(63) Continuation of application No. 09/824,830, filed on Apr. 3, 2001, now Pat. No. 6,999,469.

Message Synchronization of the present inventions begins with storing messages (e-mail, voice mail, faxes) in more than one (1) message repository allowing users multiple, differentiated access points (e.g.: IP Client, PSTN). From any of these points, messages can be altered to reflect any one or more of a number of defined messages states (e.g.: Deleted, Read, Unread). As a seamless service to the user, these changed states are reflected identically throughout the face of all access points, and the bodies of all repositories.

MESSAGE SYNCHRONIZATION IN A COMMUNICATIONS SYSTEM

CROSS-REFERENCE TO RELATED APPLICATIONS

[0001] This application is related to and claims priority from Provisional Application No. 60/229,678, entitled "A Synchronization Agent for Use in a Communications System," having a filing date of Sep. 1, 2000.

FIELD OF THE INVENTION

[0002] The invention relates generally to the field of data synchronization and more particularly to the field of synchronizing data states and data for messaging in a communications system.

BACKGROUND

[0003] Current communications technology provides for the use of numerous devices and services for sending and receiving messages. The public switch and telephone network, for example, implements a variety of data transmission services. Telephone system users are typically equipped for sending and receiving real-time voice, fax transmissions, pages and voice-mail. Recent trends in telephone system advancement have focussed on "anytime, anywhere" capability, particularly in the field of wireless communications. Users desire the ability to place real time telephone calls at anytime and from any location.

[0004] In addition to the various telephone-based communication services in common use, Internet-based communications provide users with system and service alternatives. For example, it is common for a typical Internet user to have at least one, and usually more than one, e-mail account, and various voice-over-the-Internet systems have been suggested. Services, such as e-mail forwarding, have also emerged for Internet-based systems. Capabilities in Internet-based systems, however, have not achieved the "anytime, anywhere" capability of wireless telephone communications, in part because a personal computer ("PC") provides the typical portal to the Internet. PC's are too bulky to provide "anytime, anywhere" access to the Internet, even in the laptop format.

[0005] Devices, such as handheld computers, personal digital assistants (PDA's), and wireless access protocol (WAP) devices could provide a platform for "anytime, anywhere" Internet access capability, but these devices create further difficulties for a user. Having multiple devices with multiple platforms requires a user to select among the available platforms and services. This could entail using a PC to access e-mails, a pager for messages, a telephone for voice mail, and a fax machine for faxes. Any one or more of these devices may not be available at a particular time. Additionally, the uncertainty of an intended receiver's access to these systems often causes a sender to send the same message over more than one of the systems. When the data is accessed from one platform, the message remains in the other systems. There is a need, therefore, for a system and method that provides a user the ability to seamlessly access messages and services from any available platform.

SUMMARY OF THE INVENTION

[0006] A communications system according to the principles of the invention provides for platform-independent

communication through multiple access points, and for the sending and receiving of various message formats (differentiated message data), such as e-mail, voice mail, and faxes, from various devices ("any device, any service" capability). For example, a user can obtain voice mail messages over a personal computer linked to the Internet, or can hear e-mail over a cellular telephone. The access points are any points in the communications system permitting access to the differentiated message data, including the Public Switch Telephone Network (PSTN) and the Internet. A message engine for processing and distributing the differentiated message data is provided.

[0007] A system according to the principles of the invention can also provide message synchronization of the differentiated message data. Message Synchronization includes storing message data (e-mail, voice mail, and fax) in more than one message repository. The message data can be accessed via multiple, differentiated access points, for example via an Internet Protocol Client (IP Client) or the PSTN. When a message is processed from any of these points, message attributes, such as message states, associated with the message repositories can be altered. Examples of message state attributes are "Delete", "Marked for Delete", "Read", and "Unread". When an attribute is changed via an access point, the changed attributes are reflected identically throughout the face of all access points in the communication system. The bodies of the repositories are also synchronized to reflect the message states. To the user, the system operates as a seamless, integrated communications system.

BRIEF DESCRIPTION OF THE DRAWINGS

[0008] A more complete understanding may be obtained from consideration of the following description in conjunction with the drawings in which:

[0009] FIG. 1 shows a block diagram of a system according to the principles of the invention;

[0010] FIG. 2 shows an exemplary architecture according to the principles of the invention;

[0011] FIG. 3 shows a block diagram of a message engine according to the principles of the invention;

[0012] FIG. 4 shows submodules of the message engine shown in FIG. 3;

[0013] FIG. 5 shows a diagram of a network according to the principles of the invention;

[0014] FIG. 6 illustrates an exemplary architecture for message synchronization and relay service according to the principles of the invention;

[0015] FIG. 7 illustrates process flow for polling and retrieval and message synchronization according to the principles of the invention;

[0016] FIG. 8 illustrates an object architecture for a system carrying out the processes illustrated in FIG. 7; and

[0017] FIGS. 9A and 9B illustrate synchronization according to the principles of the invention.

DETAILED DESCRIPTION

[0018] A communications system according to the principles of the invention provides for platform-independent

access to differentiated message data (“any device, any service”) and implements message synchronization across the platforms. Message synchronization provides for synchronized differentiated message data in more than one data repository. A message engine handles and distributes the message data, and a message synchronization engine synchronizes message data attributes, such as states, and the differentiated message data stored in the repositories. Exemplary interfacing through an IP client and through the PSTN will be described. A description of an exemplary message synchronization engine implemented with interfacing objects and processes is also provided.

[0019] A. Platform-Independent Communications System

[0020] A block diagram for an exemplary system 100 is shown in FIG. 1. The system 100 includes a Bridge 102, which interfaces with the PBX/PSTN 104 (Private Branch Exchange/Public Switched Telephone Network) and the Internet Protocol (IP) Network 106. The PBX/PSTN 104 provides access to the telephone system and related services, such as voice communications, fax transmission and paging. The Bridge 102 also interfaces with the IP Network 106, which can be accessed through wired and wireless systems, such as personal computers, Personal Digital Assistants (PDAs) and Wireless Access Protocol (WAP) devices. The IP Network 106 and the PBX/PSTN 104 are portals in the communications system 100. The Bridge 102 includes a message engine for distributing messages across these portals 104 and 106 and provides for platform-independent (“any device”) communication. For example, the Bridge 102 can process text e-mail data types so that they are available to a user accessing the system 100 via a telephone over the PSTN.

[0021] The Bridge 102 also provides for a platform-independent service (“any service”) capability. For example, in addition to telephone-based voice mail “Reply, Forward and Broadcast,” the Bridge 102 provides for Internet Protocol (IP) “Reply, Forwarding, Broadcast” functions. A voice reply can be supplied as an attachment to e-mail. Forwarding can also be provided over the PSTN so that, for example, fax and e-mail can be forwarded to a fax machine. The Bridge 102 also provides for notification of new messages, such as voice, e-mail and fax, to cell phones, pagers and e-mail, using Short Message Services (SMS) messages, Short Messages Peer to Peer Protocol (SMPP) and Simple Network Paging Protocol (SNPP). The Internet portal can provide voice messages, fax messages, e-mail notifications, and PSTN forwarding to fax machines. In this respect, a communications system according to the principles of the invention is an integrated, platform-independent system providing “any device, any service” capability.

[0022] FIG. 2 shows an exemplary architecture 200 for implementing the system 100 of FIG. 1, including a message engine 220. The exemplary message engine 220 can be implemented with an architecture of clustered, load-balanced, redundant modular servers. The IP and PSTN interfaces are shown as lines 202 and 204. The message engine 220 processes differentiated message data and provides message services, as will be explained hereafter. The message engine 220 communicates with an e-mail server 210, a Wireless Access Protocol (WAP) Server 212, a WEB Server 214, and a Voice Over IP (VoIP) Gateway 218. A message store database 208 stores differentiated message data for the

message engine 220. The message engine 220 can also communicate with devices over an SS7 Network 216. WAP devices 222, wired telephones and faxes 229, and e-mail clients 228 can access the message engine.

[0023] A block diagram 300 of the message engine 220 of FIG. 2 is shown in FIG. 3. The message engine 300 acts as an access point for incoming and outgoing messages, and synchronizes differentiated message data and message states so that access through any IP or PSTN portal device is uniform. In this embodiment, the message engine 300 includes a Session/Security server 302, a PRS server 304, a Notification server 306, a Media Conversion server 308, a PSTN server 310, an E-mail Filtering server 312 and an E-mail Pre-Processing server 314. The Session/Security server 302 manages all client sessions. Security can be provided via a subscriber service interface (SSI) protocol, which controls client authentication and authorization of services.

[0024] As will be explained more fully hereafter, the PRS server 304 synchronizes all PSTN and IP message types using polling and triggers to retrieve e-mail from the e-mail server, such as the e-mail server 210 of FIG. 2. Retrieved e-mails are stored in a message storage database, such as the database 208 shown in FIG. 2. The PRS server 304 can also retrieve other data types, such as voice mail and fax types, for the message storage database.

[0025] The E-mail Filtering server 312 acts as an e-mail filter to select or reject e-mails according to user preferences. Accepted e-mails are processed by the E-mail Pre-Processing module 314, which parses the mail and makes selective substitutions for e-mail by phone services. For example, text such as “A T and T” can be substituted for “ATT” so that the speech acquisition of text data types makes sense to the user. The Media Conversion server 308 digitizes and compresses voice messages and assembles telephone data types, such as voice and fax, into IP packets. This server 308 can also invoke the Text-to-Speech Engine (TTS) (not shown) to translate e-mail for e-mail by phone services. The TTS Engine stores the audio file in the message storage database. An exemplary TTS Engine suitable for this purpose is ETI-ELOQUENCE by ELOQUENT Technology, Inc.

[0026] The Notification server 306 provides the notification messages for new voice, fax and e-mail messages. These notifications can be sent to various devices, such as cell phones via Short Message Peer to Peer Protocol (SMPP), which is an input method into wireless systems for Short Messaging Services (SMS) Messages. The Notification server 306 can message pagers using the Simple Network Paging Protocol (SNPP) and e-mail accounts via the IP.

[0027] The PSTN Voice/Fax server 310 provides for receiving voice and fax data types and storing them using the message store database, and provides the ability to interface with the IP and PSTN. It includes five submodules, as shown in FIG. 4. The SMTP (IP) Interface Module 402 sends, forwards and broadcasts voice and fax messages to the appropriate e-mail account via the IP Network. The messages can be sent as e-mail attachments. The Voice Module 404 receives voice message data and stores the voice messages on the message store database, retrieves voice messages from the data store, and then plays the messages through the PSTN/IO Access Module 410. Likewise, the Fax

Module **406** receives fax messages, stores fax messages, and can retrieve stored fax messages and process them (send, forward, broadcast) over the PSTN/IO **410**. The E-mail-By-Phone Module **408** is a speech engine that plays TTS voice files to clients via the PSTN, and provides the ability to respond with a voice recording attachment sent by e-mail.

[0028] Referring again to **FIG. 3**, the database access module **320** provides the message engine **300** access to databases for storing, for example, user account information, service transactions, and status data. It also provides access to the message store database, such as the database **202** shown in **FIG. 2**, which stores differentiated message data. The message store permits access to, and storage of, voice-mails, faxes, audio e-mail (TTS) and data used for the telephone. The serverlet for Web-based Administration **326** provides for HTTP/HTTPS-based user account set up and management and HTTP/HTTPS system administration and management.

[0029] The remaining functional blocks provide the various interfaces between the message engine and the IP and PSTN. The VoIP interface module **324** provides the VOIP gateway. The module is H323, SIP, and MGCP compliant. The WAP interface module **322** is standards compliant and interfaces to third-party WAP gateways. The SS7 module **318** is a full PSTN interface providing network services, wireless services and call routing. The Simplified Message Desk Interface (SMDI) **316** provides the PBX signaling interface.

[0030] **FIG. 5** is a network diagram illustrating interfacing of the Bridge **502**, which includes the message engine, with the PBX/PSTN and with existing e-mail servers according to the principles of the invention. The Bridge interfaces with the PBX/PSTN **504**, which provides access to fax **506** and telephone **508**. The IP network cloud **522** is shown coupled to two e-mail servers and a Java client **516**. For one e-mail server **510**, the IP network is connected to a firewall **512** via a router **514**. The firewall provides access to the e-mail server **510**. The other e-mail server **521** is also accessed through a firewall **520** and a router **518**. The Java client is connected both to the e-mail servers and to the Bridge. It connects to the e-mail servers using POP3 or IMAP-4 protocols, and to the Bridge through a subscriber service interface. The Bridge **502** is addressed through a static IP address. It connects to the e-mail servers using the POP3 and IMAP-4 protocols, and it connects to the Java client **516** using a subscriber service interface. Ports are provided for sending or receiving the required information.

[0031] The Java client provides platform-independent access to the Bridge **502**, and to the e-mail servers **510** and **522**. An example of a POP3, IMAP-4 compliant Java client of the type suitable for this purpose is FreeCom^{3G} by CyberTel, Inc. This Java client can provide all in one E-mail, Voice-mail and fax capability via the Bridge **502**. It should be apparent, however, that other clients can be supported.

[0032] B. Message Synchronization

[0033] **FIG. 6** shows an exemplary PRS server architecture **600** for the message synchronization and relay functionality that can be used in a communication system according to the principles of the invention, and that can be implemented in, for example, the PRS server **304** of **FIG. 3**. Message synchronization provides for synchronizing the

differentiated message data types, such as e-mail, voice mail and fax, that are stored in the multiple message repositories. The PRS server **600** synchronizes the states of sent and received messages so that changed message states are reflected identically throughout the face of access points in the system and throughout the data repositories in the system. Data synchronization is supported on a request basis. All access points have trigger mechanisms available in a waiting state and are enabled with a server socket. Once a request is created by the access point and sent to its corresponding trigger mechanism, synchronization is activated for that user. When synchronization is activated, the data repositories are updated to reflect the identical data states.

[0034] The exemplary PRS server **600** of **FIG. 6** is a multi-threaded server composed of a data retrieval agent **602**, a data compare agent **604** and a data deletion agent **606**. Threads are grouped and pooled for efficient usage of allocated resources. The data retrieval agent **602** complies with POP3 protocol for Internet style mail, but can be fitted with other agents to comply with other protocols for retrieving structured data. The data compare agent **604** compares data attributes and generates lists of synchronized data. The data deletion agent **606** also complies with POP3 protocol for deleting Internet style mail, but can be fitted to comply with other protocols to delete other types of structured data.

[0035] To facilitate message synchronization, the messages are homogenized and provided with superficial attributes. Homogenization of messages means that all data types are expressed in a single message format, and can be carried out with a suitable SMTP agent. In a system such as the system of **FIG. 2** implementing the PRS server **600** of **FIG. 6**, the differentiated data types are homogenized as POP3 compliant, Internet style e-mail. Non-mail messages, such as voice and fax, are converted to e-mail messages in the e-mail server by attaching the messages to an e-mail, although homogenization could take place elsewhere in the system. The homogenized messages are then given superficial attributes, such as READ, UNREAD, MARKED FOR DELETE, and DELETE. The POP3 format remains unaltered. The attributes permit the messages to be synchronized from a common anchor point.

[0036] The PRS server provides for three event-triggered synchronization scenarios. **FIG. 7** shows a process flow **700** for Compare/Retrieve, Delete and Retrieve synchronization. To reduce latency in the system the PRS server also provides for continuous polling and message retrieval. Message flow for synchronization is explained with reference to the message flow diagram **700** of **FIG. 7**. The diagram **700** indicates message flow and events among selected servers, agents and clients of the overall system, an example of which is shown in **FIG. 2**.

1. Synchronization-Compare/Retrieve

[0037] Compare and retrieve synchronization involves the SCS server **702**, a mail server **706**, a database **708**, the PRS server **718**, and the PSTN server **710**. The mail server **706** and the database **708** store lists of mail messages that may require synchronization. The database **708** is the repository for the message engine. The mail data includes superficial attributes (such as for indicating states). A mail client **704** communicates with the SCS server **702**. The PRS server **718**

includes the compare 724, delete 722 and retrieve 720 agents. The Internet 723 is accessed via the mail server 706 and the SMTP agent 714.

[0038] Compare and retrieve synchronization works like this. The mail client 704 logs on, logs off, or requests to send or receive a message. The SCS server 702 receives the request, and requests the mail server 706 to download all new messages to the SCS server 702, where they are temporarily stored. The SCS server 702 then sends a trigger event to the compare agent 724. In response to the trigger event, the compare agent 724 retrieves the list of messages on the database 708, compares the list to the list retrieved by the SCS server 702 from the mail server 706, and generates a new synchronized list. The synchronized list reflects messages with synchronized states. The compare agent 724 sends the new list to the SCS server 702, which provides the list to the mail client 704. The mail client 704 updates its local list from the new list. The retrieve agent 720 receives a trigger event from the compare agent 724, and then retrieves all new messages from the mail server 706 and writes the messages to the database. At the end of this processing, the mail server, mail client, and database have synchronized mail messages.

2. Synchronization Delete

[0039] Still referring to the flow diagram 700 of FIG. 7, synchronization after a DELETE request is explained. In this example, the user requests to delete a message from the database 708 via the PSTN server 710, although other methods of accessing the database can be implemented. The delete request invokes a trigger to the delete agent to synchronize newly deleted messages. The delete agent 722 retrieves messages having a message state of delete from the database 708, and instructs the mail server 706 to delete all messages marked for delete from the server 706. When the message records are successfully deleted from the mail server 706, the corresponding records are deleted from the database.

3. Synchronization Retrieve

[0040] Retrieve synchronization is invoked when a new message is left for a user. In this example of retrieval synchronization, a message, such as a voice or fax message, is left via the PSTN server 710. The voice or fax file is sent to the SMTP agent 714 for sending, and the SMTP agent 714 composes an Internet style message that includes the voice or fax message as an attachment. The message is sent via the Internet 722 to the POP3 compliant mail server 706. The SMTP agent 714 initiates a trigger to the retrieve agent 720, which retrieves all new messages from the mail server 706. The retrieve agent 720 writes all the new messages to the database 708, synchronizing the mail server 706 and the database 708.

4. Continuous Polling and Retrieval

[0041] In addition to the trigger-invoked retrieval discussed above, the PRS server 718 also implements polling based retrieval. The polling/retrieve routine causes the synchronization agent to inquire of client e-mail accounts or other message data repositories to determine whether any changes have occurred to these databases. Without polling, saving messages to the database 708 would rely on triggers. Using polling, if new messages are present, the synchronization agent retrieves the message and deposits it in a data

repository, such as the message database 708. Polling and retrieving messages periodically reduce latency caused by the transfer of large amounts of messages produced when synchronization is triggered.

5. List Comparison

[0042] Message synchronization according to the principles of the invention is further illustrated with reference to FIGS. 9A and 9B as well as FIG. 7. In an exemplary embodiment, a trigger event for the compare agent 724 is the passing of one of two sets of parameters. The first set 900 of FIG. 9A includes two lists. The first is a data list 902 representing all of the required message data from some mail server, and the second 904 is a data list representing all of the required message data from a database, such as a message store database. The mail server data list 902 is an ordered list (reflecting the exact order kept in the mail server), which contains unique message IDs (UIDs) 906 that have been generated by the mail server. The database list 904 is an ordered list and also contains the same unique message IDs (UIDs) 906 that have been generated by the mail server, unique message IDs 908 that have been generated by the database (unique sequence number), as well as an additional character 910. This character is a superficial attribute added to all messages indicating the current state of the corresponding message. Possible message states are as follows:

[0043] D=Delete

[0044] M=Marked For Delete

[0045] R=Read

[0046] U=Unread

[0047] Since both lists 902 and 904 are ordered, comparisons can be made efficiently by simply comparing the values from matching indices, as indicated by arrows 912. If UID values do not match, as at 914, the compare agent recognizes that this message has been deleted from the mail server and responds by removing the corresponding element from the database list, as shown in the synchronized list 920. In the synchronized list 920, message 2 of the database list has been deleted. In the scope of message deletion, message records in the database cannot be deleted unless the corresponding message has been deleted from the mail server first. This rule allows the compare agent to be assured that if two UIDs being compared from both lists do not match, that the message represented by the UID in the database list has been deleted from the mail server.

[0048] While iterating through both lists, the compare agent will also detect for message states of 'D' in the database list. If a 'D' is encountered it is evidence that the corresponding message has been requested for deletion. For each state of 'D' that is found, the compare agent passes the corresponding UID and sequence index number to the deletion agent which first deletes the message from the mail server, and then deletes the corresponding record from the database. Once iteration of these lists is complete, all deleted messages should no longer exist, either in the mail server, or the database.

[0049] The lists 936 and 938 in FIG. 9B illustrate operation of the compare agent when passed the second set of parameters. The first list 936 represents a data list from a client, while the second represents a data list 938 from the message database. The client data list 936 is an ordered list

(reflecting the order kept in the mail server), which contains unique message IDs (UIDs) **940** that have been generated by the mail server and an additional character **942** representing the current state of the corresponding message ('D', 'M', 'R', 'U'). The database list **938** has the structure, content, and format of the database list **904** of **FIG. 9A**.

[0050] The ordered nature of these lists allows for the comparison of matching/non-matching values by indices. During the iterative comparison between the lists, the compare agent conducts a conditional two-phase assessment and generates a new, synchronized list **950** that will be returned to the client, and used to update all client messages. The first phase is a check for matching UIDs, as indicated by arrow **952**. If two UIDs are found to match, the compare agent enters the second phase assessment, which compares the message states from both lists, as at **954**. In comparing message states, if message states differ, whichever state takes precedence will be the state that is added to the newly generated synchronized list. The precedence in this embodiment is D>M>R>U, where D has highest precedence. This synchronization is reflected in the synchronized list **950**.

[0051] Referring now to **FIGS. 9A and 9B**, since the client can only mark a message as 'D' (not physically delete the message), the compare agent is guaranteed to register this message and its last known state/state change from the client. Contrary to this, the management of the database list allows for the complete physical deletion of message records, which can only be triggered by one of the three following events:

[0052] 1) Formal request.

[0053] 2) A message state of 'D' is detected while iterating the client data list.

[0054] 3) A non-matching UID is detected while iterating through the mail server data list.

This delete methodology allows one list (database list) to be the single anchor point of reference for synchronizing message states.

C. Object Architecture for PRS Server

[0055] **FIG. 8** illustrates the object architecture **800** for an exemplary PRS server **802** that carries out the synchronization and polling/synchronization processes according to the principles of the invention. The architecture **800** can be used in the PRS server of the message engine **300** of **FIG. 3**. Where references are made to entities external to the PRS server architecture **800**, such as the message store database, the mail client, and the mail server, reference can be had to the description of these entities in the discussion of **FIG. 2**. Additionally, the interaction of the compare **806**, delete **808** and retrieval **810** agents with the objects in an exemplary system was described with reference to the process flow diagram **700** of **FIG. 7**.

[0056] The object architecture **800** includes the message synchronization core **804**, which provides the compare, delete and retrieval functions. The compare agent **806** compares a list of message states (attributes) from a message store database to a list of message states in a mail client. If a message in one list has a state that takes precedence over a state in the other list, the compare agent **806** updates the message state. An exemplary message state precedence can be, in order of decreasing precedence, DELETE, MARKED

FOR DELETE, READ, and UNREAD. This means that when comparing the states of two messages from, for example, a mail client and the message database, the compare agent will give precedence to DELETE over MARKED FOR DELETE, READ or UNREAD and so on.

[0057] At the end of the compare process, both message state lists should be the same, and the message state lists are sent back to their respective origin to update the messages. The delete agent **808** looks for DELETE states in the list of message states in the message store database, and generates a list of references to the identified messages. The delete agent **808** then deletes the referenced messages from the mail client and the message store database. The retrieval agent **810** retrieves all new messages from the mail server, generates UNREAD states for each, and saves a copy of the message to the message store database.

[0058] Also included in the message synchronization core **804** are agents for providing session locking. Session locking prohibits multiple message retrieval processes (from different points of entry to the unified system) from writing data to a message repository more than once. These agents include bit arrays acting as a message store account registry **812**, a mail client account registry **814**, and a PSTN account registry **816**. These registries function as locking mechanisms for each session, such as a retrieval session. When a request for synchronization occurs, the registries are checked to determine if a lock (in the bit set) is activated (set to 1). In this manner, the point of access agent **818** communicates with the registries to provide mutually exclusive locking and unlocking. When an action, such as a write, is requested, the POA agent **818** checks the account registries to determine whether a session is underway. If so, the POA agent **818** locks the request out from the compare, delete and retrieve agents. Otherwise, the POA agent unlocks the agents that carry out synchronization. After processing a request for synchronization, the corresponding lock is deactivated (set to 0).

[0059] The remaining agents in the architecture **800** provide communication, control and configuration functionality. The mail server transaction agent **820** and the message store transaction agent **822** manage and execute reads, writes and updates to one or more mail servers and one or more message store database servers, respectively. The external communications agent **824** and the internal communications agent **826** support inter-process and intra-process communications. These agents **824** and **826** can be socket-based communications agents, can implement proprietary communications protocols for security, and give a common context to running processes. This allows for servers and agents to notify other dependent servers or agents of possible failures, successes, need for resources or other messages expedient to processing.

[0060] The timer agent **828** controls the invocation of each multiple account message retrieval session based upon specified time intervals. The configuration agent **830** configures configuration parameters. The event agent **832** handles errors and exceptions in the server. For example, the event agent **832** formats errors and writes them to a log file.

[0061] An exemplary object table for a PRS server according to the invention is provided below:

PRS SERVER/OBJECT TABLE	
ccTimer	Establishes a time interval for polling and initiates multiple message retrieval process.
ccINIT	Connects to database to retrieve user account(s) information. Initializes user data for single account retrieval. Initializes user data for multiple account retrieval.
ccMRA	Manages message retrieval thread pool(s). Creates thread for single/multi user message retrieval. Supports multiple encoding/character set messages. Implements message notification services. Determines message type (e-mail, voice, and fax). Writes all retrieved messages to database server.
ccCOMM_PRS	Establishes multi-threaded listener socket for clients. Processes client requests - delegating tasks. Coordinates protocol parsing.
ccSYNC	Implements parser for protocol authentication. Accepts client requests for synchronizing messages. Creates and compares message state lists for sync. Deletes messages from database for synchronization. Deletes messages from e-mail server for synchronization. Distributes updated message state list for continuity.
ccMSOBJ	Establishes e-mail server connectivity Proxy for all e-mail server specific requests. Shared object.
ccDBOBJ	Establishes database server connectivity. Proxy for all database server specific requests. Shared object.
ccEVENTS	Shared object - open for all agents. Creates log file. Responsible for logging all events, errors, exceptions.
ccCONFIG	Creates configuration file with user defined values. Used to read server parameters from configuration file. Supports on-the-fly parameter value.
ccSHUTDOWN	Analyzes current PRS processes/threads. Locks communication layer from further client requests. Terminates all server processes.

[0062] The software configuration for synchronization according to the principles of the invention can include a JAVA Virtual Machine. The user's e-Mail servers should include an SMTP Server address and an IMAP-4 or POP3 Server address. In view of the foregoing description, numerous modifications and alternative embodiments of the invention will be apparent to those skilled in the art. Accordingly, this description is to be construed as illustrative only and is for the purpose of teaching those skilled in the art the best mode of carrying out the invention. Details of the structure may be varied substantially without departing from the spirit

of the invention, and the exclusive use of all modifications, which come within the scope of the appended claim, is reserved.

What is claimed is:

1. A communications system comprising:

a message engine adapted to handle differentiated message data, the message data having assignable attributes;

at least one access to the differentiated message data; and
repositories for storing the differentiated message data, wherein the message engine includes a synchronization engine for synchronizing the differentiated message data according to the attributes.

2. The communications system according to claim 1 wherein the differentiated message data includes a plurality of message data types.

3. The communications system of claim 1 wherein the at least one access includes a trigger mechanism for activating the synchronization engine.

4. The communications system of claim 1 wherein the synchronization engine includes:

a retrieval agent for retrieving ones of the differentiated message data from ones of the repositories and writing the ones of the differentiated message data to other ones of the repositories;

a compare agent for comparing the differentiated message data stored in the repositories and for generating a synchronized list of the differentiated message data according to the attributes; and

a delete agent for retrieving messages marked for delete and for causing deletion of the messages.

5. The system according to claim 1 wherein the synchronization engine is operable to poll at least one of the repositories for a change and to change at least another of the repositories to reflect the change.

6. The system according to claim 1 further comprising a client operable to request a message engine event, the message engine event triggering the synchronization engine to implement a synchronization event.

7. The system according to claim 1 further comprising an agent operable to homogenize the differentiated message data, the differentiated message data being of one data type.

8. A communications system comprising:

a mail server operable to process messages;

a client operable to process the messages;

a session server in communication with the client and operable to upload and download messages from the mail server;

a PSTN server operable to receive messages delivered via the PSTN;

an SMTP agent operable to receive messages from the PSTN server and to send messages to the mail server;

a message store database operable to receive-messages from the mail server; and

a synchronization server operable to synchronize messages among the mail server, the client and the message store database.

9. The communications system according to claim 8 wherein the synchronization server includes a compare agent and a retrieve agent,

wherein, in response to at least one designated event, the session server receives unread messages from the mail server,

the compare agent

compares the unread messages in the session server with the messages stored in the message store database,

generates a synchronized message list, and

sends the synchronized message list to the session server,

the session server sends the synchronized message list to the client,

the client updates messages according to the list, and

the retrieve agent retrieves the unread messages and writes the unread messages to the message store database.

10. The system according to claim 8 wherein the synchronization server includes a delete agent which, in response to a request from the PSTN server to delete a message from the message store database, deletes corresponding messages from the mail server.

11. The system according to claim 8 wherein the synchronization server includes a retrieve agent, which, in response to a new message delivered via the PSTN server and the SMTP agent to the mail server, retrieves the new message and writes the new message to the message store database.

12. A method for providing access to differentiated message data stored in a plurality of data stores, comprising the steps of:

assigning attributes to ones of the differentiated message data, the attributes having a precedence;

maintaining lists corresponding to the message data stored in ones of the data stores, the lists including the attributes assigned to the ones of the differentiated message data;

in response to a trigger event, comparing ones of the lists; providing a synchronized list according to the attributes; and

updating ones of the data stores according to the synchronized list.

13. The method of claim 12 wherein the attributes comprise states of the differentiated message data.

14. The method of claim 13 wherein the precedence comprises Delete>Marked for Delete>Read>Unread.

15. The method of claim 12 wherein the lists further comprise message data identifiers, the data stores include at least a first data store and a second data store and the lists include a first ordered list corresponding to the message data stored in the first data store and a second ordered list corresponding to the message data stored in the second data store, the comparing step including the step of comparing the first ordered list and the second ordered list.

16. The method of claim 15 wherein the step of providing the synchronized list includes the step of excluding message data corresponding to message data identifiers in the second ordered lists that are not in the first ordered list.

17. The method of claim 12 wherein at least one of the data stores comprises a mail server, the method comprising the further step of providing access to the mail server via the Internet and via the PSTN.

18. The method of claim 17 wherein and at least a second of the data stores comprises a message store data base, the method comprising the further step of providing access to the message store data base via the Internet and via the PSTN.

19. The method of claim 12 comprising the further step of homogenizing the message data.

20. The method of claim 19 wherein the homogenizing step includes the step of generating the differentiated message data in one data type.

21. The method of claim 20 wherein the one data type is an e-mail data type.
