(57) **ABSTRACT**

A software engine for decomposing work to be done into tasks, and distributing the tasks to multiple, independent CPUs for execution is described. The engine utilizes dynamic code generation, with run-time specialization of variables, to achieve high performance. Problems are decomposed according to methods that enhance parallel CPU operation, and provide better opportunities for specialization and optimization of dynamically generated code. A specific application of this engine, a software three dimensional (3D) graphical image renderer, is described.

GENERAL PURPOSE SOFTWARE PARALLEL TASK ENGINE

CROSS-REFERENCE TO RELATED APPLICATIONS

[0001] This application is a continuation of U.S. patent application Ser. No. 13/597,403, filed on Aug. 29, 2012, which is a continuation of U.S. Pat. No. 8,284,206, filed on Mar. 14, 2007, which claims the benefit of provisional of U.S. Patent Application No. 60/781,961, filed on Mar. 14, 2006, the disclosures of which are hereby incorporated by reference.

FIELD

[0002] The present description relates to the field of parallel processing of tasks in computer system. The description also relates to the field of software 3D image rendering.

BACKGROUND

[0003] Parallel Processing. Using multiple computer CPUs simultaneously or in parallel, to solve a single problem, or execute a single program, and by doing so, reducing the time required, is an old and well-studied idea. In fact parallel processing is an entire sub-discipline of computer science. Any system for accomplishing parallel solution of a problem or execution of a program has two components: A 'problem decomposition' strategy or scheme or method, or combination of methods, and an execution vehicle or machine or system. In other words, the problem must be broken down into multiple parts, and then these parts must be distributed to and executed by the multiple CPUs. Problems can sometimes be broken down into parts that are independent, which may be pursued completely in parallel, with no interaction between, or no specific ordering of, sub-programs to be executed on the CPUs required. Sometimes problem decompositions have inter-dependent parts, implicit in the problem, or created by the decomposition.

[0004] Problem decomposition methods can be sorted into two large categories: decomposition by domain, where the function to be performed remains the same, and the data to be processed is distributed to multiple CPUs, and decomposition by function, where the work to be done on each datum is broken up into sub-functions, and each CPU is responsible for performing its sub-function on all the data. Both types of decomposition can be achieved through two major means—implicit or problem-aware, specific, ad hoc means, built into the system, or 'algorithmic decomposition'. In algorithmic decomposition, the original program, or a representation of that program, which encapsulates the single-CPU, sequential semantics of a solution to the problem, is decomposed into multiple programs. Most interesting problem decompositions are a combination of both types of decomposition, using elements of both means of decomposition. The resulting CPU sub-programs may be completely independent, or 'perfectly parallel', or they may be organized into successive, overlapping, sub-functional stages, as in an assembly line or 'pipeline', or there may be any number of dependencies and independences, in any sort of dependency graph.

[0005] Systems of parallel execution of the sub-programs can be classified in terms of their similarity to two opposing models—those that have a central, master unit directing the flow of work, and those that are modeled as a de-centralized

network of independent processors. Of course, many systems lie on the line somewhere in between these polar extremes.

[0006] As stated above, the field of parallel processing is rich in research, and there is much prior art. However there is as yet no general solution for all problems, and every parallel processing system is better at some sorts of problems than others. There are yet many problems with unexploited potential for parallelism, and many improvements may be made to parallel processing systems for different classes of problems.

[0007] Dynamic Code Generation. 'Dynamic code generation' is a technique whereby code is compiled or prepared for execution dynamically, by a program which will need to call or invoke it. This code is often created at the last possible moment, or 'just-in-time'. If the code is created only when it is about to be used, it will not be generated if it is never used, and this can represent savings in compilation time and program space. After compilation, the new routine can be retained, or cached, in case it is needed again. The required routine may be called under a particular set of prevailing conditions or with specific arguments that suggest a simpler, more efficient, custom compilation unique to that invocation or set of conditions. In that case, the dynamic compiler might create a special version of the code to be used only under those conditions or with a similar invocation. Dynamic compilation may also allow superior general-purpose optimizations due to facts unknown at the time the program in question was specified, but known at the time of execution.

[0008] Dynamic code generation has often been used in environments where there is no obvious 'program' to be compiled, where a fixed function is replaced by a run-time generated, run-time specialized and optimized routine, in order to gain improved performance over statically compiled, necessarily general code. Because the 'program' is often not represented in formal semantic terms, or is represented only by the previously compiled, machine code for the function to be replaced, and because of the need to produce new code quickly in a run-time environment, dynamic code generators and optimizers are frequently simple affairs, exploiting high-leverage, problem-aware ad hoc methods or tricks to achieve their ends. In this case, the more high-leverage, informal or implicit, problem-specific information that can be imparted to these code generators, the better they can potentially perform.

[0009] One application in which parallel processing and dynamic code generation may be combined is a three-dimensional graphical image rendering system, or 'graphics pipeline'.

[0010] Definition of Graphics Pipeline. Three dimensional (3D) computer graphics display programs simulate, on a two dimensional display, the effect that the display is a window into a three dimensional scene. This scene can contain multiple 3D objects, at different apparent distances from the window, and the window has a viewpoint or camera angle with respect to the scene and its objects. Objects can be colored and textured, and the objects can seem to be illuminated by light sources of different types and color.

[0011] A software program that models and displays 3D objects can be divided into two parts: an 'application program' which relies on a set of high-level functions to manipulate and display graphical data, and a graphics software library that provides these functions

[0012] 3D objects consist of geometric shapes, at certain positions in the 3D world, with certain properties or attributes. These objects are defined and maintained by the

application program, as a collection of geometric primitives, and then these primitives are defined and described to the graphics library, which draws, or renders them onto the two dimensional (2D) display, with all necessary positioning, orientation, perspective scaling, coloring, texturing, lighting, or shading effects performed on each primitive as it appears in the window view. This represents a series of processing steps on geometric primitives and their component data, as they progress from spatial coordinate and attribute definition to final 2D picture element (pixel) form on the screen. A software and hardware system that accomplishes this drawing of geometric primitives is called an image renderer, or a rendering 'engine', and the series of processing stages used is termed the 'graphics pipeline'.

[0013] Definition of terms, description of pipeline processing stages. FIG. 1 shows a generic graphics pipeline 100 for a rendering engine according to the prior art. Different renderers support different options and features, and use various techniques to perform the required processing at each stage. Operations and stages can also be, explicitly or implicitly, performed in different orders in different implementations, while preserving the same apparent rendering model. Stages or portions of stages may be performed to varying degrees by either software or hardware. There are also many different groupings or organizations of the component operations into pipeline stages for the purposes of exposition, and the terminology in the art is not uniform from one implementation to another.

[0014] The following definitions are used in the descriptions of the graphics pipelines below:

[0015] Primitive: a collection of points in 3D space forming a point, a line, a triangle, or other polygon, with associated properties.

[0016] Vertex: one of the points defining a primitive.

[0017] Object: a collection of primitives.

[0018] Normal: for a point on the surface of a primitive, a vector defined to be normal or perpendicular to the surface of the primitive at that point.

[0019] Model space: a 3D coordinate space in which an individual object is defined, apart from a 3D scene in which it may be placed.

[0020] World space: the coordinate space of the 3D scene.

[0021] Viewport or Camera: the window, with its associated orientation, position and perspective relative to the scene, through which the 3D scene is apparently being viewed.

[0022] View space: the coordinate space of the 3D scene, as seen from the viewpoint of the camera.

[0023] Face: a planar polygon in an object, either front-facing (toward the camera), or back-facing (away from the camera).

[0024] Model Transformation: scaling and placing an object in the scene, transforming its vertex coordinates from model space to world space.

[0025] Viewing transformation: translating (moving, positioning), and rotating (orienting) vertices to account for viewing position and orientation with respect to the scene, transforming vertex coordinates from world space to view space.

[0026] Material: light reflectivity properties.

[0027] Texture, or texture map: an image, which may be designed to visually mimic the surface properties of a physical material.

[0028] Lighting: the interaction of light sources of different types and colors, with colors and materials and textures, at vertices.

[0029] Primitive assembly: determining primitives as defined by the application, and gathering their component vertex coordinates and attributes, in preparation for further processing.

[0030] Clipping: removing primitives or portions of primitives which are not visible, or fall 'outside' the field and depth of view of the viewport.

[0031] Projection Transformation: creating the 2D projection of points in view space, onto the plane of the viewport or "film" of the camera, transforming spatial coordinates of vertices to 2D display locations and depths.

[0032] Culling: removing (deciding not to render) a face of a polygon.

[0033] Vertex Processing: vertex coordinate transformations, and lighting of vertices.

[0034] Frame buffer: a 2D memory array containing bit patterns encoded in a form which directly represents the colored dots or rectangles on the computer's hardware display screen.

[0035] Pixel: a single colored picture element (dot or rectangle) in the frame buffer.

[0036] Fragment or pre-pixel: a single colored picture element, located in a 2D image corresponding to the frame buffer, before it is written to the display frame buffer.

[0037] Rasterize: to choose the fragments in the 2D projected image that correspond to the outline and/or interior of a primitive.

[0038] Shading, or Fragment Shading: determining the color of a fragment, taking into account vertex colors, lighting, and textures.

[0039] Buffer or Raster operations: raster (pixel) operations done on fragments after shading, as they are written to pixels in the frame buffer, or to determine whether or not they should be written, according to a number of tests.

[0040] Fragment processing: fragment shading and buffer operations on starting with fragments, and yielding pixels.

[0041] A detailed description of the stages in the pipeline of FIG. 1 follows:

[0042] Transform 102: All vertices are transformed from model space to world space, and then transformed to view space, i.e., translated and rotated correctly in order to account for the viewpoint.

[0043] Light 104: Vertices are lighted from different sources, and the resulting color is dependent on the source color and intensity, incidence angle of a directional source with the vertex's normal, distance of the source, the reflectivity of an associated material, and the original vertex color. If the primitive is a polygon, and a texture is to be applied to the face, texture map coordinates are assigned to the vertices.

[0044] Assemble 106: Vertices are assembled into primitives, as they have been defined by the application program.

[0045] Project 108: Primitives are clipped to conform to the field and depth of view, the 'viewing volume'. They are then projected, possibly with perspective, onto the plane of the viewport, yielding a 2D image, with each vertex position now represented as a 2D display location and a depth. Polygon faces to be culled are discarded, and not processed further.

[0046] Rasterize 110: Primitive fragments corresponding to outlines and interiors are identified in the 2D image. Anti-

aliasing', or modification of fragment colors at outlines of primitives in order to make the outline appear smoother, is done at this stage.

[0047] Shade 112: Primitive fragments are shaded, or colored, according to one of several possible methods, by either interpolating the colors at the vertices of the enclosing primitive or by interpolating from vertex normals and re-lighting the fragments individually. If a texture is to be applied, texture map coordinates are interpolated and assigned to each fragment, and the indicated texture color is mixed in to yield the shaded fragment color.

[0048] Buffer 114: As fragments are converted to pixels and written to the frame buffer, several tests are performed in order to determine whether or not they should be written, in order to allow displaying the image inside a stencil, or window, or rectangle. Hidden surface removal may also be done by recording the depth, or 'z' value of a pixel in a 'z-buffer', as the pixel is written to the 2D frame buffer. As new pixels are written to the frame buffer, their depth or z value is compared to the z-buffer value of the pixel previously written at that 2D location. If the new pixel is closer to the viewport, it is written, if it is further away than (behind) the old pixel, it is not written.

[0049] Pixel colors may also be blended with the color of pixels already in the frame buffer, depending on the opacity of those colors, in order to simulate transparency of nearer surfaces. Pixel colors may be 'dithered' or modified based on their near neighbors as a way of smoothing color transitions or simulating shades. Finally, source and destination pixels in the frame buffer may be combined according to one of several logical operations performed as part of the block transfer (BLT) to the frame buffer.

[0050] Another view of a graphics pipeline according to the prior art is seen in FIG. 2. In this pipeline 200, there are just three stages: 'Process Vertices' 202, 'Process Primitives' 204, and 'Process Fragments' 206. FIG. 1 'Transform' (model and view transformations) 102, and FIG. 1 'Light' 104 (lighting) are collapsed into FIG. 2 'Process Vertices' 202, yielding lighted, 3D position-transformed vertices. FIG. 2 'Process Primitives' 204 combines FIG. 1 'Assemble' 106 (primitive assembly), FIG. 1 'Project' 108 (clipping, projection, and culling), and FIG. 1 'Rasterize' 110 (rasterization) yielding visible fragments within the 2D image corresponding to primitive outlines and/or interiors. FIG. 2 'Process Fragments' 206 incorporates FIG. 1 'Shade' 112 (fragment shading and texture application to color fragments), and FIG. 1 'Buffer' 114 (raster or buffer operations), finally yielding pixels 116 in the frame buffer.

[0051] In typical practice, aspects of the 'Project' 108 computation may be split across vertex processing and primitive processing. All vertex position transformations, including those due to projection onto multiple depth 2D planes, can be done in 'Process Vertices', while those aspects of projection necessary for clipping and final mapping to the viewport are done in 'Process Primitives'. This may be done in order to group all like position transformations, involving matrix arithmetic on vertex vectors, into one phase. How parts of the logical graphics computations are actually effected in which stages is not of primary importance. More important is that each of the three large stages is concerned with processing associated with one major data type: either vertices, or primitives, or fragments.

[0052] Existing practice in graphics pipelines.

[0053] SIMD CPU instructions. Many computer CPUs now incorporate SIMD (single-instruction-multiple-data) types of instructions, which can perform certain single operations on multiple data at once. These instructions have been geared toward common low-level operations in the graphics pipeline, and software graphics library implementations can show dramatically improved performance through their use. It is important however, that the library organizes its computations so that data is available and staged accordingly, to take best advantage of these SIMD capabilities.

[0054] Multi-core CPUs. CPUs are now available with multiple instruction-processing cores, which may run independently of each other. If tasks in the graphics pipeline can be divided and scheduled so that many different operations can be done in parallel, independent threads of execution, this can provide a geometric speed increase over a single program that must perform all the operations in sequence. Multi-core techniques have heretofore seen limited application in software graphics pipeline implementations.

[0055] Hardware GPU functions. Many of the functions of a graphics pipeline can be performed by the hardware graphics processing unit, or GPU. GPUs support many fixed-functionality operations, and many also have the capability of running programs locally, independent of the computer CPU. Hardware GPU functions or GPU programs may be considerably faster than their main CPU software counterparts.

[0056] Shader Programs. 'Vertex shaders' or 'vertex programs', can optionally be supplied to the graphics library to perform some or all of the functions of vertex processing. Likewise, 'Fragment Shaders' or 'Pixel Shaders' can take over much of the job of fragment processing. These programs can be executed by the computer's CPU, or they may run in part or entirely on the hardware GPU. Several standards and languages exist for these vertex and fragment shader programs, which are then compiled for execution on CPU and/or GPU.

[0057] Programmable vertex and fragment processing allow flexibility and specialization in the performance of these operations, allowing new functionality, or higher performance. Support for programmable shaders is a required feature in several graphics library definitions, and many compatible implementations exist. However, the compilation of the shader program, the quality of the resulting code, and the use of CPU and GPU resources and their effects on performance, differ considerably from one implementation to another.

[0058] Dynamic code generation. Dynamic code generation is used in various ways in many aspects of existing fixed-function and programmable graphics pipelines, but generation and caching policies, language translation techniques and optimizations, and effectiveness and scope of utility vary with the implementation.

[0059] For example, in some graphics libraries, dynamic code generation is limited to the compilation of application-provided vertex and fragment programs. Or, if dynamic code is also used to accelerate fixed graphics pipeline functions, there may be some elements of the graphics pipeline implementation which must be implemented in a static fashion, or by separate dynamically created functions, to leave those stages 'open' for replacement by either application-provided or GPU-supported functions. The ideal case is to have all functions of the graphics pipeline supported by dynamically created code optimized for the specific CPU and GPU capabilities of the computer system.

SUMMARY

[0060] The description relates to the general prosecution of work on multiple, independent computer CPUs, and the

4

design of systems, methods, and policies, to accomplish that work efficiently, with respect to time and resources.

[0061]   One application of such systems is the task of rendering (drawing) to a computer display a three dimensional image represented by an abstract collection of graphical data, and the many processing steps required to appropriately reduce this data to a two dimensional color picture. The description addresses this application, as well as others.

[0062]   There is described a design for a software Parallel Task Engine which combines dynamic code generation for processing tasks with a scheme for distributing the tasks across multiple CPU cores. Dynamic code generation provides the best possible per-processor performance, and fully parallel execution provides the best use of multiple CPUs. However, when combined in the right way, the two techniques can have a beneficial 'multiplicative' effect as well—because the processing routines are created for certain sub-tasks of the larger problem or operate only on particular subsets of data, they can be even more specifically or efficiently coded than before, as they operate under more specific circumstances, or are less constrained by processor resources. The result is better performance than would be expected from the sum of the benefits of these two practices, applied independently—or in other words, a 'super-linear' acceleration when multiple CPUs are applied to the problem.

[0063]   Application to Graphics Processing. Methods of dynamic code generation can be used to create all the software routines necessary to execute the stages of a graphics pipeline. These routines can be more efficient than code that is statically compiled in advance, because they can take advantage of facts that are not known until the time of execution, and because they can be created specifically for the job at hand, and need not satisfy the full range of requirements that their interface and surrounding state might demand of a single, static routine.

[0064]   New computers have multiple, independent CPU cores that can execute software routines in parallel. The workload of a graphics processing task can be distributed across multiple CPUs, achieving performance acceleration that is linear with the number of CPU cores employed.

[0065]   When the parallel task engine is applied to the problem of graphics processing, in other words, configured as a graphics pipeline engine, it can provide dynamically generated code for all stages of computation, and exploit specific task decompositions that take best advantage of the strengths of dynamic code generation and multiple CPU resources applied to graphics processing, resulting in high speed image rendering.

[0066]   According to an embodiment, there is provided, in a computer system, a parallel task engine for performing tasks on data. The parallel task engine comprising: an input for receiving tasks; a scheduler for decomposing the tasks into one or more new tasks, the decomposing being dependent on at least one policy selected from a given set of policies; a run-time dynamic code generator for generating or locating, from the new tasks, operation routines; a set of job loops, at least one of the job loops for performing the new tasks on at least part of the data by executing the operation routines; the scheduler for distributing and assigning the new tasks to the at least one of the job loops; and the scheduler for making the selection of the at least one policy as a function of characteristics of the operation routines generated or located by the run-time dynamic code generator.

[0067]   According to an embodiment, there is provided, in a computer system, a method for performing tasks on data. The method comprises: receiving tasks; decomposing the tasks into one or more new tasks, the decomposing being dependent on at least one policy selected from a given set of policies; generating or locating, from the new tasks, operation routines; making the selection of the at least one policy as a function of characteristics of the operation routines generated or located by the run-time dynamic code generator; providing a set of job loops; distributing and assigning the new tasks to at least one of the job loops; and the at least one of the job loops performing the new tasks on at least part of the data by executing the operation routines.

BRIEF DESCRIPTION OF THE DRAWINGS

[0068]   Further features of the present application will become apparent from the following detailed description, taken in combination with the appended drawings, in which:

[0069]   FIG. 1 is flow diagram depicting a generic graphics pipeline according to the prior art;

[0070]   FIG. 2 is a flow diagram depicting another, simpler graphics pipeline organization according to the prior art;

[0071]   FIG. 3 is a block diagram depicting a parallel task engine according to an embodiment;

[0072]   FIG. 4 is a block diagram showing the composition of a job according to an embodiment;

[0073]   FIG. 5 is a block diagram showing the composition of a task according to an embodiment;

[0074]   FIG. 6 is a block diagram showing the composition of a command according to an embodiment;

[0075]   FIG. 7 is a block diagram showing the cache as a collection of entries, and the composition of those entries according to an embodiment

[0076]   FIG. 8 is a block diagram depicting the components of code generation according to an embodiment;

[0077]   FIG. 9 is a block diagram depicting task (problem) decomposition according to an embodiment;

[0078]   FIG. 10 is the source code for a routine which performs a full-datum matrix-vector multiplication with SSE3 instructions according to an embodiment;

[0079]   FIG. 11 is the source code for a routine which performs a half-datum matrix-vector multiplication with SSE3 instructions according to an embodiment

[0080]   FIG. 12 is the source code for a routine which performs a specialized half-datum matrix-vector multiplication with SSE3 instructions according to an embodiment;

[0081]   FIG. 13 is the source code for a routine which performs an optimal half-datum matrix-vector multiplication with SSE2 instructions according to an embodiment;

[0082]   FIG. 14 is the source code for a routine which performs a pipelined half-datum matrix-vector multiplication with SSE2 instructions according to an embodiment.

[0083]   FIG. 15 is a representation of a graphics pipeline consisting of multiple tasks being done by multiple programs, utilizing multiple stage units, according to an embodiment;

[0084]   FIG. 16 depicts the sub-stages of the primitive setup stage of the graphics processing pipeline according to an embodiment;

[0085]   FIG. 17 depicts the convex polygon outline rasterization algorithm according to an embodiment

[0086]   FIG. 18 depicts alternative approaches to construct polygons covering the fragments of line primitives according to an embodiment;

[0087] FIG. **19** is a flow chart depicting the Parallel Task Engine Main Program, according to an embodiment;

[0088] FIG. **20** is a flow chart depicting the Job Loop Program, according to an embodiment;

[0089] FIG. **21** is a flow chart depicting an alternative Parallel Task Engine Main Sub-program, according to an embodiment; and

[0090] FIG. **22** is a flow chart depicting an alternative Job Loop Program, according to an embodiment.

[0091] It will be noted that throughout description and the appended drawings, like features are identified by like names, e.g. "Command, "Task", "Job", and reference numerals direct the reader to the appropriate drawing to show the instance or aspect of the feature in the frame of reference of the discussion. For example, in the discussions below, 'input Task **302**' is a Task **500**, the structure of which is detailed in FIG. **5**, but in this reference, attention is directed to this specific Task in FIG. **3**. Sometimes the same instance of an element will be described with different reference numerals, in order to direct the reader's attention to different aspects of it or operations being performed on it. Numerals do not specify unique structures, nor do they specify the instance of an element being discussed. Elements with the same name have the same structure, and particular instances of elements are specified in the discussion explicitly.

DETAILED DESCRIPTION

[0092] Referring to FIG. **3**, a Parallel Task Engine **300** is an apparatus for performing Tasks **302** on arrays of Primary Data **306**. Primary Data **306** is data external to the apparatus. A Task **500** (see FIG. **5**) is a Command **510** and a collection of one or more Data Pointers **520**, which are POINTERS referencing Primary Data **306**. A POINTER is an address, index, or token that can be used to locate a single datum or an array of data, either directly or indirectly via one or more tables. A Command **600** (see FIG. **6**) is an Operation **610** and zero, one or more Parameters **620**. An Operation **610** is a value that indicates a specific function to be performed on the Primary Data **306** referenced by the Data Pointers **520**, and Parameters **620** are values that further specify the Operation **610**, for example, a number of data items to be processed.

[0093] Parallel Task Engine **300** is composed of:

[0094] 1. The current CONTEXT, which is a set of variables, or a POINTER to a set of variables, containing auxiliary data, modes and details of computations to be performed on the Primary Data **306** to be processed. The CONTEXT is only read by the Parallel Task Engine, and not written by it. CONTEXT variables are initialized and written by the external software entities that send Tasks **302** to the engine, the "users" of this engine. If the CONTEXT is a POINTER to a set of variables, it points to a set of variables maintained by, and the value of this POINTER is set by, external software entities.

[0095] 2. A Task input **303**, to receive input Tasks **302**.

[0096] 3. A Task Pool **310** of Tasks **500**, awaiting dispensation.

[0097] 4. One or more Job Loops **318**. In a typical embodiment, one Job Loop **318** will be allocated per CPU available for use by the Parallel Task Engine **300** in the dispensing of work. It is also possible to run more than one Job Loop **318** on a CPU, or to run a Job Loop **318** on a CPU also running other programs. The multiple CPUs, and the computer hardware, software, and operating facilities which allow a software system to establish programs running on multiple CPUs, are

those known to persons skilled in the art, and will vary from computer system to computer system. The Parallel Task Engine **300** assumes and utilizes these facilities in a particular way, setting up programs on CPUs as necessary in order to dispatch and accomplish Tasks **500**. The Job Loop **318** receives a Job **320**, from the Parallel Task Engine Main Program (not shown, but described in detail below). Now referring to FIGS. **4**, **5**, and **6**, a Job **400** is the combination of a Task **420** and a Code Pointer **410** to a routine which can execute an Operation **610**. When the Main Program assigns the Job **320** to the Job Loop **318**, the Job Loop **318** calls the Operation **610** routine, with Parameters **620**, via the Code Pointer **410**, in order to process the Primary Data **306** specified by the Task **420** via its Data Pointers **520** according to the Command **510** specified by the Task **420**. After the Operation **610** routine returns, the Job Loop **318** will wait to receive the next Job **320** from the Main Program.

[0098] 5. A Code Generator **314**, which is responsible for creating or finding Operation **610** routines, which perform Operations **610** on Primary Data **306**, under the current CONTEXT.

[0099] 6. A Cache **316**, detailed on FIG. **7** as Cache **700**, which is a Directory **710** composed of Entries **720**, and a Code Buffer **750**. The Entries **720** are composed of a Tag **730** to be matched, which consists of an Operation **732** and a Context **734**, and Data **740**, which is a Code Pointer **742** to a routine which performs the Operation **732**. A CONTEXT, as defined above, specifies the conditions under which Operations **610** are to be performed, or augments or modifies the meaning of Operations **610**, and thereby influences the generation of code to perform Operations **610**, or influences the execution of that code. The Context **734** accompanying the Operation **732** and the Code Pointer **742** to the Operation **732** routine in an Entry **720** is the specific CONTEXT that was current at the time the Operation **732** routine was created or located by the Code Generator **314**, and the Entry **720** was created. To find a routine in a Cache **700** to perform an Operation **610** under the current CONTEXT, it is necessary to match the specified Operation **610** and the current CONTEXT with the Tag **730** (Operation **732** and Context **734**) of an Entry **720**. The Code Buffer **750** is the repository for storage of Operation **610** routines created dynamically by the Code Generator **314**. How the Entries **720** in the Cache **316** Directory **710** are organized for lookup, via indexing, hashing, or sequential search is not essential to the present description. Likewise, when new Entries **720** are created, given that the Directory **710** is of fixed size, this will necessitate at times overwriting old Entries **720**. The policies for Entry **720** eviction in such cases are also considered to be implementation specific details.

[0100] 7. A Scheduler **312**, which when requested, surveys the Task Pool **310** of Tasks **500**, and determines the appropriate Task **500** to assign to a specified Job Loop **318**. The Scheduler **312** is responsible for decomposing Tasks **905** as necessary, maintains the Task Pool **310**, maintains a record of Tasks **500** in progress on the Job Loops **318**, and understands the dependencies between Tasks **500**.

[0101] 8. A Parallel Task Engine Main Program, which directs the operation of the engine, and communicates with the Job Loops **318**. The Main Program dispenses Jobs **320** to Job Loops **318**. The Main Program gets the Task **420** for the Job **320** from the Scheduler **312**, and looks up the Code Pointer **410** for the Job **320** by matching the Operation **610** in the Command **510** in the Task **420**, and the current CON-

TEXT, to the Tag **730** of an Entry **720** in the Directory **710** of the Cache **316**. If the proper Code Pointer **410** for the Operation **610** cannot be found in the Cache **316** Directory **710**, the Main Program calls the Code Generator **314** to create or find a suitable routine, and then creates a Directory **710** Entry **720** for future reference.

[0102] All elements of the Parallel Task Engine **300** operate under, and may read from the current CONTEXT, including the Operation **610** routines executed by the Job Loops **318**. Only Operation **610** routines actually access the Primary Data **306** for which the engine is configured to process. The rest of the Parallel Task Engine **300** is concerned with dispensing Jobs **320** to the Job Loops **318**.

[0103] Also, the Job **400**, Task **500**, and Command **600** data structures are 'nested' structures—they could each be represented by other structures that incorporate the same basic information in a less hierarchical form—the exact form of these data structures is not relevant to the essential operation of the Parallel Task Engine **300**, other representations of the same information would serve as well—these forms were chosen because they represent a unit of work or a key aspect of that work at the level at which they are created or utilized.

[0104] A detailed, step by step description of the operation of the Parallel Task Engine programs follow. These descriptions employ single-threaded loops that may be represented by a flow chart. No reference is made to processes or synchronization mechanisms or other features of computer operating systems that may be used to improve the efficiency of an implementation of this engine. An embodiment may implement the following step-by-step methods directly, or it may employ system-specific features or alternative formulations that preserve the functional operation of the engine as described here. This description is not the only representation or embodiment possible, and others are easily imaginable. However this description does suffice to demonstrate the proper operation of the engine in a form that is transferable to many computer systems, assuming some multiple, parallel CPU facility, and a shared memory to which all CPUs have access.

[0105] Parallel Task Engine Main Program (FIG. **19**):

[0106] Step **1901**. Initialize the Cache **316** Directory **710** Entries **720**, making all the Tags **730** 'un-matchable', (perhaps by loading Context **734** with a value that will never match any current CONTEXT).

[0107] Step **1902**. Set up multiple Job Loops **318**, according to CPUs of different numbers and types available. For each Job Loop **318**, set REQUEST and DISPATCH counts to zero. These counts are integers, which may be of any width, including 1 bit. Each Job Loop **318** also has an incoming Job **320** POINTER variable. Start the Job Loops **318** on the CPUs (Job Loop **318** detailed below).

[0108] Step **1903**. Set L, an integer variable, to 0. Set N, an integer variable, to the number of Job Loops **318**. L represents the index of the Job Loop **318** under consideration in steps **1904** through **1910**, below, and ranges from 0 to N—1.

[0109] Step **1904**. Inspect Job Loop **318** L's REQUEST count. If it is the same as the DISPATCH count, go to step **1910**.

[0110] Step **1905**. Call the Scheduler **312** to pick a Task **500** for Job Loop **318** L, and remove it from the Task Pool **310**. If necessary, the Scheduler **312** will decompose a Task **905** and place the new Tasks **940** in the Task Pool **310**, before picking

a Task **500** for the Job Loop **318**, which it returns to the Main Program via a POINTER. If no Task **500** can be found, go to step **1910**.

[0111] Step **1906**. Look in the Cache **316** Directory **710** for an Entry **720** with a Tag **730** that matches the Operation **610** specified by the Task **500** and the current CONTEXT. If a matching Entry **720** is found, go to step **1908**.

[0112] Step **1907**. Call the Code Generator **314** to create or find a routine for the Operation **610** under the current CONTEXT. Create an Entry **720** in the Cache **316** Directory **710** containing the specified Operation **610** in Operation **732**, the current CONTEXT in Context **734**, and a pointer to the Operation **610** routine in Code Pointer **742**. Go to Step **1906**.

[0113] Step **1908**. Compose the Scheduler **312** in Task **420**, and the matching Entry **720** Code Pointer **742** in the Scheduler **312** in Task **420**, and the matching Entry **720** Code Pointer **742** in Code Pointer **410**, and place a POINTER to Job **320** in Job Loop **318** L's incoming Job **320** variable.

[0114] Step **1909**. Set Job Loop **318** L's DISPATCH count to the value of its REQUEST count.

[0115] Step **1910**. Increment L. If L is less than N, go to step **1904**.

[0116] Step **1911**. Pull the next input Task **302** from the Task input **303**, if there is one, and place it in the Task Pool **310**. Go to step **1903**.

[0117] Job Loop **318** (FIG. **20**):

[0118] Step **2001**. Increment this Job Loop's **318** REQUEST count.

[0119] Step **2002**. Inspect this Job Loop's **318** DISPATCH count. If it is not the same as the REQUEST count, go to step **2002** (repeat this step).

[0120] Step **2003**. From the incoming Job **320** POINTER variable, get the Job **320** to do. Call the Operation **610** routine, via the Code Pointer **410** with Parameters **620**, to process the Primary Data **306** as specified by the Task **420** Data Pointers **520**, according to the Command **510** of the Task **420**. Go to step **2001**.

[0121] The preceding two program descriptions characterize the complete, high-level operation of the Parallel Task Engine **300**, in an embodiment without program or execution thread synchronization or signaling. Both the Main Program and the Job Loops **318** are polling loops. When there is no work to do, both programs 'spin' or are 'busy waiting'. A first improvement to this implementation, in a program environment that supports it, would be to cause the Main Program and Job Loops **318** to block or sleep when there are no input Tasks **302** to decompose or dispatch, and no Jobs **320** to do, and to resume operation when input Tasks **302** and Jobs **320** arrive. This would make more efficient use of any CPU that is shared by multiple programs. In the case of the Main Program and a Job Loop **318** running on the same CPU, it would also be desirable for the Main Program to run at a lower priority than the Job Loop **318**, or utilize some other mechanism to ensure that the Main Program does not continue to spin or accept input Tasks **302** when the Job Loop **318** on the same CPU is executing a Job **320**. The two program loops operate in a producer/consumer relationship. The Main Program produces Jobs **320**, and the Job Loops **318** consume and do the Jobs **320**. Any sequence or coordination scheme that reliably effects the same results, with the same components, is an alternative embodiment of the Parallel Task Engine **300**.

[0122] In another possible embodiment, the Job Loops **318** may incorporate and call a version of the Main Program directly. In this case it is necessary to ensure that multiple Job

Loops **318** have mutually exclusive access to the Main (sub) Program. This can be done by using operating system software facilities, atomic read-modify-write CPU instructions, or through any one of several software mutual exclusion algorithms, such as Dekker's algorithm, or Peterson's algorithm.

[0123] In this case, the Main Program becomes a sub-program or subroutine which executes according to the following procedure:

[0124] Alternative, Parallel Task Engine Main (Sub) Program (FIG. **21**):

[0125] L, an integer variable, is passed into the Main (sub) Program by the calling Job Loop **318**, and represents the index of the Job Loop **318** under consideration in the following steps.

[0126] Step **2101**. Call the Scheduler **312** to pick a Task **500** for Job Loop **318** L, and remove it from the Task Pool **310**. If necessary, the Scheduler **312** will decompose a Task **905** and place the new Tasks **940** in the Task Pool **310**, before picking a Task **500** for the Job Loop **318**, which it returns to the Main Program via a POINTER. If a Task **500** is found, go to step **2103**.

[0127] Step **2102**. Pull the next input Task **302** from the Task input **303**, if there is one, and place it in the Task Pool **310**. If there was an input Task **302**, go to step **2101**. If there was no input Task **302**, go to step **2106**.

[0128] Step **2103**. Look in the Cache **316** Directory **710** for an Entry **720** with a Tag **730** that matches the Operation **610** specified by the Task **500** and the current CONTEXT. If a matching Entry **720** is found, go to step **2105**.

[0129] Step **2104**. Call the Code Generator **314** to create or find a routine for the Operation **610** under the current CONTEXT. Create an Entry **720** in the Cache **316** Directory **710** containing the specified Operation **610** in Operation **732**, the current CONTEXT in Context **734**, and a pointer to the Operation **610** routine in Code Pointer **742**. Go to Step **2103**.

[0130] Step **2105**. Compose the Job **320** as a Job **400** with the Task **500** from the Scheduler **312** in Task **420**, and the matching Entry **720** Code Pointer **742** in Code Pointer **410**, and place a POINTER to Job **320** in Job Loop **318** L's incoming Job **320** variable.

[0131] **2106**. Return to the calling Job Loop **318**, indicating whether or not a Job **320** is ready. The Job Loop **318** which calls the Main (sub) Program is detailed below.

[0132] Alternative Job Loop **318** which calls Main (Sub) Program (FIG. **22**):

[0133] Step **2201**. If this is the first Job Loop **318**, initialize the Cache **316** Directory **710** Entries **720**, making them 'unmatchable'.

[0134] Step **2202**. If this is the first Job Loop **318**, set up multiple other Job Loops **318**, according to CPUs of different numbers and types available. Each Job Loop **318** has an incoming Job **320** POINTER variable. Start the other Job Loops **318** on the CPUs.

[0135] Step **2203**. Obtain exclusive access to the Main (sub) Program.

[0136] Step **2204**. Call the Main (sub) Program.

[0137] Step **2205**. Yield exclusive access to the Main (sub) Program.

[0138] Step **2206**. If there is no Job **320** to do, go to step **2203**.

[0139] Step **2207**. From the incoming Job **320** POINTER variable, get the Job **320** to do. Call the Operation **610** routine, via the Code Pointer **410** with Parameters **620**, to process the

Primary Data **306** as specified by the Task **420** Data Pointers **520**, according to the Command **510** of the Task **420**. Go to step **2203**.

[0140] The two other sub-program components of the Parallel Task Engine **300**, the Code Generator **314** and the Scheduler **312**, are now detailed in turn.

[0141] Code Generator (or Run-Time Code Generator): The Code Generator **314** is an element of the Parallel Task Engine **300**. The design of any particular Code Generator **314**, and the specific methods by which the Code Generator **314** accomplishes its work will vary according to the specifics of the embodiment The way in which a Code Generator **314**, fulfilling the requirements detailed below, is used by the Parallel Task Engine **300**, as described above, and as will be detailed further in the exposition of specific applications, is part of an embodiment, and its application of techniques of dynamic code generation.

[0142] As shown in FIG. **8**, the Code Generator **314** may 'generate' an Operation **810** routine in one of two ways:

[0143] 1. It may Synthesize **820** code to perform the Operation **810**, from a higher level, meta-code description of Operations **810**, or from ad-hoc code emitting routines, one for each Operation **810**, or through other means.

[0144] 2. It may have 'canned', statically compiled (Locate Static Code **830**) Operation **810** routines, or fragments of Operation **810** routines, which may be used as-is, or concatenated together, to form Operation **810** routines.

[0145] Either method is acceptable, or code generators in typical embodiments may use both methods. Method 2 extends the notion of Code Generator **314** to a function which simply looks up a static Operation **810** routine in a table—for the purposes of the description, this style of code 'generation' is sufficient.

[0146] The Code Generator **314** must also have the capability of 'specializing' the code generated, by the CONTEXT outstanding at the time of generation, resulting in an Operation **810** routine specifically generated for use in that CONTEXT.

[0147] For example, if a generic routine for an Operation **810** has execution conditional on CONTEXT variables, and these variables are known to be of a certain value that will remain constant over the execution of the routine, the Code Generator **314** may generate custom code that assumes these values. Again, this may be done as simply as modifying a table look-up of the Operation **810** requested by adding elements from the CONTEXT to the index into the table, returning the proper, more specific static routine.

[0148] The Code Generator **314** may also contain a general Optimizer **840**, which can accept as input, generated (Locate Static Code **830** or Synthesized **820**) Operation **810** routines, or meta-code representations of those routines, and output more efficient routines or meta-code representations. Optimization techniques well-known in the art include constant-folding, reductions in strength, dead store elimination, common sub-expression elimination, copy propagation, instruction combination, branch chaining and elimination, loop unrolling and loop-invariant code motion, and global register allocation. These techniques and others may be used by an Optimizer **840**.

[0149] The Code Generator **314** may also use the Optimizer **840** in order to accomplish specialization of a Synthesized **820** or static routine. For example, if a generic Operation **810** routine computes four values as output, but a more specific sub-Operation **810** requires only one value as output, the

8

Code Generator **314** may select the generic routine, and pass it to the Optimizer **840**, informing the Optimizer **840** that the three unwanted values are to be considered dead stores. The Optimizer **840** will then create the specialized, one-value-computing routine.

[0150] The Code Generator **314**, when generating new Operation **610** routines, will store the code contents of these routines to the Cache **316** Code Buffer **750**. Because that storage space is finite, it will eventually be exhausted, and require some existing code to be overwritten, destroying some Operation **610** routines that reside in the Code Buffer **750**. How storage space is managed in this buffer is an implementation detail. However it is required that the Code Generator **314** invalidate, or make un-matchable, any Cache **316** Directory **710** Entries **720** with Code Pointers **742** that reference code that has been overwritten, at the time that the corresponding Operation **610** routines are destroyed.

[0151] Scheduler: Alternate embodiments may pursue different strategies or policies, as appropriate for the particular application of the Parallel Task Engine **300**, but there are basic functions that all Scheduler **312** implementations must perform, and there are certain constraints that must be observed.

[0152] The Scheduler **312** maintains the Task Pool **310** of outstanding Tasks **500**, and keeps a record of the Task **500** in progress on each Job Loop **318**. With the Tasks **500** the Scheduler **312** may, but is not required to, keep additional information, such as: 1. The time, or a sequence counter, indicating when the input Task **302** was received from the Task input **303**. 2. An estimate of the size of a Task **500**, or time to completion. 3. Any other statistics or auxiliary information that may assist the Scheduler **312** in its work.

[0153] The Scheduler **312** has one function, as called from the Main Program—to remove a Task **500** from the Task Pool **310**, and assign it to a Job Loop **318**, returning that Task **500** to the Main Program, which will compose a Job **400** consisting of a Task **420** and an Operation **610** routine Code Pointer **410**, and pass this Job **320** to the Job Loop **318**. In the process of doing so, it may decide to decompose a Task **905** into other Tasks **940**, adding the Tasks **940** to the Task Pool **310**, before choosing and assigning the Task **500** to the Job Loop **318**.

[0154] As shown in FIG. **9**, the Scheduler **312** from FIG. **3** may use one of three policies to decompose a Task **905**:

[0155] 1. By-Function **920**—the Task **905** can be effected by one or more Tasks **940** which each applies sub-FUNC-TIONS or sub-Operations **610**, to the indicated Primary Data **306**. If the sub-Operations **610** must be applied sequentially, the original Task **905** becomes new Tasks **940** which form a pipeline. If the Operations **610** are independent, they may be dispatched in parallel. The new Operations **610** and Tasks **940** may have arbitrary dependencies, allowing some to be dispatched in parallel or in arbitrary order, and requiring some to be dispatched only after the completion of others. The new Tasks **940** reference the same Primary Data **306**, but have different Commands **510** (Operations **610** and Parameters **620**).

[0156] 2. By-Domain **925**—the Command **510** can be effected by independently applying the Operation **610** to different sub-sets or domains of the Primary Data **306**. One Task **905** becomes one or more independent Tasks **940**, which may be executed in parallel The new Tasks **940** all contain the original Operation **610**, but the Parameters **620** and/or Data Pointers **520** are modified to assign different Primary Data **306** domains to each new Task **940**.

[0157] 3. By-Component **930**—An Operation **610** is defined to operate on arrays of data, in other words, one or more data items, which are atomic from the point of view of the Operation **610**. By-Component **930** decomposition of Tasks **905** divides the Primary Data **306** to be processed, or the new Primary Data **306** to be computed, into domains which are 'sub-atomic' or sub-components of the data processed by the original Operation **610**, effecting the original Operation **610** by one or more component Operations **610**. These component Operations **610** and the resulting Tasks **940** may or may not have inter-dependencies. By-Component **930** decomposition is a combination of methods 1 and 2, it is decomposition By-Domain **925**, below the level of an Operation **610**'s natural atomic datum, in order to get, or resulting in, decomposition By-Function **920**.

[0158] As described above, the Scheduler **312** can achieve ordinary decomposition of Tasks **905** By-Domain **925**, by simply modifying a Task's **905** Data Pointers **520** or Parameters **620**. Likewise, in order effect decomposition of Tasks **905** By-Function **920**, the Scheduler **312** can simply create the requisite Tasks **940** with sub-Operations **610**. These new Operations **610** naturally suggest new Operation **610** routines, with new code. However, as described above, the Code Generator **314** may decide that the sub-Operation **810** routine code is best generated by optimizing or specializing more general Operation **810** code. In this case, the Parallel Task Engine **300** can be said to use the Optimizer **840** to accomplish functional Task **905** division by 'algorithmic decomposition'.

[0159] Given Tasks **905**, which may be decomposed as the Scheduler **312** sees fit, and a Job Loop **318** requesting a Job **400**, containing a Task **500**, the Scheduler **312** when called by the Main Program must choose a Task **500** for the Job Loop **318**. The Scheduler **312** may use any sort of ordering to choose the next Task **500**, e.g. first-come-first-served, starting the largest jobs first, finishing related Tasks **500** before others, etc., but certain rules must be followed:

[0160] The Scheduler **312**, at the time it decomposes Tasks **905**, knows the dependencies that it creates between Tasks **940** as it creates new Tasks **940** from other Tasks **905**. It records and respects these dependencies, and will not choose to start or assign a Task **500** whose dependencies have not been fulfilled (Tasks **500** on which the Task **500** depends must have completed—this means that no Tasks **500** on which it depends still reside in the Task Pool **310** or are in progress on one of the Job Loops **318**). The Task **500** dependencies, for any Task **500**, are simply a list of other Tasks **500** that the Task **500** is dependent on. Dependency lists may be associated with the Task **500**, or may be kept in a table, indexed by a Task **500** number, or may be kept by the Scheduler **312** in some other way.

[0161] A Task **500** is either in the Task Pool **310** unassigned, or assigned to one (1) Job Loop **318**. It cannot be assigned to two or more Job Loops **318**, and it cannot both be assigned and waiting to be assigned. Once assigned, it will stay with the Job Loop **318** until it is completed, at which time it ceases to exist.

[0162] A Task **500** 'A' is understood to be completed when the Main Program asks the Scheduler **312** for a new Task **500** for the Job Loop **318** which was assigned the Task **500** 'A'. When a Task **500** is completed, the Scheduler **312** updates (removes) dependencies (Task **500** indicators on a list of Tasks **500** that a Task **500** is waiting on) from Tasks **500** dependent on the completed Task **500**.

[0163] With these provisos, many implementations are possible. The following step by step description details the operation of one implementation of the Scheduler **312**.

[0164] Scheduler Routine:

[0165] Step 1. The Main Program has asked the Scheduler **312** for a Task **500** for a specific Job Loop **318**. If the Job Loop **318** was not previously assigned a Task **500**, go to step 3.

[0166] Step 2. Because the Job Loop **318** has now requested a Job **320** from the Main Program, and the Main Program has asked the Scheduler **312** for a Task **500** for the Job Loop **318**, this means that the Job Loop **318** has now completed any Task **500** previously assigned to it. Look through the Task Pool **310** and for each Task **500**, update the lists of other Tasks **500** that they are dependent on, by removing the Task **500** that this Job Loop **318** has just completed, from those lists.

[0167] Step 3. Choose a Task **500**. The choice of Task **500** can be according to any number of policies, but must be a Task **500** with no outstanding dependencies on other Tasks **500**. This Task **500** may be a Task **500** that the Scheduler **312** can decompose, or it may not be. The Scheduler **312** understands which Commands **510** and Operations **610** allow decomposition by different means. The Scheduler **312** may also make decisions to decompose Tasks **500** or not based on available CPU resources, or the number of Job Loops **318** currently occupied with Tasks **500**. If the chosen Task **500** is not to be decomposed, go to step 5.

[0168] Step 4. Decompose the Task **905** by one of the three means described above—By-Function **920**, By-Domain **925**, or By-Component **930**. Place all of the new Tasks **940** in the Task Pool **310**. Go to step **3**. Note that Tasks **905** should not be infinitely decomposable, there should be a finite number of data By-Domain **925** partitions possible, and a finite number of Operations **610** and sub-Operations **610**. Tasks **905** should not be decomposed into the same Task **940**, or into chains of Task **905** decompositions that eventually lead back to the original Task **905**, or the Scheduler **312** may get stuck in this loop—but this is an implementation detail, part of the policies and strategies chosen, and definition of Commands **510** and Operations **610**, made by the implementor when applying the Parallel Task Engine to a specific problem.

[0169] 5. Assign the Task **500** to a Job Loop **318**, and record this fact. Return a POINTER to the Task **500** to the Main Program.

[0170] It is worth noting the extent to which the Scheduler **312** may decompose a particular problem with little knowledge of it, an almost 'blind' or automatic decomposition. The Scheduler **312** need only know which Operations **610** are composed of which other Operations **610** in sequence, to perform a By-Function **920** decomposition, with dependencies among the new Tasks **940** set so that the new Operations **610** are performed in order on the same Primary Data **306**. By-Domain **925** decomposition can be done on any Task **905** by adjusting Data Pointers **520** or the Parameters **620** for an Operation **610**. And By-Component **930**, or interleaved By-Domain **925** decomposition can be done by knowing only which specific partial-datum component or alternate datum Operations **610** to substitute for the full-datum Operation **610**. The Code Generator **314**, as noted above, may or may not have 'canned' (Locate Static Code **830**) specific Operation **610** routines, and it may have to Synthesize **820** new routines. Or it may Optimize **840** a more generic routine to get the appropriate partial datum routine. This general process, especially with code specialized and optimized under specific

CONTEXTS, would seem to know more about a problem than it does—in reality it only need know Operation **610** rewriting rules.

[0171] But given a multiplicity of possible decompositions, applied blindly without knowledge of a problem, how could such a problem-agnostic Scheduler **312** choose a good decomposition ? It is possible for the Scheduler **312** to have general heuristics, along with a trial and error, run-time experimental approach. Nothing prevents the Scheduler **312** from trying a decomposition, measuring the code in the Operation **610** routines received from the Code Generator **314**, and then deciding whether or not to try something different. Or, these experiments can be done ahead of time, and fed back into the heuristics or fixed strategies built-in to the Scheduler. In short, it is possible to build both accumulated experience and run-time decision-making into the Scheduler **312** so that it can make good decompositions, on the basis of the code that will be executed in the scenario under consideration. Novel decomposition strategies, and the availability of a CONTEXT-sensitive dynamic code generator, open up possibilities for dynamic problem decomposition, and as well as dynamic code generation, in order to get the most efficient Tasks **500** under prevailing conditions.

[0172] More specifically, the Scheduler **312** can make run-time decomposition choices based on the quality of code generated by the Code Generator **314**, in the Main Program procedures as described above, with no change necessary to those procedures. Generated code quality is simply another input to the Scheduler's **312** decomposition strategy. When presented with a Task **905** to be decomposed, the Scheduler **312** can try a number of Operation **610** re-writings in terms of new Operations **610**. It can request (independently of the Main Program's call to the Code Generator **314**) the Code Generator **314** to generate code for the Operations **610** considered. The Code Generator may return statistics to the Scheduler **312**, or the Scheduler **312** may analyze the code itself. Operation **610** routines will be created differently by the Code Generator **314** at different times, depending on the CONTEXT, and the Scheduler **312** will make different decomposition decisions accordingly. The Scheduler **312** uses the Code Generator **314** in order to effect 'dynamic problem decomposition'.

[0173] Example Applications: The following applications demonstrate the use of the Parallel Task Engine design and scheme of computation to provide solutions to specific computational problems, using dynamic code generation, in a multi-CPU environment.

[0174] Application 1: Matrix-Vector Multiplication: A matrix K, with M rows and N columns, may be multiplied by a column vector V, with N rows, to get a column vector P, with N rows. Element "I" of P is the vector dot product of row I of matrix K with the vector V. Or, assuming rows are numbered 0 to M−1 and columns 0 to N−1:

$$P[I] = \text{SUM}_{J=0}^{N-1} K[I][J] * V[J]$$

[0175] Matrix-vector multiplication of this sort comprises a linear transformation of the vector V by the function represented by the matrix K, and has many applications in various domains of computation.

[0176] FIG. **10** shows a routine, written in Intel x86 assembly language, using the SSE3 instruction set extensions,

which loops through vector data, multiplying these vectors by a constant matrix, and creating an output set of vectors. The semantics of the individual Intel x86 instructions are defined in the Intel Architecture Software Developer's Manual. This routine computes the multiplication of a 4×4 matrix with a 4×1 (4 row, 1 column) vector. All matrix and vector elements are double precision (64 bit) IEEE 754 format floating point numbers. The loop body computes two row-vector dot products at a time, using the HADDPD (Horizontal ADD Packed Double-precision) instruction and then does the next two. It is limited in the amount of computation it can accomplish before loading more data from memory, because the Intel x86 architecture only provides eight registers for vector data, which may be operated on with the SSE3 instructions. This routine is a reasonably efficient implementation, although greater efficiencies may be achieved by unrolling the loop, and reordering (scheduling) the instruction sequence to allow the processor to execute the instruction stream more quickly.

[0177] A Parallel Task Engine software system can be constructed to perform matrix-vector multiplication, starting from the program in FIG. **10** as the template for a generic Operation **610** routine.

[0178] Define the following Commands **510**/Operations **610**/Tasks **302**: Operation **610** MATVEC4×4-Multiply a 4×4 matrix by a 4×1 vector, for all the vectors in an input array, computing product vectors, which are stored in an output array (as in the routine in FIG. **10**). A Command **510** specifying this Operation **610** is Parameterized **620** by the number of vectors to process, the offset in bytes from the beginning of the array of the first input vector and first output vector to process, and an offset mask, which is the ((number of vectors to process multiplied by the vector size in bytes)–1). Data Pointers **520** are provided in the enclosing Task **500** to specify the base addresses of the input and output vector arrays.

[0179] Operation **610** XY_MATVEC4×4, and Operation **610** YZ_MATVEC4×4 These Operations **610** are sub-Operations **610** of MATVEC4×4, and Tasks **905** with MATVEC4λ4 Operations **610** may be decomposed into one Task **940** each with XY_MATVEC4×4 and YZ_MATVEC4×4 Operations **610**. These Operations **610** compute (only) either the x and y (0 and 1), or y and z (2 and 3) elements of the four element product vector, in the matrix-vector multiply of the MATVEC4×4 Operation **610**. A Command **510** specifying either of these Operations **610** is Parameterized **620** by the number of vectors to process in this Task **500**, the starting offset of vectors input and output in this Task **500**, and the offset mask from the full-datum Task **500** from which it was decomposed. The Data Pointers **520** are copied from the full-datum Task **500** into these half-datum sub-Tasks **500**.

[0180] The machine receives MATVEC4×4 Tasks **302** (Tasks **302** with Commands **510** with Operation **610** of MATVEC4×4) from the outside world, and processes them; that is its sole function. It decomposes and dispatches these Tasks **302** or sub-Tasks **500** as it deems necessary in a one, two, or four CPU environment. The matrix used for the matrix-vector multiplication is part of the CONTEXT.

[0181] The Scheduler **312** for this matrix-vector multiplying machine has the following policies:

[0182] First-in, First-out (FIFO), or "first come, first served". As Tasks **302** are received at the Task input **303**, they are placed in the Task Pool **310** in a linked list, such that new Tasks **500** are placed at the end of the list. Tasks **500** are

assigned to Job Loops **318** (after being decomposed, if the Scheduler **312** chooses to do so) from the front of the list.

[0183] If there is only one CPU present, the Scheduler **312** will not decompose MATVEC4×4 Tasks **500**. If there are two CPUs present, the Scheduler **312** will decompose MATVEC4×4 Tasks **905** By-Component **930** to get XY_MATVEC4×4 and YZ_MATVEC4×4 Tasks **940** (Tasks **940** with Commands **510** with Operations **610** which are XY_MATVEC4×4 and YZ_MATVEC4×4). These two sub-Tasks **940** each process all the vectors, but start at different points in the arrays—the XY sub-Task **500** will start at the beginning and the YZ sub-Task **500** will start at the middle of the input and output arrays. If there are four CPUs present, XY_MATVEC4×4 and YZ_MATVEC4×4 Tasks **905** are further decomposed By-Domain **925**, splitting the XY Task **905** into two XY sub-Tasks **940**, and the YZ Task **905** into two YZ sub-Tasks **940**, each responsible for half of the vectors covered by the larger Task **500** from which it was decomposed. A MATVEC4×4 Task **302** becomes 1, 2, or 4 Tasks **500**, for 1, 2, or 4 CPUs.

[0184] Decomposed Tasks **940** replace the original Task **905** in the same position on the linked list of Tasks **500** in the Task Pool **310**—in other words, one MATVEC4×4 Task **500** in the second position from the head of the linked list can become XY_MATVEC4×4 and YZ_MATVEC4×4 Tasks **500** in positions **2** and **3**, in front of the Task **500** that was previously at position **3**.

[0185] There are no dependencies between any Tasks **500** or sub-Tasks **500** in this MATVEC4×4 engine.

[0186] These policies applied to the step-by-step description of the general Scheduler **312** procedure given above characterize the specific Scheduler **312** for the MATVEC4×4 engine.

[0187] The Code Generator **314** for this MATVEC4×4 engine operates as follows:

[0188] The MATVEC4×4 Operation **810** routine is as shown in FIG. **10**. It can be used unchanged for a MATVEC4×4 operation.

[0189] The XY_MATVEC4×4 Operation **810** routine is shown in FIG. **11**. It can be used directly, or it could also be derived from the MATVEC4×4 routine by applying the Optimizer **840**—note that when the z and w components are considered dead, all of the instructions that contribute to the computation of these values (the last 12 instructions in the second half of the loop body) can be eliminated. Once these instructions are eliminated, the four matrix-row register loads in the second half of the loop body become redundant, and the first four loads of these values to registers, which are now constant over the loop, can be moved outside the loop. The YZ_MATVEC4×4 Operation **810** routine is symmetrical to the XY routine, and is of the same length.

[0190] The XY_MATVEC4×4 and YZ_MATVEC4×4 Operation **810** routines can be specialized by knowledge of the constant matrix, in the CONTEXT, that is used over the routine. Of course, when the CONTEXT changes, Operation **610** routine look-ups in the Cache **326** Directory **710** will fail, and new Operation **610** routines must be generated, and new Entries **720** created. In this example engine, the Code Generator **314** will take note of which matrix elements are zero and nonzero. FIG. **12** shows a routine that has been specialized with such knowledge of matrix zero elements. It can be derived from XY and YZ routines as shown in FIG. **11**, by

using the Optimizer **840** to systematically apply simple substitutions and rules, as noted in the comments accompanying the code.

[0191] FIG. **13** shows an extremely optimized version of the XY_MATVEC4×4 Operation **810** routine, specialized with the same matrix knowledge as in FIG. **12**. Achieving this code is challenging, but possible for an Optimizer **840**. It represents a dramatic example of the possible performance advantage of specialized, optimized, decomposed Operation **810** routines.

[0192] The MATVEC4×4 engine will basically operate as follows:

[0193] MATVEC4×4 Tasks **302** will arrive at the Task input **303**.

[0194] The engine will dispatch the Tasks **500** to the Job Loops **318** in order.

[0195] 1, 2, or 4 Job Loops **318** will execute either:

[0196] 1 CPU/Job Loop **318**: 1 MATVEC4×4 Operation **610** routine per incoming MATVEC4×4 Task **302**.

[0197] 2 CPUs/Job Loops **318**: 1 XY_MATVEC4×4 Operation **610** and 1 YZ_MATVEC4×4 Operation **610** per incoming MATVEC4×4 Task **302**.

[0198] 4 CPUs/Job Loops **318**: 2 XY_MATVEC4×4 Tasks **500**, and 2 YZ_MATVEC4×4 Tasks **500**, each XY or YZ Task **500** operating on half of the vectors, for each MATVEC4×4 Task **302**.

[0199] Performance of the MATVEC4×4 Parallel Task Engine: In the case of CPU/Job Loop **318**, the performance of a Parallel Task Engine implementation of MATVEC4×4 Operations **610** on arrays of vector data is substantially the same as simply calling the Operation **610** routine directly—there is a very small amount of overhead for SCHEDULING and communication, but the processing of the Primary Data **306** is unchanged.

[0200] Looking at FIG. **10** more closely, we see that this processing consists of 32 instructions, 12 memory reads, and 2 memory writes, in the body of the loop, in order to compute one complete product vector. The instructions ahead of the loop and at the very end of the loop, which update offsets and loop count, are not counted. The instructions ahead of the loop are not counted because they are executed once per routine, and with a large number of vectors to be processed, the time spent in the loop will represent almost all the time spent in the routine. The reason the instructions at the end of the loop should not be counted is that this loop may easily be 'unrolled' that is, the body of the loop may be duplicated some number of times, and the offset and loop count updates may be amortized over the entire resulting loop body. For clarity and brevity, none of the code examples are unrolled, but they all may be, and so the metrics for comparison include the length in instructions of the core loop body, and the quantity of results achieved by that code. It is also possible, for any particular CPU and computer system, to estimate or measure the actual time in CPU clock cycles for a small 'kernel' computation such as this, but the cycle counts for instructions on different models of CPU vary. For any one CPU, however, given a base routine using particular instruction set features, routines with shorter core sequences will in general be faster. As long as these shorter routines do not use 'extra' CPU features that would have also been useful in the base routine, these are fair comparisons. Lastly, the code in these Operation **610** routines can be re-ordered, or scheduled, in particular ways for particular CPU models, and this can improve the performance of this code on a particular CPU. Instructions

can have various latencies (time to creation of results), but another instruction may start execution before a previous instruction has completed, as long as the later instruction does not require the results of the previous instruction. So instruction execution may be overlapped, and instructions can be re-ordered to take advantage of this overlap. Instructions may only be re-ordered insofar as long as they preserve the semantics of the original sequence—in other words, data dependencies and the essential computations must remain the same in the re-scheduled code. The fewer data dependencies, and the more independent computations, or the more computations that may remain independent because there are free registers to hold their intermediate results, the more freedom a scheduler has in re-ordering instructions. None of the examples have been optimally scheduled for any particular CPU, but arguments will be made that some of the examples are more amenable to scheduling than others.

[0201] In the case of two or four CPUs, XY_MATVEC4×4 and YZ_MATVEC4×4 Operations **610**, as in FIG. **11**, will be used. The core of the loop is 12 instructions, with two memory reads, and 1 memory write. Because it is only computing the x and y components of the output vector, only the first two rows of the matrix are required, and the four registers containing the first two rows may be loaded ahead of, and remain constant throughout, the loop. In 12 instructions two of the four components of the output vector are computed. The YZ Operation **610** routine is symmetrical, and performs the same intrinsic computations. This scheme of computing two components at a time results in a more efficient loop body. However, in most cases, it would not be a good problem organization on a single CPU, because this would mean traversing the input and output arrays twice for the same computation, doubling the total number of memory reads and writes, and this would likely overwhelm the 25% (12 for XY+12 for YZ=24, compared to 32) reduction in the length of the loop body. With a large array of vectors, the required reads and writes to input and output vector arrays will outstrip the single CPU's data cache capacity, and some number of cache misses will occur. Double the cache misses will occur if XY and YZ routines are executed in sequence on a single CPU, unless the original MATVEC4×4 Task **302** was first decomposed By-Domain **925** into a series of small vector batches (which could be done without the Parallel Task Engine, by simply nesting an XY loop and a YZ loop in an outer loop, or could also use a Parallel Task Engine configured for this application, to do the decomposition, even with one CPU). However, even in this case, any single CPU has a limited size data cache, and two CPUs of the same model will have twice the data cache, and this can be exploited. An XY and a YZ Task **500** can be dispatched to different CPUs, and in this case, each CPU will see roughly the same number of cache misses as a single CPU running the full-datum routine of FIG. **10** (or less, because the matrix rows are not reloaded), but enjoy the 25% reduction in loop body length, and the factor of three reduction in memory reads. Each XY or YZ loop does half as much work, but it is more than twice as fast, and so using two CPUs in this fashion is faster than using two CPUs and decomposing a MATVEC4×4 Task **905** simply By-Domain **925**, giving half the full-datum computations to each processor (which, of course, can be done with the Parallel Task Engine). An advantage of this two-processor XY, YZ decomposition, over one in which (a series of smaller) XY and YZ routines are performed in sequence on a single CPU, which would then be decomposed By-Domain **925** to two sets

12

of Tasks **940** for 2 CPUs, is that there are fewer Tasks **940** (the same number of Tasks **940** for all models of CPU, no matter what the data cache capacity), and the Scheduler **312** does not have to estimate the appropriate working set to avoid data cache thrashing on any single CPU—the two CPU data caches are used to advantage transparently and in a way that works on any model of CPU. It is true that in total, under a By-Component **930** decomposition, the number of input data reads done by the CPUs in combination, may be more than the number of reads done by full-datum routines on the same number of CPUs (although this is not the case in the current example, due to the dearth of registers, and the requirement to reload the input vectors, in the full-datum routine), and this may be how we "pay" for the extra registers available in partial-datum routines—but those reads are covered by the individual data caches on the CPUs, and the fact that the total load on memory is higher will not be important, unless the two CPUs contend for access to memory.

[0202] To keep the two CPUs from contending for access to the same memory at the same time, the XY Task **500** starts at the beginning of the input and output arrays, and YZ Task **500** starts in the middle. As the input and output offsets are advanced through the arrays in each routine, they are masked (logical "and" operation) with the offset mask as defined above, which has the effect of "wrapping" the offset around at the end of the vector arrays—the XY Task **500** starts at vector 0 and ends at vector N−1, and the YZ Task **500** starts at N/2, wraps past the end to 0, and ends at vector N/2−1. Thus, if the two Operations **610** proceed at roughly the same rate, they will rarely contend for read access to the same memory. They will of course, not ever write the exact same memory, as one Task **500** will write only x and y, and the other will write only y and z, but they could possibly at times contend for write access to the same local area of memory, as they can when reading—logically, if both are started at the same time, and are running at the same speed, they will not contend, but because they are independent, unsynchronized CPUs, with independent asynchronous events and independent resource management, they may drift forward and backward with respect to each other, and very occasionally need access to the same memory. Since their starting and ending locations are N/2 vectors apart, minor variations in moment to moment progress should make instances of access to the same vector, or even the same large group of vectors, very rare. (This same multi-CPU, multi-cache, non-contending access scheme can be used in any scenario of decomposition By-Domain **925** in which the two domains are interleaved, and would require multiple passes through the data on a single CPU, deriving the same benefit of allowing separate computation on interleaved sets of data with no memory access penalty.)

[0203] With two or more CPUs, the XY and YZ problem breakdown takes advantage of having two sets of registers and two data caches to apply to the problem.

[0204] In the case of four CPUs, the XY and YZ Tasks **905** can be decomposed by Domain **925**, each Task **905** splitting into two of the same sorts of Tasks **940**, with each responsible for one half the vectors. This will cut the time per vector in half. Each Task **940** will now be starting on a separate quarter of the vector arrays, with each task reading and writing half of them, as follows: CPU 0; XY Task **500**, vectors 0 to N/2−1, CPU 1: YZ Task **500**, vectors N/4 to 3N/4−5 CPU 2: XY Task **500**, vectors N/2 to N−1, CPU 3: YZ Task **500**, vectors 3N/4 to N/4−1.

[0205] When the XY or YZ routines of FIG. **11** are specialized to account for the knowledge of the matrix, they can be even more efficient. FIG. **12** shows that in a case where only one element in each of the two matrix rows being used are nonzero, and the two elements are diagonally adjacent (not that uncommon a case in many matrix applications), a routine specialized through simple optimization can be almost twice as fast as the un-specialized routine, needing only seven instructions in the loop body to complete its work. (Larger, full-datum routines can also be specialized, of course—but the smaller the generic routine, the smaller the resulting specialized routine).

[0206] FIG. **13** shows an optimally specialized routine, under the same conditions as in FIG. **12**. This result is achievable by a Code Generator **314** and an Optimizer **840**, but not as easily as the routine in FIG. **12**. This routine requires just three instructions in the core of the loop. Such a short loop suggests a pipelined stream of instructions, one that could be scheduled to achieve maximum overlap of long-latency instructions, as in FIG. **14**. The total number of instructions per half-vector output does not change from FIG. **13**, but as four half-vectors are "in flight" at the same time (which is possible because of the freeing of registers due to the By-Component **930** decomposition and the constant matrix specialization), this code will probably schedule better on many CPUs.

[0207] To summarize the performance of a MATVEC4×4 Parallel Task Engine, we can see from this example, that given what we take as an efficient routine for computing a 4×4 matrix-vector product, i.e. FIG. **10**, using By-Component **930** decomposition, with two or four CPUs, we can generate vector products roughly 4/3 as fast (loop body length ratio of 12/16) as any ordinary By-Domain **925** decomposition to multiple CPUs, with no extraordinary effort. When routines are dynamically generated with specialized knowledge of matrix contents, they can be faster (16/7 as fast, loop body length ratio of 7/16, in this example), again without extraordinary effort. With a very advanced Optimizer **840** the performance of specialized code can be even better (16/3 faster, in this example).

[0208] By-Component **930** or other By-Function **920** decompositions are useful when the full-datum or full-function routine is "too big" to fit in the register set of the CPU. By-Domain **925** decompositions are generally productive, and in a multi-CPU environment, domains may also be interleaved. As shown by this example, several aspects of the Parallel Task Engine **300** can leverage each other to provide greater than linear speed-up when applying multiple CPUs to the data processing problem:

[0209] The availability of multiple CPUs with multiple data caches makes certain problem decompositions practical, which would not be practical in a single-CPU environment. This is true for By-Component **930** and any other interleaved By-Domain **925** decompositions.

[0210] By-Domain **925** interleaved decompositions may contain address arithmetic or other expressions which can be simplified in more specific variants of Operation **810** routines, because of knowledge of evenness, oddness, or other implicit numeric properties of data indices under the interleaved decomposition.

[0211] The appropriate By-Component **930** or By-Function **920** problem decomposition can yield Operation **610** routines that are simpler and faster, splitting the computation of results over multiple CPU register sets. These routines can

then make better use of individual CPU resources, which may allow more data to be computed per iteration, and which may schedule better, leading to better overall efficiency per CPU. They are also easier for a static or dynamic Optimizer **840** to improve.

[0212] By-Component **930** and other By-Function **920** decomposed routines can be created dynamically ('algorithmically decomposed') by the Code Generator **314**, deriving them from generic routines by applying the Optimizer **840** to the generic code.

[0213] Specialization of Operation **810** routines with knowledge of run-time constants can lead to great improvements in processing speed. The presence of a dynamic Code Generator **314** and an Optimizer **840** that can derive specialized routines from generic routines is a general solution to the specialization problem. Small, simple routines, obtained from better decompositions, are also easier to specialize.

[0214] Decompositions are chosen, either at run-time, or by experimentation, the results of which are then fed back into the configuration of the Scheduler **312**, so that the decompositions produce the best sum total performance, based on an examination of the operation routines generated. The example just given is a methodical exercise in this decomposition process. When the Scheduler **312** makes these decisions at run-time, it must perform a similar analysis of code, weighing the benefits of different decompositions, optimizations, and specializations. Decomposing to get the same amount of work done across all CPUs, with best per-CPU code in dynamically generated Operation **810** routines, is a novel decomposition strategy, and a means for pursuit of this strategy as presented here, is a feature of the invention.

[0215] Application 2: 3D Graphic Image Renderer. A 3D graphics image renderer, like the pipeline **200** represented in FIG. **2**, can be implemented with the Parallel Task Engine **300**. It consists of: Vertex processing (position transformations and lighting); Primitive assembly or "setup", clipping, culling, and rasterization; and Fragment or pixel "shading" (coloring, texturing, buffer operations).

[0216] Each of these stages of computation can be performed by a dynamically generated Operation **810** routine that is specialized according to run-time values of graphics CONTEXT variables. The processing involved in the graphic pipeline is ripe for parallel decomposition—many primitives, defined by many vertices, enclosing many pixels, all of these stages have many processing steps, and all of these basic data types have many independent properties.

[0217] This graphics pipeline can also support application-provided vertex programs and pixel shaders. These programs are simply part of the graphics CONTEXT, and the Code Generator **314** now creates vertex, setup, and pixel Operation **810** routines using these programs as a source of semantics, instead of the usual fixed function definitions. The result is the same, Operation **610** routines for the three stages specific to the CONTEXT.

[0218] These computations at the three stages require large amounts of temporary state, such as buffers and data structures that represent the initial conditions or intermediate results of the computation as it progresses. For example, vertex processing may keep a cache of already-processed vertices, as vertices may be shared by contiguous primitives. For this reason, it is convenient to have stages perform their computations 'at', or conjunction with stage Units **1510**. Units **1510** are static data structures enclosing temporary data, utilized by the stage computations, and specific to a

particular kind of stage (vertex, setup, or pixel) computation. Stage computations must be attached to an available (no other computation in progress) Unit **1510** of the right kind in order to commence.

[0219] FIG. **15** shows the data flow and stages of computation in the graphics pipeline. The horizontal rows show vertex, setup, and pixel Units **1510**, with all Units **1510** of the same kind in their own column. There is no specific relationship between the rows and Job Loops **318**, or any partition of Primary Data **306**. The diagram depicts an array of Units **1510**, and the paths that the data may follow, as it is transformed. Any Task **500**, for any stage of processing, may be attached to any available Unit **1510** of the right kind, and then the Task **500** may be assigned to any Job Loop **318**. The system is set up with as many Units **1510** of a certain kind as required to support concurrent stage computations of that kind.

[0220] In the Parallel Task Engine implementation of the graphics pipeline, input Tasks **302** specify lists of graphics primitives to be rendered. The input Primary Data **306** is a collection of vertices and primitive definitions. The output Primary Data **306** is the display frame buffer. Auxiliary data such as transformation and projection matrices, texture and light source definitions reside in the graphics CONTEXT.

[0221] The Scheduler **312** for this graphics pipeline has these policies:

[0222] Primitives are drawn in first-in, first-out order. All pixels of a primitive may not be displayed at once, but for any pixel in the frame buffer, pixels from primitives are written in the same order as the primitives themselves are (requested to be) drawn, e.g. the pixel resulting from the first primitive drawn will be written first, and the pixel from the last primitive drawn will be written last. This will preserve the effect of primitives that are drawn over portions of other primitives.

[0223] Pixel Tasks **500** are dependent on setup Tasks **500** that process the outlines, compute gradients for interpolation, and perform the rasterization of the primitives that enclose or bound them. Primitive setup Tasks **500** are dependent on the vertex Tasks **500** that process the vertices that define the primitive.

[0224] Pixels are written to the frame buffer as soon as possible, while preserving drawing order as described above. Pixel sub-Tasks **500** are done before their enclosing primitive setup Tasks **500**, which are done before their defining vertex Tasks **500**, in other words, as soon as the Tasks **500** on which they are dependent have completed. For any set of pixels covered by a pixel Task **500**, the pixel Tasks **500** for primitives drawn earlier are done before the pixel Tasks **500** for that same set of pixels resulting from primitives drawn later. The same ordering with respect to their source primitives is true for setup and vertex Tasks **500**.

[0225] Tasks **500** must be assigned to a Unit **1510** of the right kind to do their work. If the right kind of Unit **1510** is not available (free) for use, the Task **500** cannot be scheduled. When a Task **500** is assigned a Unit **1510**, the Unit **1510** is unavailable until the Task **500** is complete.

[0226] Tasks **500** are decomposed in several ways:

[0227] The input Task **302** is a list of primitives to render. This input Task **905** is first split into Tasks **940** for two passes. These two passes are a decomposition By-Component **930** of the final frame buffer pixels—the first pass computes only the z-buffer value of the rendered pixels. The second pass computes everything but the z-buffer value, and uses the first pass

14

z-buffer value in the traditional way, in order to determine whether the pixel should be drawn or not.

[0228] A (pass 1 or pass 2) primitive-list rendering Task **905** can be decomposed By-Domain **925** into Tasks **940** with shorter lists, or batches of one or more primitives to render.

[0229] A primitive-list rendering Task **905** is decomposed by FUNCTION into a vertex Task **940**, a primitive assembly or setup Task **940**, and a pixel Task **940**, modeling the pipelines **200** of FIGS. **2** and **1500** of FIG. **15**. These Tasks **940** are successive stages, the pixel Task **940** is dependent on the setup Task **940**, and the setup Task **940** is dependent on the vertex Task **940**.

[0230] The vertex Task **500** has a Data Pointer **520** from the input Task **302** to a vertex buffer containing all of the vertices for all of the primitives, to be processed en masse, regardless of their primitive associations. This vertex Task **905** can be decomposed By-Domain **925** into multiple independent vertex Tasks **940**. This decomposition may be 'blind', or it could be sorted according to association with groups of primitives.

[0231] Vertex processing includes many cases of matrix-vector multiplication, which may be decomposed By-Component **930** and By-Domain **925**, as in the matrix-vector example described above.

[0232] The primitive setup Task **905** has a Data Pointer **520** to a list of primitives to render, from the input Task **302**. It can be subdivided By-Domain **925** into multiple independent Tasks **940** with shorter lists of primitives. Depending on how the original vertex Task **905** was decomposed, some setup sub-Tasks **940** may not be dependent on all of the vertex sub-Tasks **940**.

[0233] The pixel Task **905** can be decomposed By-Domain **925** into pixel groups of various kinds. One alternative is multiple sections of the display screen. Another is interlaced, or alternating horizontal bands on the display, one or more pixels tall. Or the pixel Tasks **940** can be sorted according to primitive groups, or types. The pixel Tasks **905** may also amenable to By-Component **930** decompositions, e.g. color values, the components of which can be computed independently, in certain lighting and shading operations.

[0234] In order to effect its Task **500** ordering policy, the scheduler must look for the earliest pixel Task **500** (from the earliest primitive), check its dependencies, and if none are ready, look for the earliest setup Task **500**, and if none are ready, choose the earliest vertex task. This can be done in a number of ways. One convenient way is to keep the Tasks **500** on a linked list, as in the matrix-vector example above. When decomposing primitive-list rendering Tasks **905** into vertex, setup, and pixel Tasks **940**, they are added to the list in reverse order: pixel, setup, and vertex. Now the scheduler can start from the head of the list, and simply choose the first Task **500** with no outstanding dependencies, and for which a Unit **1510** of the right kind is available.

[0235] The Code Generator **314** for the graphics pipeline can take advantage of the following opportunities for specialization and optimization:

[0236] The first pass and second pass are By-Component **930** final pixel decompositions of the pixel's depth, z, and the complementary components to z. The first pass Operation **610** routines can be dramatically reduced, as most of the results which will be computed in pass 2 Tasks **500** are not needed in pass 1.

[0237] Because the z-buffer is filled early (before pass 2 starts), as soon as rasterization is complete, it is known for any pixel whether or not the pixel will eventually be written to the frame buffer. No additional processing will be done for pixels that are not displayed. This is a kind of 'depth-sorting' that occurs naturally with this decomposition and this engine.

[0238] All of the graphics processing stages depend on many variables, options, and auxiliary data in the graphics CONTEXT. There are hundreds of opportunities to specialize Operation **610** routines by knowledge of variables that are constant at run-time, and therefore many conditional tests and branches in generic Operations **810** will be removed by the Synthesizer **820**, Optimizer **840**, or by substituting canned routines (Locate Static Code **830**) for specific variants of Operations **810**. For example, multiplying or dividing by a constant of one means that the multiplication or division can be eliminated.

[0239] Vertex processing includes many cases of matrix-vector multiplication, and the optimizations presented in the matrix-vector multiplication example above may be used in vertex processing.

[0240] Logical primitive setup stages. Primitive setup can be broken into several stages, as depicted in FIG. **16**. Stage **1601** assembles the vertices of the primitive, in the illustration a triangle. Stage **1602** performs back-face culling by determining the winding order of the triangle's vertices. This stage is skipped for line and point primitives. Stage **1603** constructs a polygon covering the primitive's fragments and clips it against the visible region. Stage **1604** projects the clipped polygon into screen space and scan-converts its edges. Stage **1605** computes z and vertex attribute gradients. A detailed description of the operations performed in stages **1603** and **1604** related to rasterization, together called the rasterization stage, follows in the next section.

[0241] Primitive setup rasterization stage. The first step in rasterizing primitives is to construct a polygon covering their fragments. Triangle primitives can use their vertex positions directly as such a polygon. Line primitives require the construction of a thick line shaped polygon surrounding the line in screen space. One way to achieve this is to construct a 1-pixel wide rectangle as depicted in FIGS. **18**(a) and (b). The white-filled circles connected by the dotted line represent the vertex positions in screen space. The black dots represent the screen space positions of the newly constructed polygon. In FIG. **18**(b) every polygon edge is located at 0.5 pixel distance from the polygon, to avoid underdraw (missing pixels) in between connecting lines. To comply with the industry-standard 'grid-intersect quantization' (or 'GIQ', described in "The m-Dimensional Grid Point Space", Reinhard Klette, Computer Vision Graphics Image Processing. Vol. 30, pp. 1-12, 1985) rasterization rule using diamonds, two 1-pixel sized diamonds have to be constructed in screen space, centered around the line's vertices, as depicted in FIG. **18**(c). The six points forming the convex hull of the diamonds are used as the polygon for rasterization. Point primitives require the construction of an axis-aligned square polygon in screen space, centered on the point's position. The second step in rasterization consists of clipping the constructed polygon using the Sutherland-Hodgman clipping algorithm, against viewing frustum planes and optional application-controlled clipping planes. The viewing frustum and viewport scaling can be adjusted to provide viewport and scissor clipping functionality. Only positions are clipped; the constructed polygon does not include vertex attribute data. The next step is to rasterize the outline of the (clipped) polygon, and is illustrated in FIG. **17**. For every edge of the polygon (a pair of points), it is determined whether it is on the left or right side of the polygon. For every scanline **1703** intersecting the edge, the x-coordinate of the intersection is computed, and stored in the left outline array **1701** or right outline array **1702** depending on which side the edge is located, at an index corresponding to the scanline's y-coordinate. For anti-aliasing purposes intersections can be computed at higher resolution. The inter-

sections can be computed efficiently using a variant of Bresenham's line drawing algorithm, the 'digital differential analyzer' (DDA) algorithm or a fixed-point or floating-point edge stepping method. Together with the outline arrays the top and bottom index where the polygon is located in the outline arrays **1701** and **1702** is stored. The (clipped) polygon can now be discarded. Gradient setup calculations use the original vertices of the primitive. The outline arrays and top and bottom indices can now be used by the interpolators to determine coverage masks for pixels or groups of pixels: For every fragment the coverage can be determined by comparing it's x-coordinate to the left and right outline arrays at the index corresponding to the fragment's y-coordinate. This process can be done in parallel for a group of fragments. Advantages of the whole rasterization algorithm compared to prior art are the ability to clip every type of primitive to viewport and scissor edges at an early stage, computing fragment coverage at a lower per-fragment cost than using half-space functions (as described in "Triangle Scan Conversion using 2D Homogeneous Coordinates", Marc Olano and Trey Greer, Proceedings of the 1997 SIGGRAPH/Eurographics Workshop on Graphics Hardware), and computing coverage of groups of fragments in parallel on the same processor and in parallel for multiple groups of fragments on multiple processors.

[0242] Performance of the Graphics Pipeline. A graphics pipeline implemented via the Parallel Task Engine **300** as described above can keep multiple CPUs busy throughout every stage of image rendering, from the original list of primitives to display, to the final pixel frame buffer operations. This, in concert with the previously described beneficial problem decomposition, and dynamically generated context-specific optimized code, as well as specific, novel graphics processing algorithms detailed above, can give a super-linear acceleration of the rendering process when applied via this engine to multiple CPUs.

[0243] While illustrated in the block diagrams as groups of discrete components communicating with each other via distinct data signal connections, it will be understood by those skilled in the art that an embodiments are provided by a combination of hardware and software components, with some components being implemented by a given function or operation of a hardware or software system, and many of the data paths illustrated being implemented by data communication within a computer application or operating system. The structure illustrated is thus provided for efficiency of teaching the present embodiment.

[0244] It should be noted that the present description is meant to encompass embodiments including a method, a system, a computer readable medium or an electrical or electro-magnetic signal.

[0245] The embodiments described above are intended to be exemplary only. The scope of the description is therefore intended to be limited solely by the scope of the appended claims.

1. In a computer system, a parallel task engine for performing tasks on data, the parallel task engine comprising:

an input for receiving tasks, each task for performing an operation;

a scheduler for decomposing the tasks into one or more new tasks, the decomposing being dependent on at least one policy selected from a given set of policies;

a run-time dynamic code generator for generating, for the new tasks, operation routines, the run-time dynamic code generator comprising a dynamic compiler, the dynamic compiler being adapted to output the operation routines for execution;

a set of job loops, at least one of the job loops for performing the new tasks on at least part of the data by executing the operation routines, the job loops running in parallel on two or more CPUs;

the scheduler for distributing and assigning the new tasks to the at least one of the job loops; and

the scheduler for making the selection of the at least one policy based on general heuristics.

2. The parallel task engine of claim **1**, wherein the given set of policies include one or more of: by-domain policies, and by-component policies.

3. The parallel task engine of claim **2**, wherein the scheduler performs by-domain decomposition on a given task by modifying data pointers or parameters of the given task.

4. The parallel task engine of claim **2**, wherein the scheduler performs by-component decomposition on a given task having a full datum operation, by dividing the full datum operation into a plurality of component operations, and determines whether the component operations must be applied sequentially, in parallel or in an arbitrary order.

5. The parallel task engine of claim **1**, wherein the scheduler decomposes the tasks into new independent tasks to be performed in parallel on two or more CPUs.

6. The parallel task engine of claim **5**, wherein the new independent tasks associated with a given task have different parameters and data pointers than the given task and perform the same operation associated with the given task.

7. The parallel task engine of claim **1**, further comprising a cache for retaining and retrieving the operation routines, wherein the cache comprises a directory of cache entries, each entry comprising:

an operation routine pointer, and

a tag to be matched when searching the cache for operation routines, the tag consisting of an operation routine identifier and a context, the context having a collection of variables, or a pointer to a collection of variables.

8. The parallel task engine of claim **7**, wherein the run-time dynamic code generator further comprises an optimizer, the optimizer taking as input an operation routine from the operation routines, or a pointer to an operation routine from the operation routines, the optimizer producing as output an output operation routine, or a pointer to the output operation routine, which is semantically equivalent to the operation routine at the input.

9. The parallel task engine of claim **1**, wherein the tasks comprise graphics processing tasks for 3D objects defined as a collection of geometric primitives, and further wherein the scheduler is for decomposing the graphics processing tasks into one or more new graphics processing tasks.

10. The parallel task engine of claim **9**, further comprising a rasterization module for identifying pixel fragments covered by the primitives, the rasterization module being configured for:

assembling vertices of each of the primitives;

constructing a polygon covering the pixel fragments;

scan converting the polygon to obtain coordinates of the scan converted polygon; and

storing the coordinates in an outline buffer;

the coordinates being used in the identifying of the pixel fragments covered by the primitives.

11. The parallel task engine of claim **10**, wherein the rasterization module is further configured for clipping the polygon against a visible region prior to the scan converting.

12. In a computer system, a method for performing tasks on data, the method comprising:

receiving tasks;

decomposing the tasks into one or more new tasks, the decomposing being dependent on at least one policy selected from a given set of policies;

generating for the new tasks, operation routines, the generating comprising outputting the operation routines for execution using a dynamic compiler;

making the selection of the at least one policy based on general heuristics;

providing a set of job loops;

distributing and assigning the new tasks to at least one of the job loops;

running the job loops in parallel on two or more CPUs; and

the at least one of the job loops performing the new tasks on at least part of the data by executing the operation routines.

13. The method of claim 12, wherein the generating of operation routines uses a context having a collection of variables, or a pointer to a collection of variables, specifying at least one of options, parameters, conditions, constant data, and other data apart from the data on which tasks are performed, the context for influencing the tasks performed on the data.

14. The method of claim 12, wherein the tasks comprise a matrix multiplication of a vector by a matrix, the matrix comprised in the context.

15. The method of claim 12, wherein tasks and new tasks comprise:

a command, comprising:

a name having a numeric or symbolic identifier, or a pointer to such an identifier, the name defining an abstract operation to be performed on data;

zero, one, or more parameters; and

one or more pointers or parameters, identifying the data on which the command is to be performed.

16. The method of claim 12, wherein the run-time dynamic code generator further comprises an optimizer, producing, from an input operation routine from the operation routines, or a pointer to an operation routine from the operation routines, an output operation routine, or a pointer to the output operation routine, which is semantically equivalent to the input operation routine.

17. The method of claim 16, wherein the generating of operation routines uses a context and wherein the production of an output operation routine, or a pointer to the output operation routine, results in an output operation routine which is equivalent to the input operation routine under limitations or conditions described by the context.

18. The method of claim 12, wherein the decomposing the tasks is performed according to at least one of the following policies:

decomposing a task into one or more new tasks by partitioning the data on which the task is to be performed into

one or more subsets of that data, each new task being responsible for performing the same operation as the original task on a corresponding data subset;

decomposing a task into one or more new tasks, each of which performs a different operation than the original task, but which performs this operation on the same data set as the original task; and

decomposing a task into one or more new tasks, by partitioning an individual datum of the data on which the task is to be performed, into sub-components, each new task creating one sub-component of each resulting datum for all the data.

19. The method of claim 12, further comprising estimating, for an operation routine from the operation routines, a performance, the operation routine comprising instruction code, the estimating comprising at least one of analyzing, inspecting and measuring characteristics of the operation routine instruction code.

20. The method of claim 19, further comprising selecting the policy for decomposition which yields the highest estimated performance, based on the estimated performance of operation routines.

21. The method of claim 12, wherein the tasks comprise graphics processing tasks for 3D objects defined as a collection of geometric primitives, and wherein the decomposing comprises decomposing the graphics processing tasks into one or more new graphics processing tasks.

22. The method of claim 21, wherein the decomposing comprises decomposing the graphics processing tasks into at least one of one or more vertex processing tasks, one or more primitive processing tasks, and one or more pixel processing tasks.

23. The method of claim 21, further comprising pixel processing tasks which draw the 3D objects to a rendered image, wherein the decomposing comprises decomposing the pixel processing tasks into one or more new pixel processing tasks whereby at least two of the new pixel processing tasks contain fragments of non-overlapping regions in the rendered image, and the new pixel processing tasks are assigned to at least two job loops.

24. The method of claim 23, wherein the new pixel processing tasks are assigned to a job loop when no other new pixel processing tasks containing overlapping fragments is executing in any of the job loops.

25. The method of claim 21, wherein the new graphics processing tasks are assigned to a job loop which previously executed a new graphics processing task which shares part of the data of the new graphics processing task.

26. The method of claim 12, further comprising:

decomposing the tasks into new independent tasks; and

performing the new independent tasks in parallel on two or more CPUs.
