculate an optimal curve to avoid the risk of tripping (the protection relay) for this given meter. Additionally, the system may decide to turn off typical loads which are known (or calculated) as possible causes of a power quality event (e.g., voltage

sags), or cut first (faster) other potential process steps which may generate risks of increasing or maintaining longer duration of the power quality event.

[0398] It is understood that one or more steps of method 5400 may be combined with one or more steps of other methods discussed throughout this disclosure, for example, for generating, updating and/or deriving dynamic tolerance curves.

[0399] Referring to Figs. 55-59, systems and methods for analyzing effects of electrical perturbations on equipment in an electrical system are disclosed. As discussed above, a power quality event is one example type of an electrical perturbation.

[0400] As is known, it is important for end-users to understand the impact of power quality events (e.g., voltage sags, undervoltage events, etc.) to their operation and equipment. However, most end-users do not have the time nor inclination to understand how to interpret data provided by today's monitoring systems. If the end-user does not have a comprehensive control mechanism or system that accounts for voltage perturbations, their equipment's reliability and mean-time-to-failure (MTTF) may be adversely impacted. To address this concern (and other concerns), systems and methods are provided herein for automatically analyzing waveforms associated with power quality events to provide additional information that can be used to increase MTTF, improve uptime, and reduce maintenance costs, for example. In some embodiments, the disclosed systems and methods may leverage the end-user's existing monitoring system to provide and track important details associated with power quality events heretofore overlooked or disregarded.

[0401] Referring to Fig. 55, a flowchart illustrates an example method 5500 for analyzing effects of electrical perturbations on equipment in an electrical system. In accordance with some embodiments of this disclosure, method 5500 may be implemented alone or in combination with any of the above-described methods. Similar to the above-described methods, method 5500 may be implemented on a processor of at least one IED (e.g., 121,

shown in Fig. 1A) and/or remote from the at least IED, for example, in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0402] As illustrated in Fig. 55, the method 5500 begins at block 5505, where energy-related signals (or waveforms) are measured and data is captured, collected, stored, etc. by at least one IED in the electrical system. The at least one IED may be installed or located, for example, at a respective metering point of a plurality of metering points in the electrical system. In some embodiments, the energy-related signals measured by the at least one IED include at least one of a voltage signal, a current signal, and a derived energy-related value, and the data captured corresponds to measurement data required for identifying an electrical perturbation in the electrical system at block 5510.

[0403] The derived energy-related value may include, for example, at least one of a calculated, derived, developed, interpolated, extrapolated, evaluated, and otherwise determined additional energy-related value from the at least one of the voltage signal and the current signal. Additionally, the derived energy-related value may include at least one of active power, apparent power, reactive power, energy, harmonic distortion, power factor, harmonic power, harmonic voltages, harmonic currents, interharmonic currents, interharmonic voltages, interharmonic power, individual phase currents, phase angle, impedance, sequence component, total voltage harmonic distortion, total current harmonic distortion, three-phase currents, phase voltage(s), line voltage(s) or other similar parameters. Further, the derived energy-related value may include at least one energy-related characteristic, the energy-related characteristic including magnitude, phase angle, duration, associated frequency components, impedance, energy-related parameter shape (e.g., rise time, decay rate).

[0404] At block 5510, an electrical perturbation is identified in the electrical system based on the energy-related signals measured at block 5505. In some embodiments, the electrical perturbation includes at least one of a voltage perturbation, a current perturbation, and a derived energy value perturbation. The voltage perturbation, for example, may include at least

one of a voltage sag, a voltage swell, a voltage transient, a voltage interruption, and a long-duration root-mean-square (rms) variation. It is understood that the electrical perturbation may be identified using one or more of the techniques described in connection with figures above.

[0405] In some embodiments, a location of the electrical perturbation is also identified at block 5510. The location of the electrical perturbation may, for example, be identified based on a location of the at least IED measuring the energy-related signals. Additionally, the location of the electrical perturbation may be identified or derived based on information in or tagged to the measured energy-related signals.

[0406] At block 5515, electrical measurement data from or derived from the energy-related signals is analyzed to identify and quantify the effects of the electrical perturbation on equipment in the electrical system. Example effects are described further in connection with figures below. However, let it suffice here to say that the effects may include, for example, equipment restarts/re-energizations due to the electrical perturbation. As is known, equipment restarts/re-energizations may produce or lead to stresses that may shorten life of the equipment. These stresses may include, for example, electrical, thermal and mechanical stresses.

[0407] In some embodiments, an end time of the electrical perturbation is also determined at block 5515, and electrical measurement data from prior to, during and/or after the end time of the electrical perturbation is analyzed to identify and quantify the effects of the electrical perturbation. The end time may be determined, for example, by the at least one IED indicating the voltage (as indicated by the energy-related signals measured at block 5505) has recovered to a range within the normal range (which is indicative of “normal” operation of the equipment). In some embodiments, the electrical measurement data from prior to the end time of the electrical perturbation corresponds to electrical measurement data from immediately prior to the end time, or a predetermined time prior to the end time. Similarly, in

some embodiments, the electrical measurement data from after the end time of the electrical perturbation corresponds to electrical measurement data from immediately after the end time, or a predetermined time after the end time. The predetermined time(s) may be a user configured time(s), for example.

[0408] At block 5520, one or more actions are taken to reduce the effects of the electrical perturbation and extend the life of the equipment. Example actions are described further in connection with figures below. However, let it suffice here to say that the actions may include, for example, at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system. In some embodiments, the at least one component corresponds to at least one of the equipment experiencing restarts/re-energizations due to the electrical perturbation.

[0409] After block 5520, the method may end in some embodiments. In other embodiments, the method may return to block 5505 and repeat again (e.g., for capturing additional energy-related signals, and identifying additional electrical).

[0410] It is understood that method 5500 may include one or more additional blocks in some embodiments. For example, in some embodiments the method may further include generating an alarm in response to the equipment restarting/re-energizing immediately after the electrical perturbation. Additionally, the method may include taking one or more actions in response to the alarm being triggered. Example actions that may be performed in response to the alarm being triggered may include, for example, reporting the equipment restart/re-energization and/or operating a switch to prevent future equipment restarting/re-energizing if it is determined that restarting/re-energizing is not necessary.

[0411] It is understood that one or more steps of method 5500 may be combined with one or more steps of other methods discussed throughout this disclosure, for example, for identifying electrical perturbations and associated power quality events.

[0412] Referring to Fig. 56, a flowchart illustrates an example method 5600 for identifying, quantifying and communicating the effects of electrical perturbations in accordance with embodiments of this disclosure. In accordance with some embodiments of this disclosure, method 5600 is illustrative of examples steps that may be performed at blocks 5515 and 5520 of method 5500 discussed above in connection with Fig. 55. Similar to method 5500, method 5600 may be implemented on a processor of at least one IED (e.g., 121, shown in Fig. 1A) and/or remote from the at least one IED, for example, in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0413] Returning briefly to method 5500, at block 5515 of method 5500 electrical measurement data from or derived from the energy-related signals is analyzed to identify and quantify the effects of the electrical perturbation on equipment in the electrical system. As previously discussed, the effects may include, for example, equipment restarts/re-energizations due to the electrical perturbation.

[0414] Referring now to method 5600, at block 5605 power quality event(s) which impact a load/equipment and lead to restarts/re-energizations are identified from the electrical measurement data. In some embodiments, these events are identified by considering changes with respect to the time prior to the electrical perturbation (e.g., “pre-event” data) in the electrical measurement data, as shown in Fig. 57, for example. For example, the pre-event data, which is indicative of data during normal equipment operation, may be compared with “post-event” data (i.e., data from after the electrical perturbation) and/or data during the electrical perturbation to determine equipment disconnects and equipment restarts/re-energizations. Changes to be considered may include, for example, at least one of a change in the true or displacement power factor, impedance, signal shape, voltage signal distortion, current signal distortion, and power signal distortion. Analysis of several example electrical characteristics to determine equipment disconnects and equipment restarts/re-energizations of a non-linear load, for example, a motor (i.e., one example type of equipment), are described below in connection with method 5800 shown in Fig. 58.

[0415] At block 5610, power quality event(s) which impact a load/equipment but do not lead to restarts/ re-energizations are identified from electrical measurement data analyzed to identify and quantify the effects of the electrical perturbation (e.g., at block 5505 of method 5500). For example, changes may be considered between the pre-event data and the post-event data and/or data during the electrical perturbation to identify power quality event(s) that impact equipment in the electrical system, but do not result in equipment restarts/re-energizations. In some embodiments, these events may impact operation (or effectiveness) of the equipment and and/or the electrical system including the equipment. This, in turn, may impact an output of the system, for example, the production, quality, rate, etc. of a product generated by the equipment and/or system. In some embodiments, the product may be a physical/tangible object (e.g., a widget). Additionally, in some embodiments the product may be a non-physical object (e.g., data or information).

[0416] At block 5610, power quality event(s) which do not impact a load/equipment and do not lead to restarts/re-energization are identified from the electrical measurement data. These events may, for example, correspond to events that do not interrupt (or minimally interrupt) operation (or effectiveness) of the equipment and/or the electrical system including the equipment.

[0417] At block 5620, at least one dynamic tolerance curve is generated or updated to indicate the event(s) identified at blocks 5605, 5610, 5615, as shown in Fig. 57A, for example. As illustrated in Fig. 57A, the identified event(s) may be indicated on a dynamic tolerance curve using one or more respective indicators or symbols. It is understood that the dynamic tolerance curve may be generated or updated using techniques discussed in connection with figures above. Additionally, it is understood that the dynamic tolerance curve may include one or more indicators other than those shown in Fig. 57A (i.e., the illustrated indicators are but a few of many potential indicators). For example, in some embodiments, attempts to restart/re-energize loads/equipment may also be indicated on the at least one dynamic tolerance curve. As described further below in connection with Fig. 58, attempts to restart/re-energize

loads/equipment may be determined in a number of ways, for example, by analyzing power factor levels.

[0418] In accordance with some embodiments of this disclosure, a dynamic tolerance curve is one example way in which the equipment restarts/re-energizations may be communicated, for example, at block 5520 of method 5500.

[0419] After block 5620, the method may end in some embodiments. In other embodiments, the method may return to block 5605 and repeat again (e.g., for identifying additional impacting and non-impacting events in the electrical system). It is understood that method 5600 may include one or more additional blocks in some embodiments. Additionally, it is understood that one or more steps of method 5600 may be combined with one or more steps of other methods discussed throughout this disclosure.

[0420] Referring to Fig. 58, a flowchart illustrates another example method 5800 for identifying, quantifying and communicating the effects of electrical perturbations in accordance with embodiments of this disclosure. In accordance with some embodiments of this disclosure, method 5800 is illustrative of examples steps that may be performed at blocks 5505, 5510, 5515 and 5520 of method 5500 discussed above in connection with Fig. 55, and blocks 5605, 5610, 5615 of method 5600 discussed above in connection with Fig. 56. Similar to methods 5500 and 5600, method 5800 may be implemented on a processor of at least one IED (e.g., 121, shown in Fig. 1A) and/or remote from the at least one IED, for example, in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0421] As illustrated in Fig. 58, the method 5800 begins at block 5805, where the at least one IED, cloud-based system, on-site software, gateway, or another head-end system, etc. on which the method 5800 is implemented, is/are configured to be able to identify, quantify and communicate the effects of electrical perturbations. In some embodiments, the configuration (e.g., a software and/or hardware configuration) is automatically performed, for example, in

response to a user requesting the electrical perturbation detection feature. Additionally, in some embodiments the configuration is manually performed, for example, by the user. Further, in some embodiments the configuration is in part automatically performed and in part manually performed. It is understood that configuration of the at least one IED, cloud-based system, on-site software, gateway, or another head-end system, etc. on which a method (e.g., 5800) disclosed herein is implemented may be performed in any of the above or below described methods.

[0422] At block 5810, it is determined if an electrical perturbation has occurred/is occurring in the electrical system. In some embodiments, this determination is made based on an analysis of energy-related signals captured by at least one IED in the electrical system. As discussed above in connection with method 5500, for example, the electrical perturbation may include at least one of a voltage perturbation, a current perturbation, and a derived energy value perturbation. As also discussed above in connection with method 5500, the electrical perturbation may be identified using one or more of the techniques described throughout the disclosure.

[0423] If it is determined an electrical perturbation has occurred/is occurring, the method proceeds to block 5815. Alternatively, if it is determined an electrical perturbation has not occurred/is not occurring, the method may end in some embodiments or return to block 5810, for example, with block 5810 repeated until an electrical perturbation is detected.

[0424] At block 5815, pre-event/event/post-event energy-related signals are captured and stored, for example, in one or more databases or devices (i.e., memory of devices) associated with the electrical system for analyzing the electrical perturbation. The database may be a historical database 5855 in some embodiments. Additionally, the devices may be an IED, gateway, on-site software, and/or cloud storage. In accordance with some embodiments of this disclosure, a user may access the information from the databases or devices associated

with the electrical system using a user device, for example, a desktop computer, a laptop computer, a handheld computer, a tablet computer, a smart phone, and/or the like.

[0425] At block 5820, characteristics of the pre-event/event/post-event energy-related signals are evaluated on one or more phases corresponding with the electrical perturbation. The characteristics may be evaluated, for example, by analyzing frequency aspects (e.g., at blocks 5825, 5830, 5835) and/or by analyzing non-frequency aspects (e.g., at blocks 5840, 5845, 5850) of the energy-related signal(s).

[0426] As illustrated in Fig. 58, the characteristic evaluation includes determining, at block 5825, if total harmonic distortion characteristics on at least one phase are indicative of a load restart/re-energization. For example, total harmonic distortion (current), or THDi, and/or total harmonic distortion (voltage), or THDv, may be analyzed to identify the stop/start of non-linear loads (e.g., a variable speed drive) in the electrical system in accordance with embodiments of this disclosure. For example, as is known, non-linear loads such as variable speed drives (VSDs) inject specific harmonics into the electrical system. Evaluating the presence/absence/change of these associated harmonics may indicate the stop/start of non-linear loads in the electrical system.

[0427] If it is determined the total harmonic distortion characteristics on at least one phase are indicative of a load restart/re-energization, the method may proceed to block 5860 or proceed to one or more of the other characteristic evaluations at blocks 5830, 5835, 5840, 5845, 5850. Alternatively, if it is determined the total harmonic distortion characteristics on at least one phase are not indicative of a load restart/re-energization, the result of the determination may be stored in a database at block 5855 and the method may proceed to one or more of the other characteristic evaluations at blocks 5830, 5835, 5840, 5845, 5850.

[0428] At block 5830, it is determined if discrete harmonic component characteristics on at least one phase are indicative of a load restart/re-energization. For example, similar to

THDv/THDi discussed above at block 5825, the sudden injection of even harmonics that dissipates over several cycles indicates the occurrence of inrush current on an inductive load (e.g., motor, transformer, etc.). Moreover, changes in presence of specific harmonic components may indicate starting/energization of certain load types (e.g., 5th and 7th harmonic components may indicate a 6-pulse drive). Evaluating the behavior of specific harmonic components is useful to identify the stop/start of non-linear loads.

[0429] If it is determined the discrete harmonic component characteristics on at least one phase are indicative of a load restart/re-energization, the method may proceed to block 5860 or proceed to one or more of the other characteristic evaluations at blocks 5835, 5840, 5845, 5850. Alternatively, if it is determined the discrete harmonic component characteristics on at least one phase are not indicative of a load restart/re-energization, the result of the determination may be stored in a database at block 5855 and the method may proceed to one or more of the other characteristic evaluations at blocks 5835, 5840, 5845, 5850.

[0430] At block 5835, it is determined if non-harmonic (i.e., interharmonic) frequency characteristics on at least one phase are indicative of a load restart/re-energization. For example, evaluating interharmonics provides information regarding special frequencies associated with motors. In this example, slip frequencies (i.e., an interharmonic frequency) in induction motors are produced by the differential between a motor's synchronously rotating magnetic field on the stator and the actual rotational speed of the motor's rotor (e.g., sidebands shown in Fig. 59). Accordingly, analysis of changes in the slip frequencies may indicate that a motor is restarting or has restarted.

[0431] If it is determined non-harmonic frequency characteristics on at least one phase are indicative of a load restart/re-energization, the method may proceed to block 5860 or proceed to one or more of the other characteristic evaluations at blocks 5840, 5845, 5850. Alternatively, if it is determined non-harmonic frequency characteristics on at least one phase are not indicative of a load restart/re-energization, the result of the determination may be

stored in a database at block 5855 and the method may proceed to one or more of the other characteristic evaluations at blocks 5840, 5845, 5850.

[0432] At block 5840, it is determined if voltage/current/power signature characteristics on at least one phase are indicative of a load restart/re-energization. For example, the rms shape associated with a voltage event may be evaluated to indicate a load starting, as illustrated in Fig. 59A. For example, inductive load currents and powers exhibit a significant positive impulse followed by an exponential decay rate (as the magnetizing field of the load is energized). Referring briefly to Fig. 59A, this figure illustrates the rms real power associated with an impactful voltage sag event on a real customer site. In this case, the voltage sag lasts for approximately one-third of a second. At the end of the voltage sag event, an undetermined load attempts to restart as indicated by the impulsive characteristics of the rms real power on the right side of the graph. This load restart may have been intentional or unintentional; however, the stress experienced by the load is pertinent in either case. If the load is a compressor motor, it may be important to defer restarting/re-energizing for a longer period of time to allow the system to equalize before attempting to restart. Alternatively, if the load is related to an extrusion process, it may be important to identify the need to provide ride-through capabilities on the motor controls to keep the motor running. In both cases, tracking these types of unscheduled restarts (and the time between running, stopping, and restarting) may be an important aspect in predicting the longevity of equipment.

[0433] Another example may be evaluating the voltage waveform signature for notches (e.g., as shown in Fig. 59C) or the current waveform signature for capacitor charging or evidence of a rectifier energizing/operating (e.g., as shown in Fig. 59C for a single-phase rectifier, and as shown in Fig. 59D for a three-phase rectifier). This may be done, for example, by evaluating the presence of certain harmonic voltage and current components and/or by evaluating the shape of the voltage and/or current signatures.

[0434] If it is determined voltage/current/power signature characteristics on at least one phase are indicative of a load restart/re-energization, the method may proceed to block 5860 or proceed to one or more of the other characteristic evaluations at blocks 5845, 5850.

Alternatively, if it is determined voltage/current/power signature characteristics on at least one phase are not indicative of a load restart/re-energization, the result of the determination may be stored in a database at block 5855 and the method may proceed to one or more of the other characteristic evaluations at blocks 5845, 5850.

[0435] At block 5845, it is determined whether impedance (e.g., load impedance) characteristics on at least one phase are indicative of a load restart/re-energization. As is known, complex impedance, for example, typically changes during a voltage sag. A decrease in impedance after the end of the voltage sag, for example, may indicate that a motor or other load is attempting to restart/re-energize.

[0436] If it is determined the impedance characteristics on at least one phase are indicative of a load restart/re-energization, the method may proceed to block 5860 or proceed to the characteristic evaluation at block 5850. Alternatively, if it is determined the impedance characteristics on at least one phase are not indicative of a load restart/re-energization, the result of the determination may be stored in a database at block 5855 and the method may proceed to the characteristic evaluation at block 5850.

[0437] At block 5850, it is determined if true and/or displacement power factor characteristics on at least one phase are indicative of a load restart/re-energization. As is known, power factor is typically very low (e.g., 20-30% range) when a motor is energized. As the restarted/re-energized motor accelerates (comes up to speed), the power factor will typically recover to its rated power factor based on corresponding motor load. With this information, the power factor of the motor may be used to determine motor starts coincident with the dropout of voltage events. Significantly lower power factor levels for short durations during or after voltage sag

events followed by some degree/amount of recovery, for example, may indicate a motor attempting to start (i.e., equipment restarts).

[0438] If it is determined the power factor characteristics on at least one phase are indicative of a load restart/re-energization, the method may proceed to block 5860. Alternatively, if it is determined the power factor characteristics on at least one phase are not indicative of a load restart/re-energization, the result of the determination may be stored in a database at block 5855.

[0439] At block 5860, in response to it having been determined that one or more characteristics are indicative of a load restart/re-energization at blocks 5825, 5830, 5835, 5840, 5845 and/or 5850, an output (or outputs) is/are provided to indicate a load restart/re-energization was attempted. The output(s) may include, for example, at least one of a status change, an alarm, a text, email, audibly, GUI interface, control signal output, etc.

[0440] At block 5865, one or more actions are taken to reduce the effects of current and/or future electrical perturbations. Example actions are described further in connection with Figs. 60 and 61, for example.

[0441] At block 5870, which is optional in some embodiments, one or more reports may be provided for individual IEDs, sub-systems, processes, and/or systems. Some examples may include current and historical restart characterizations, trends (or other statistical evaluations), potential impacts, suggested mitigative solutions, potential costs and/or losses, load responses, objective/subjective analyses of equipment life expectancies, etc.

[0442] It is understood that any one or more of the above-described analyses (e.g., at blocks 5825, 5830, 5835, 5840, 5845, 5850) may be run in serial and/or parallel, in different sequences, on different processors, at different location within the system (or remotely), etc. It is possible that a given IED may be incapable of running some analyses, so a subset of analyses

(one or more) may be run. It is understood the order of the process(es) shown may not be run precisely according to the order shown herein, but the output may be effectively the same.

[0443] While the description above is made with reference to a motor in many instances, it is understood that other types components/loads/equipment besides motors are applicable for the systems and methods disclosed herein.

[0444] Referring to Fig. 60, a flowchart illustrates an example method 6000 for taking actions to reduce stresses and extend the life of equipment in an electrical system in accordance with embodiments of this disclosure. In accordance with some embodiments of this disclosure, method 6000 is illustrative of examples steps that may be performed at block 5520 of method 5500 discussed above in connection with Fig. 55. Similar to method 5500, method 6000 may be implemented on a processor of at least one IED (e.g., 121, shown in Fig. 1A) and/or remote from the at least one IED, for example, in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0445] Returning briefly to method 5500, at block 5520 of method 5500 one or more actions are taken to reduce the effects of the electrical perturbation and extend the life of the equipment. As previously discussed, the actions may include, for example, at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.

[0446] Referring now to block 6005 of method 6000, at block 6005 it is determined if the equipment restarts/re-energizations will be communicated. In some embodiments, indications may be communicated based on any occurrence, based on a threshold, number of attempted restarts, location (within the electrical system), criticality of the IED reporting the restarts, or other parameters of importance. Communications may, for example, originate from hardware, software, gateways, cloud-based applications, or any other head-end system managing the relevant information.

[0447] If it is determined the equipment restarts/re-energizations will be communicated, the method proceeds to block 6010. Alternatively, if it is determined the equipment restarts/re-energizations will not be communicated, the method proceeds to block 6020.

[0448] At block 6010, at least one means for communicating the equipment restarts/re-energizations is determined. For example, it may be determined to communicate the equipment restarts/re-energizations via at least one of: an alarm, a report, a text, an email, audibly, and an interface of a screen/display. Additionally, it may be determined to communicate the equipment restarts/re-energizations on at least one dynamic tolerance curve associated with the electrical system, with the at least one dynamic tolerance curve to be included, presented, etc. on the report, text (e.g., multimedia messaging service text), email, interface of the screen/display, etc. At block 6010, it may also be determined to communicate the equipment restarts/re-energizations to particular devices and/or users (e.g., building management), for example, based on location(s) of the equipment restarts/re-energizations, devices associated with the equipment restarts/re-energizations, etc. Equipment restarts/re-energizations meeting the configured requirements may result in an alarm from hardware, software, gateway, and/or other head-end system managing the relevant information. The alarm may or may not be associated with the voltage perturbation initiating the equipment restarts/re-energizations. It is understood that the above-discussed means for communicating the equipment restarts/re-energizations are but several of many potential means for communicating the equipment restarts/re-energizations.

[0449] At block 6015, the equipment restarts/re-energizations are communicated based on/using the at least one means determined at block 6010. For example, if it is determined that the equipment restarts/re-energizations will be communicated via at least one of: a report, a text, an email, audibly, and an interface of a screen/display, at block 6015 a corresponding report, text, email, etc. will be generated to indicate the equipment restarts/re-energizations.

[0450] As discussed above, in some embodiments the report, text, email, etc. may include at least one dynamic tolerance curve. In these embodiments, at block 6015 at least one dynamic tolerance curve may be generated and/or updated to indicate the equipment restarts/re-energizations and be formatted based on the type of communication(s) (i.e., report, text, email, etc.). The at least one dynamic tolerance curve may indicate, for example, at least one of severity, magnitude, phase, phase angle, duration, location, process and equipment/load(s) impacted by the electrical perturbation, etc. It is understood that other information may be indicated on the dynamic tolerance curve. For example, as illustrated in Fig. 57A, the at least one dynamic tolerance curve may indicate power quality event(s) which impact a load and lead to restarts/re-energizations, power quality event(s) which impact a load but do not lead to restarts/re-energizations, and power quality event(s) which do not impact a load and do not lead to restarts/re-energizations. The event waveforms may also be associated/linked with each respective occurrence in Fig. 57A.

[0451] At block 6020, it is determined if at least one component in the electrical system will additionally or alternatively be controlled, if specific mitigative devices or other mitigative approaches or techniques will be added, and/or if the quality or type of equipment should be changed, for example, in response to the equipment restarts/re-energizations. For example, it may be determined that by adjusting at least one parameter associated with a component, adding specific mitigative devices, and/or changing the quality or type of equipment, the number of equipment restarts/re-energizations due to the electrical perturbation may be reduced or eliminated.

[0452] If it is determined at least one component in the electrical system will be controlled, the method proceeds to block 6025. Alternatively, if it is determined at least one component in the electrical system will not be controlled, the method proceeds to block 6040.

[0453] At block 6025, it is determined which component(s) in the electrical system will be controlled. For example, it may be determined that the at least one component corresponds to

or includes at least one of the equipment experiencing restarts/re-energizations due to the electrical perturbation.

[0454] At block 6030, it is determined how to control the component(s) to reduce the effects of the electrical perturbation and extend the life of the equipment. For example, as briefly discussed above, it may be determined that by adjusting at least one parameter associated with a component, adding specific mitigative devices or other mitigative approaches or techniques, and/or changing the quality or type of equipment, the number of equipment restarts/re-energizations due to the electrical perturbation may be reduced or eliminated. At block 6030, for example, it may be determined by how much the at least one parameter should be adjusted.

[0455] At block 6035, the component(s) are controlled, for example, by a control system associated with the electrical system based on the determination at block 6030. For example, the control system may generate a control signal providing for adjustment of the above-discussed at least one parameter and provide the control signal to the component(s) (or other equipment in the electrical system) for adjusting the at least one parameter. As discussed in figures above, in some embodiments the at least one IED may include or correspond to the control system. Additionally, in some embodiments the control system may include the at least one IED.

[0456] In some embodiments, the component(s) are automatically controlled (e.g., by the control system) in response to the communicated equipment restarts/re-energizations at block 5815. In these embodiments, blocks 6020, 6025 and 6030 may be optional.

[0457] At block 6040, it is determined if any other actions will be taken in response to the equipment restarts/re-energizations. For example, it may be determined that an alarm should be triggered in response to the equipment restarting/re-energizing immediately after the electrical perturbation, as briefly discussed above in connection with Fig. 55.

[0458] If it is determined other actions will be taken, the method proceeds to block 6045 where the actions to be taken (e.g., generating an alarm) are determined. Alternatively, if it is determined no other actions will be taken, the method may end.

[0459] At block 6050, the action(s) determined at block 6045 are taken/performed.

[0460] After block 6050, the method may end in some embodiments. In other embodiments, the method may return to block 6050 and repeat again (e.g., for taking further actions to reduce the effects of the electrical perturbation and extend the life of the equipment, for making recommendations for mitigative equipment or other mitigative approaches or techniques, better quality equipment, better configuration of the control scheme, etc.). It is understood that method 6000 may include one or more additional blocks in some embodiments. Additionally, it is understood that one or more steps of method 6000 may be combined with one or more steps of other methods discussed throughout this disclosure.

[0461] Referring to Fig. 61, a flowchart illustrates an example method 6100 for evaluating the effectiveness of actions taken to reduce stresses and extend the life of equipment in an electrical system in accordance with embodiments of this disclosure. In accordance with some embodiments of this disclosure, method 6100 is illustrative of examples steps that may be performed at block 5520 of method 5500 discussed above in connection with Fig. 55, alone or in combination with methods 5600, 5800 and 6100. Similar to method 5500, for example, method 6100 may be implemented on a processor of at least one IED (e.g., 121, shown in Fig. 1A) and/or remote from the at least one IED, for example, in at least one of: a cloud-based system, on-site software, a gateway, or another head-end system.

[0462] Returning briefly to method 5500, at block 5520 of method 5500 one or more actions are taken to reduce the effects of the electrical perturbation and extend the life of the equipment.

[0463] Referring now to block 6105 of method 6100, at block 6105 at least one action for reducing the effects of the electrical perturbation and extending the life of the equipment is determined. As discussed above in connection with methods 5500 and 5900, for example, the actions may include at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.

[0464] At block 6110, one or more of the actions determined at block 6105 are taken/performed. It is understood that multiple actions may be taken, as described above in connection with method 5800, for example.

[0465] At block 6115, the effectiveness of the actions taken/performed at block 6110 is evaluated. In particular, at block 6115 it is determined if the actions taken/performed at block 6110 are effective. In some embodiments, effectiveness is determined based on observed changes between electrical measurement data from prior to the actions being taken/performed and electrical measurement data from after the actions are taken/performed. For example, if it is observed that fewer equipment restarts/re-energizations occur after the actions are taken/performed, it may be determined that the actions are effective. For example, when the incoming voltage levels are marginally low (but still within the normal tolerance range), equipment is more susceptible to voltage sag events. A solution is to raise the voltage level applied to the equipment to mitigate some power quality event(s) which impact a load/equipment and may lead to restarts/re-energizations. Raising the equipment's applied voltage level may make the equipment less susceptible to some voltage sags (and equipment restarts/re-energizations), and it may be determined that the actions are effective. If it is observed that a same number of equipment restarts/re-energizations occur after the actions are taken/performed, it may be determined that the actions are not effective.

[0466] In some embodiments, the effectiveness may be determined based on an evaluation of a dynamic tolerance curve generated prior to the actions being taken/performed and a dynamic

tolerance curve generated after the actions are taken/performed. The dynamic tolerance curve may be generated or updated, for example, at block 5620 of method 5600 discussed above.

[0467] In further embodiments, determining the effectiveness of the actions taken/performed at block 6110 includes determining if the effectiveness of the actions taken/performed is above or below one or more so-called effectiveness thresholds. In some embodiments, the effectiveness thresholds may be based on one or more pre-event/event/post-event factors, metrics, and/or characteristics and in some embodiments, have an associated magnitude, duration, phase angle, or other relevant parameter. For example, an effectiveness threshold may be based on one or more combinations of targeted improvements including a reduction in the number of impactful events, accrued recovery time due to the power quality events, load impact magnitudes, economic losses (e.g., capital costs, maintenance costs, etc.), unproductive recovery energy consumed, CO₂ emissions from recovery energy, etc.

[0468] If it is determined the actions taken/performed are effective, the method may end. Alternatively, if it is determined the actions taken/performed are not effective, the method proceeds to block 6120.

[0469] At block 6120, it may be determined if there are any other actions that may be taken/performed to reduce the equipment restarts/re-energizations due to the electrical perturbation, for example, using the process discussed above in connection with method 6000.

[0470] If it is determined that there are other actions that may be taken/performed, the method may proceed to block 6125. Alternatively, if it is determined that there are no other actions that may be taken/performed, the method may end.

[0471] At block 6125, at least one other action is selected and taken to reduce the equipment restarts/re-energizations due to the electrical perturbation.

[0472] After block 6125, the method may end in some embodiments. In some embodiments, the method may be initiated again from time-to-time, for example, to evaluate the effectiveness of an action (or actions) taken, and to incorporate potentially new or more effective actions and/or elimination techniques or apparatuses into the electrical system.

[0473] In other embodiments, the method 6100 may include one or more additional steps. For example, in one embodiment the method 6100 may further include indicating a best means for reducing the effects of the electrical perturbation (e.g., restarts/re-energizations) and extending the life of the equipment, for example, on a dynamic tolerance curve (e.g., as shown in Fig. 57A). In some embodiments, the best means for reducing the effects of the electrical perturbation and extending the life of the equipment may correspond to a most effective (e.g., electrically effective, cost-effective, etc.) means for reducing the effects of the electrical perturbation and extending the life of the equipment. Additionally, in some embodiments the best means for reducing the effects of the electrical perturbation and extending the life of the equipment corresponds to a least disruptive means for reducing the effects of the electrical perturbation and extending the life of the equipment. It is understood that multiple actions may be taken/performed at different points in a system or at a single location in the system.

[0474] As illustrated above, and as will be appreciated by one of ordinary skill in the art, embodiments of the disclosure (with particular reference to Figs. 55-61) provide many benefits. Example benefits include latching evaluations to detected power quality events (anomalous electrical conditions) and non-latching evaluations of load starting and restarting (i.e., duty cycles). Example benefits also include identifying potential restart issues, for example, using market segment metadata to determine criticality of issue to customer type (e.g., injection molding systems may have one goal; refrigeration systems may have another), and identifying some potential equipment types that are restarting. Additional benefits include quantifying potential restart issues, for example, by location(s), number of restarts associated with discrete power quality events such as voltage sags and undervoltage conditions and accumulating other restart information associated with specific event characteristics (i.e., magnitude, duration,

frequencies present, etc.). Further benefits include reducing equipment stress, extending equipment operational life, reducing maintenance costs, inhibiting the notification of unexpected or excessive equipment restarts (if they are deemed to be acceptable), and recommending mitigative techniques to minimize/eliminate restart issues (if they exist).

[0475] Embodiments of this disclosure also provide end-users with a better understanding of how equipment is operating on their electrical system. For example, embodiments of this disclosure provide end-users with detailed information on the impact of electrical perturbations (and anomalous voltage conditions) to their loads. Leveraging data from normal and abnormal voltage conditions as provided by metering instrumentation or other IEDs provides the ability to identify, quantify, and notify end-users of the universal and isolated stresses experienced across their electrical system and/or at discrete loads. When deployed in cloud-based applications, the disclosure may allow statistical analysis, analytics, baselining and/or classifying across comparable market segments and/or equipment, identifying opportunities for new solutions and services, and strengthening equipment, customer, and market awareness.

[0476] As also illustrated above, and as will be appreciated by one of ordinary skill in the art, embodiments of the disclosure promote “more and better” metering within facilities. For example, the more IEDs installed in an energy consumer’s electrical system, the more beneficial these embodiments may be for the energy consumer. As will also be appreciated by one of ordinary skill in the art, there are significant opportunities for voltage event mitigation products. Further, it will be appreciated by one of ordinary skill in the art that it is important to identify and promote opportunities that would have typically been overlooked, misunderstood, or simply ignored by energy consumers. The ability to quantify voltage events creates a justifiable sense of urgency for the energy consumer to resolve these issues. The various embodiments described in this disclosure should allow services-based organizations to more readily identify opportunities and be retained for designing and installing the most economical solution. By leveraging products to identify opportunities for improving voltage event

mitigation and reduced recovery time, for example, energy consumers may improve their operational availability and increase their profitability.

[0477] The embodiments described in this disclosure may also create many opportunities for cloud-based services. While the prospect of using on-site software to evaluate, quantify, and mitigate voltage events may be more ideal in some embodiments, direct (or substantially direct) participation/interaction with energy consumers may tend to promote many more services and products sales opportunities. By evaluating the voltage event data in the cloud, active engagement in a timelier manner with relevant information and practical solutions may yield further possibilities.

[0478] As illustrated above, voltage sags/dips have a significant impact on industrial equipment, processes, products, and ultimately a customer's bottom-line. In embodiments, voltage sags/dips are the biggest (or close to the biggest) source of power quality issues, and can originate both inside and outside an energy consumer's facility. Using dynamic voltage tolerance curves and the other embodiments described herein will provide the ability to localize, quantify, and rectify the impact of voltage sags/dips and shorten event recovery time. Moreover, dynamic voltage tolerance curves provide the ability to target, design and validate custom mitigative solutions and services, which helps the energy consumer reduce interruptions to their operations, maximize their system performance and availability, increase their equipment life, and reduce their total operating costs. In short, the embodiments disclosed in this application may be incorporated in meters, gateways, on-site software such as PME, and cloud-based offers such as Power Advisor by Schneider Electric.

[0479] As described above and as will be appreciated by those of ordinary skill in the art, embodiments of the disclosure herein may be configured as a system, method, or combination thereof. Accordingly, embodiments of the present disclosure may be comprised of various means including hardware, software, firmware or any combination thereof.

[0480] It is to be appreciated that the concepts, systems, circuits and techniques sought to be protected herein are not limited to use in the example applications described herein (e.g., power monitoring system applications) but rather, may be useful in substantially any application where it is desired to manage power quality events in an electrical system. While particular embodiments and applications of the present disclosure have been illustrated and described, it is to be understood that embodiments of the disclosure not limited to the precise construction and compositions disclosed herein and that various modifications, changes, and variations can be apparent from the foregoing descriptions without departing from the spirit and scope of the disclosure as defined in the appended claims.

[0481] Having described preferred embodiments, which serve to illustrate various concepts, structures and techniques that are the subject of this patent, it will now become apparent to those of ordinary skill in the art that other embodiments incorporating these concepts, structures and techniques may be used. Additionally, elements of different embodiments described herein may be combined to form other embodiments not specifically set forth above.

[0482] Accordingly, it is submitted that that scope of the patent should not be limited to the described embodiments but rather should be limited only by the spirit and scope of the following claims.

What is claimed is:

CLAIMS

1. A method for analyzing effects of electrical perturbations on equipment in an electrical system, comprising:

processing energy-related signals from at least one intelligent electronic device (IED) in the electrical system to identify an electrical perturbation in the electrical system;

determining an end time of the electrical perturbation;

analyzing electrical measurement data from prior to, during and/or after the end time of the electrical perturbation to identify and quantify the effects of the electrical perturbation on equipment in the electrical system, the effects including equipment restarts/re-energizations due to the electrical perturbation; and

taking one or more actions to reduce the effects of the electrical perturbation and extend the life of the equipment, the actions including at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.

2. The method of claim 1, wherein the equipment restarts/re-energizations produce or may lead to stresses that may shorten life of the equipment.

3. The method of claim 2, wherein the stresses include electrical, thermal and mechanical stresses.

4. The method of claim 1, wherein communicating the equipment restarts/re-energizations, includes: communicating the equipment restarts/re-energizations via at least one of: a report, a text, an email, audibly, and an interface of a screen/display.

5. The method of claim 1, wherein communicating the equipment restarts/re-energizations, includes: indicating the equipment restarts/re-energizations on at least one dynamic tolerance curve associated with the electrical system.
6. The method of claim 1, wherein communicating the equipment restarts/re-energizations, includes: indicating at least one of severity, magnitude, phase, phase angle, duration, location, process and equipment/load(s) impacted by the electrical perturbation on at least one dynamic tolerance curve associated with the electrical system.
7. The method of claim 1, wherein the at least one component is automatically controlled by a control system associated with the electrical system in response to the communicated equipment restarts/re-energizations.
8. The method of claim 7, wherein the at least one component corresponds to at least one of the equipment experiencing restarts/re-energizations due to the electrical perturbation.
9. The method of claim 1, wherein the energy-related signals include at least one of a voltage signal, a current signal, and a derived energy-related value.
10. The method of claim 9, wherein the derived energy-related value includes at least one of a calculated, derived, developed, interpolated, extrapolated, evaluated, and otherwise determined additional energy-related value from the at least one of the voltage signal and the current signal.
11. The method of claim 9, wherein the derived energy-related value includes at least one of active power, apparent power, reactive power, energy, harmonic distortion, power factor, harmonic power, harmonic voltages, harmonic currents, interharmonic currents, interharmonic voltages, interharmonic power, individual phase currents, phase angle, impedance, sequence component, total voltage harmonic distortion, total current harmonic distortion, three-phase currents, phase voltage(s), line voltage(s) or other similar parameters.

12. The method of claim 9, wherein the derived energy-related value includes at least one energy-related characteristic, the energy-related characteristic including magnitude, phase angle, duration, associated frequency components, impedance, energy-related parameter shape, rise time, and decay rate.

13. The method of claim 9, wherein the analyzing electrical measurement data from prior to, during and/or and after the end time of the electrical perturbation, includes: considering changes with respect to the time prior to the electrical perturbation in the at least one of the voltage signal, the current signal, and the derived energy value.

14. The method of claim 13, wherein the changes to be considered include at least one of a change in the true or displacement power factor, impedance, signal shape, voltage signal distortion, current signal distortion, and power signal distortion.

15. The method of claim 13, wherein the changes to be considered indicate the equipment restarts/re-energizations.

16. The method of claim 1, wherein the electrical perturbation includes at least one of a voltage perturbation, a current perturbation, and a derived energy value perturbation.

17. The method of claim 16, wherein the voltage perturbation includes at least one of a voltage sag, a voltage swell, a voltage transient, a voltage interruption, and a long-duration root-mean-square (rms) variation.

18. The method of claim 1, further comprising: generating an alarm in response to the equipment restarting/re-energizing immediately after the electrical perturbation.

19. The method of claim 1, wherein the end time is determined by the at least one IED indicating the voltage has recovered to a range within the nominal voltage.

20. A method for analyzing effects of electrical perturbations on equipment in an electrical system, comprising:

- processing energy-related signals from at least one intelligent electronic device (IED) in the electrical system to identify an electrical perturbation in the electrical system;

- analyzing electrical measurement data from or derived from the energy-related signals to identify and quantify the effects of the electrical perturbation on equipment in the electrical system, the effects including equipment restarts/re-energizations due to the electrical perturbation; and

- taking one or more actions to reduce the effects of the electrical perturbation and extend the life of the equipment, the actions including at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.

21. A system for analyzing effects of electrical perturbations on equipment in an electrical system, comprising:

- at least one processor;

- at least one memory device coupled to the at least one processor, the at least one processor and the at least one memory device configured to:

- process energy-related signals from at least one intelligent electronic device (IED) in the electrical system to identify an electrical perturbation in the electrical system;

- determine an end time of the electrical perturbation;

- analyze electrical measurement data from prior to, during and/or after the end time of the electrical perturbation to identify and quantify the effects of the electrical perturbation on equipment in the electrical system, the effects including equipment restarts/re-energizations due to the electrical perturbation; and

take one or more actions to reduce the effects of the electrical perturbation and extend the life of the equipment, the actions including at least one of communicating the equipment restarts/re-energizations and controlling at least one component in the electrical system.
