(54) Title: FALSE DENSITY CONTOUR SUPPRESSION USING RANDOMLY MODIFIED INPUT SIGNALS FOR COMPARISON TO THRESHOLD VALUES

(57) Abstract

False contouring of a screened halftone image without including more sub-elements in each cell, increasing the size of each cell, or decreasing the screen frequency of the image is accomplished by assigning to each sequential sub-element of a halftone cell a weighted probability of being "ON" in accordance with the value of the associated input signal.

FALSE DENSITY CONTOUR SUPPRESSION USING RANDOMLY
MODIFIED INPUT SIGNALS FOR COMPARISON TO
THRESHOLD VALUES

Technical Field

5 This invention relates generally to encoding
pictorial imagery for reproduction on binary display
and/or printing systems, and more particularly to
suppressing false density contours caused by an
insufficient number of output gray levels in the
10 reproduction system.

Background Art

Binary displays and printers are capable of
making a mark, usually in the form of a dot, of a
given, uniform size and at a specified resolution in
15 marks per unit length, typically dots per inch. It
has been common to place the marks according to a
variety of geometrical patterns such that a group of
marks when seen by the eye gives a rendition of an
intermediate color tone between the color of the
20 background (usually white paper stock) and total
coverage, or solid density.

Continuous tone images are simulated by
organizing groups of sub-elements into $j \times k$ matrix
halftone cells, where j and k are positive integers.
25 The halftone cells have gray level capabilities equal
to the number of sub-elements in the cell plus one.

Halftone image processing algorithms are
evaluated in part by their capability to deliver a
complete gray scale at normal viewing distances. The
30 capability of a particular process to reproduce high
frequency renditions (fine detail) with high contrast
modulation makes that procedure superior to one which
reproduces such fine detail with lesser or no output
contrast.

35 Another measure of image processing

-2-

algorithm merit is the tendency to produce visual details in the output image that are not part of the original image, but are the result of the image processing algorithm. Such details are called artifacts, and include moiré patterns, false contours, and false textures. Moiré patterns are false details created most often by the beating between two relatively high frequency processes resulting in a signal whose spacial frequency is low enough to be seen by the viewer. False textures are artificial changes in the image texture which occur when input gray levels vary slowly and smoothly and the output generates an artificial boundary between the textural patterns for one gray level and the textural patterns for the next gray level. False contours are the result of gray scale quantization steps which are sufficiently large to create a visible density step when the input image is truly a smooth, gradual variation from one to the other.

Briefly, several of the commonly used processing algorithms include fixed level thresholding, adaptive thresholding, orthographic tone scale fonts, and electronic screening. The present invention is concerned with the latter, electronic screening, and with suppressing false contours in screened images.

There are many formats for electronic halftone cells at various screen angles and screen frequencies. Figure 1 shows a sequence number matrix for a halftone screen design at 97 lines per inch ruling with a 400 dpi at 400 x 400 addressable points per square inch. There are eighteen levels of gray (17 sub-elements plus white) associated with each halftone cell which is enclosed within the thick lines in the figure. The numeral that is associated

-3-

with each sub-element within a halftone cell is the sequence number that the sub-elements within the cell is filled sequentially as the density in the cell increases. Each halftone cell is stacked to form a
5 halftone screen with screen angle of 104° .

A problem exists with the number of density levels attainable with a limited resolution and acceptable screen frequency. Eighteen levels is not generally sufficient; more gradations being preferred
10 to suppress false contouring. One way to get more gray levels is to include more sub-elements in a cell by increasing the size of the cell, but this reduces the number of lines per inch and decreases the screen frequency to a visible level. That is, the more
15 sub-elements in a cell, the more gray levels can be reproduced, but larger cells become more observable and objectionable.

Disclosure of Invention

It is an object of the present invention to
20 suppress false contouring of a screened halftone image without including more sub-elements in each cell.

It is another object of the present invention to suppress false contouring of a screened
25 halftone image without increasing the size of each cell.

It is still another object of the present invention to suppress false contouring of a screened halftone image without decreasing the screen
30 frequency of the image.

It is yet another object of the present invention to suppress false contouring of a screened halftone image by changing the threshold level associated with each sub-element in a halftone cell
35 in accordance with the value of the input variable.

-4-

It is another object of the present invention to suppress false contouring of a screened halftone image by assigning each sub-element a weighted probability of being printed in accordance
5 with the value of the input variable.

These and other objects of the present invention are realized by apparatus which includes means for converting a continuous tone original image into a series of input signals whose values are
10 representative of the gray level of successive picture elements of the original image; means for printing groups of sub-elements sequentially organized into two dimensional matrix halftone cells, each halftone cell being associated with one of the
15 input signals; and means for assigning to each sequential sub-element of a halftone cell a weighted probability of being "ON" in accordance with the value of the associated input signal.

The invention, and its objects and
20 advantages, will become more apparent in the detailed description of the preferred embodiments presented below.

Brief Description of the Drawings

In the detailed description of the preferred
25 embodiments of the invention presented below, reference is made to the accompanying drawings, in which:

Figure 1 is a typical electronic halftone function unit cell known in the prior art;

30 Figure 2 is a schematic view of the electronic screening process known in the prior art;

Figure 3 is a plot of the apparent output lightness produced by the sequential activation of the unit cells of Figure 2;

35 Figure 4 is a probability curve of the

-5-

output sub-element being "ON" when the input pixel value is at a certain lightness;

Figure 5 is a plot of digitized lightness threshold values verses sequence numbers of a
5 halftone cell according to the present invention;

Figure 6 is a schematic view of one embodiment of the electronic screening process according to the present invention;

Figure 7 is a schematic view of another
10 embodiment of the electronic screening process according to the present invention; and

Figure 8 is a schematic view of a memory device according to one embodiment of the present invention.

15 Best Mode for Carrying Out the Invention

The present description will be directed in particular to elements forming part of, or cooperating more directly with, apparatus in accordance with the present invention. It is to be
20 understood that elements not specifically shown or described may take various forms well known to those skilled in the art.

Figure 2 shows a schematic view of the electronic screening process. Signal X_i represents
25 the lightness or gray level information at a pixel sampling point "i" of an image. Input signal X_i of sample image picture elements is compared with a series of threshold values C_i selected in sequential order from a lookup table of
30 two-dimensional matrix values defined to be the halftone cell threshold set, and a print/no-print decision is made. The series of threshold values and their arrangement within the threshold set determine the gray scale range, the frequency, angle, and other
35 properties of the halftone pictorial image. Each

-6-

threshold level C_i is determined by a comparison
j x k matrix. When the input signal X_i exceeds the
threshold level C_i , the corresponding sub-element
is determined to have a print level or logic level
5 "ONE". By comparing the input signal X_i with the
threshold levels, j x k output signals O_i are
produced. A density pattern consisting of a
combination of j x k sub-elements is obtained by
dividing each picture element into j x k sub-elements
10 and systematically printing them or leaving them
blank.

Figure 3 is a plot of the apparent output
lightness threshold values " L_i " produced by the
sequential activation of the unit cells of Figure 1
15 plotted against the sequence number of the halftone
matrix cell, where:

$$L_i = 25.4(100 R_i + 0.1)^{0.33} - 16$$

and R_i is the input reflectance. In lightness
space, equal step changes have equal visual impact.

20 As can be seen from Figure 3, in a halftone
system with limited numbers of addressable
sub-elements per halftone cell, and if the threshold
values are fixed in the output threshold matrix,
there will be significant output density contouring
25 in the low density (high lightness) region. If, for
example, the input pixel lightness value at the sixth
sequence number (threshold value = 117) is at a value
of 118, this output sub-element is not turned "ON".
If the input pixel lightness value is at a value of
30 117, this output sub-element is turned "ON"; thereby
creating an output density jump. This output density
jump occurs when the input pixel lightness value is
near a threshold value on the output threshold
matrix, thereby creating density contouring in broad,
35 flat field areas. In color reproductions, hue shift

-7-

can sometimes occur due to this problem.

According to the present invention, instead of using a fixed threshold value for a particular sequence number, each sequence number is assigned a probability that the associated sub-element is turned "ON" for a given lightness value. This eliminates the sudden jump in density when the input pixel lightness value is close to an output threshold value.

Figure 4 is a portion of a probability curve of the output sub-element being "ON" when the input pixel value is at a certain lightness. One way to provide a probability of turning "ON" a particular sub-element is to allow a 50% probability sub-element turn-on rate at a predetermined lightness value, and to assume an equal probability distribution on each side of the threshold value from 0% to 100%. This would preserve the tone reproduction of the system in a broad area, and would, in effect distribute the output threshold values into spacial frequency space to give a sensation of gray that is not available when the number of addressable sub-elements within a halftone cell is limited.

In the illustrated example of Figure 4, a 50% probability of turning "ON" the sub-element at sequence number 6 is set at an input pixel lightness value of 117 (117 was chosen for this example because it was the threshold value of sequence number 6 in Figure 4). A uniform probability distribution is assumed on both sides of the 50% position to preserve tone reproduction. In this case a linear distribution is assumed, although it does not need to be. At an input lightness value of less than 112, the probability of that sub-element being "ON" is 100%. Similarly, at an input lightness value of more than 123, the probability of that output sub-element

-8-

being "ON" is 0%. Between these two values, the probability varies linearly.

The probability distributions of each threshold value can overlap that of the neighboring
5 threshold values. Alternatively, as shown in Figure 4, it may be desirable to leave a "dead band" between the probability distributions to reduce granularity; especially when there are very few gray levels available (very few addressable sub-elements)
10 within a halftone cell. The width of the dead band is a trade off between contouring and granularity, and less dead band is needed as the number of gray levels increase to, say, about 32 gray levels; beyond which generally no dead band is needed.

15 Figure 5 is a plot of the digitized threshold values verses the sequence number for the latter case, where a dead band is provided. Note that the sudden jumps in lightness threshold values as a function of sequence number apparent in Figure 4
20 have been greatly smoothed in Figure 5. As a result, the density contouring problem has been greatly reduced.

Figure 6 is a schematic view of one embodiment of specific components, and the way those
25 components are interconnected, for effecting false density contour suppression according to the present invention. Signal X_i represents the lightness or gray level information at a pixel sampling point "i" of an image. A randomly generated value between
30 $\pm(a_{i1}-a_{i0})/2$ is added to input signal X_i , and the sum is compared with a series of threshold values C_i selected in sequential order from a lookup table of two-dimensional matrix values defined to be the halftone cell threshold set, and a print/no-print
35 decision is made. The series of threshold values and

-9-

their arrangement within the threshold set determine the gray scale range, the frequency, angle, and other properties of the halftone pictorial image. Each threshold level C_i is determined by a comparison
 5 $j \times k$ matrix. When the input signal sum exceeds the threshold level C_i , the corresponding sub-element output O_i is determined to have a print level (logic level "ONE"). A density pattern consisting of a combination of $j \times k$ sub-elements is obtained by
 10 dividing each picture element into $j \times k$ sub-elements and systematically printing them or leaving them blank.

Figure 7 is a schematic view of another embodiment of specific components, and the way those
 15 components are interconnected, for effecting false density contour suppression according to the present invention without having to use a random number generator in real time.

When a sub-element of the halftone cell is
 20 to be printed, that sub-element's number "i" is inputted to a table look-up 10. The look-up table does not contain a threshold screen function value as in the conventional system of Figure 2. Rather, if the probability factors are linear as shown in
 25 Figure 4, look-up table 10 provides the intercept " a_{i1} " (the highest lightness value for the probability function for sub-element "i") and the slope " b_i " of the line between a_{i0} (the lowest lightness value for the probability function for
 30 sub-element "i") and a_{i1} , where

$$a_{i0} = a_{i1} + 1/b_i.$$

The intercept a_{i1} and slope b_i of the sub-element in question, along with the lightness value L_i , are used to calculate a probability

-10-

factor P_i according to the following equations:

$$\text{For } L_i > a_{i11}; \quad P_i = 0$$

$$\text{For } L_i < a_{i10}; \quad P_i = 1$$

$$\text{For } a_{i10} < L_i < a_{i11}; \quad P_i = b_i(L_i - a_{i11})$$

5 Probability factor P_i is inputted to a
memory device 12 which can be pictured as a table
with "j" number of rows and "k" number of columns.
The table is made up of "print" and "no-print"
decisions. Each row represents a different
10 probability factor that a sub-element will be
printed.

For example, Figure 8 is a memory location
table for memory device 12 of Figure 7. There are 49
rows and 100 columns. The 49 rows of memory
15 represent a 2% probability increment from 2% to 98%
sub-element "ON" probability. Within each row of
memory, there are 100 memory locations which are
filled with logical ONES and ZEROs randomly
distributed within the row; with the percent of ONES
20 equal to the percent probability the sub-element
represented by that row will be "ON". For example, a
60% "ON" row will have 60 logical ONES and 40 logical
ZEROs randomly distributed within the row.

Referring back to Figure 4 an input
25 lightness value of 116 at the output sub-element
number location 6 will produce a calculated
probability factor P_i of 60%. This value inputted
to memory 12 will access the row (in this case row
number 30) which is most closely associated with the
30 P_i value. A column (0 to 99) in row 30 is randomly
selected (via a random number generator, by shifting
the address of the column after each access, or by
use of a noise generator and A/D converter to get the
random access). The value in that memory location
35 (logical ONE or Zero) represents a randomly

-11-

generated, 60% probability that the sub-element will be "ON."

While the 49 rows of memory 12 which generate the probability can be used for every
5 sequence number location "i", the values of a_{i0} and a_{i1} will of course be different. Also, if one desires a non-linear probability function, a different equation is needed to calculate P_i .
10 However, after P_i is calculated, memory 12 can be used to get a weighted value in a random fashion for contour suppression purposes. Further modification to the system can be a different number of memory locations within each row, or a different number of rows, to get different precision.

15 The invention has been described in detail with particular reference to preferred embodiments thereof, but it will be understood that variations and modifications can be effected within the spirit and scope of the invention.

-12-

What is claimed is:

1. Apparatus for suppressing false density contours in halftone reproduction of continuous tone original images, including means for converting a
5 continuous tone original image into a series of input signals whose values are representative of the gray level of successive picture elements of the original image and means for printing groups of sub-elements sequentially organized into two dimensional matrix
10 halftone cells, each halftone cell being associated with one of said input signals; characterized by means for assigning to each sequential sub-element of a halftone cell a weighted probability of being "ON" in accordance with the value of the associated input
15 signal, wherein said assigning means is adapted to provide (1) a 50% probability print versus no-print rate for each sub-element at a respective predetermined picture element gray level, and (2) a uniform probability distribution on each side of said
20 predetermined gray level from 0% to 100%.

2. Apparatus as set forth in Claim 1 wherein said uniform probability distribution is linear.

3. Apparatus for suppressing false density
25 contours in halftone reproduction of continuous tone original images, including means for converting a continuous tone original image into a series of input signals whose values are representative of the gray level of successive picture elements of the original
30 image and means for printing groups of sub-elements sequentially organized into two dimensional matrix halftone cells, each halftone cell being associated with one of said input signals; characterized by means for assigning to each sequential sub-element of
35 a halftone cell a weighted probability of being "ON"

-13-

in accordance with the value of the associated input signal, wherein the probability distribution of one sub-element of a halftone cell being "ON" overlaps with the probability distribution of the next sequential sub-element cell being "ON".
