POLYCRYSTALLINE FILMS**

CROSS REFERENCE TO RELATED APPLICATION

[0001] This application claims priority under 35 U.S.C. § 119(e) to U.S. Provisional Application Serial No. 60/989,719, filed on November 21, 2007 entitled "Methods and Systems for Backside Laser Crystallization of Textured Polycrystalline Film," the disclosure of which is hereby incorporated by reference in their entirety.

[0002] This application is related to commonly owned and co-pending application filed on even date herewith and entitled "Systems and Methods for Preparation of Epitaxially Textured Thick Films," the contents of which are incorporated by reference in its entirety, which claims priority to U.S. Provisional Application Serial No. 61/012,229, filed on December 7, 2007, entitled "Methods And Systems for Backside Laser Induced Epitaxial Growth of Thick Film," the contents of which are incorporated by reference in its entirety.

[0003] All patents, patent applications and patent publications cited herein are hereby incorporated by reference in their entirety.

BACKGROUND

[0004] The technology described herein relates to systems and methods for preparing epitaxially textured polycrystalline films.

[0005] In recent years, various laser crystallization techniques for crystallizing or improving the crystallinity of an amorphous or polycrystalline semiconductor film have been investigated. Laser crystallization has been used in the manufacture of a variety of devices, such as image sensors and displays, for example, active-matrix liquid-crystal display (AMLCD) devices. In the latter, a regular array of thin-film transistors (TFTs) are fabricated on an appropriate transparent substrate and each transistor serves as a pixel controller. Large grain polycrystalline thin-films also have been used as seed layers for polycrystalline thick-film solar cells.

[0006] Laser-induced crystalline growth in thin film semiconductors, while improving location and size of the crystalline structure, can nonetheless lead to a material with an intragrain defect density that is unacceptably high for certain microelectronics and solar cell applications. Depending on experimental conditions, including the growth velocity, film

thickness and details of the irradiation, the defects can range anywhere from closely spaced stacking faults or twin boundaries, to widely spaced sub-boundaries, e.g., several μm apart

[0007] In addition, the crystal orientation of the seed can influence defect formation. For example, in pulsed-laser irradiation experiments, it is commonly found that $\{111\}$ and in particular $\{100\}$ surface orientations typically can lead to a minimally defective material, and other orientations, such as $\{110\}$ or $\{112\}$ can lead to defective growth in one or more lateral growth directions. Conventional methods of obtaining a surface-oriented film (also referred to as a textured film) are known, including zone melt recrystallization (ZMR), solid phase recrystallization, direct deposition techniques (including, chemical vapor deposition (CVD) sputtering, and evaporation), surface-energy-driven secondary grain growth (SEDSGG) and pulsed laser crystallization (SLS, multiple-pulse excimer laser annealing (ELA)) methods.

SUMMARY

[0008] The disclosed subject matter relates to systems and methods for preparing epitaxially textured polycrystalline films.

[0009] In one or more embodiments, the disclosed subject matter relates to providing a precursor film on a substrate, the film includes crystal grains having a surface texture and a non-uniform degree of texture throughout the thickness of the film, wherein at least a portion of the this substrate is substantially transparent to laser irradiation; and irradiating the textured precursor film through the substrate using a pulsed laser crystallization technique to at least partially melt the film wherein the irradiated film crystallizes upon cooling to form crystal grains having a uniform degree of texture.

[0010] In one or more embodiments, said pulsed laser crystallization technique comprises flood irradiation to partially melt the film leaving a thin portion of the film solid at the surface of the film, wherein the thin portion consists predominantly of crystal grains having a crystallographic orientation predominantly in one direction.

[0011] In one or more embodiments, said pulsed laser crystallization technique includes sequential lateral solidification wherein a portion of the crystal grains having a crystallographic orientation predominantly in one direction are completely melted and the melted portion laterally crystallizes on said crystallographically oriented crystals.

[0012] In one or more embodiments, sequential lateral solidification crystallization includes generating a plurality of laser beam pulses, irradiating a selected region of a film with one of the plurality of laser beam pulses, said beam having an intensity that is sufficient

to melt the irradiated portion of the film, wherein the irradiated portion of the film crystallizes upon cooling into a crystallographic orientation predominantly in one direction, and irradiating successive portions of the selected region with the pulsed laser beams, to substantially crystallize the selected region of the film.

[0013] In one or more embodiments, the method includes directing the plurality of laser beam pulses through a mask to generate a plurality of patterned laser beams.

[0014] In one or more embodiments, the mask includes a dot-patterned mask.

[0015] In one or more embodiments, the mask includes opaque array patterns which include at least one of dot-shaped areas, hexagonal-shaped areas and rectangular-shaped areas.

[0016] In one or more embodiments, the textured film is generated by the direct deposition methods.

[0017] In one or more embodiments, the direct deposition methods include one of chemical vapor deposition, sputtering and evaporation.

[0018] In one or more embodiments, the pulsed laser crystallization methods include one of sequential lateral solidification and multiple-pulse excimer laser annealing processes.

[0019] In one or more embodiments, the predominant crystallographic orientation is a $\{111\}$ orientation.

[0020] In one or more embodiments, the predominant crystallographic orientation is a $\{100\}$ orientation.

[0021] In one or more embodiments, a system for processing a film on a substrate, includes at least one laser for generating a plurality of laser beam pulses, a film support for positioning the film that is capable of movement in at least one direction, at least a portion of said film support transparent to laser irradiation, a mask support, optics for directing a first set of laser beam pulses through a first mask and through the transparent portion of the film support to generate a film having a uniform high degree of texture throughout the thickness of the film and a controller for controlling the movement of the film support in conjunction with frequency of the first set of and second set of laser beam pulses.

[0022] In one or more embodiments, the system includes a mask support.

[0023] In one or more embodiments, the textured film is generated by direct deposition methods.

[0024] In one or more embodiments, the direct deposition methods include one of chemical vapor deposition, sputtering, and evaporation.

[0025] In one or more embodiments, the pulsed laser crystallization methods include one of sequential lateral solidification and multiple-pulse excimer laser annealing processes.

[0026] In one or more embodiments, a system for processing a film on a substrate includes a substrate, wherein at least a portion of the this substrate is transparent to laser irradiation, a precursor film on a substrate including crystal grains having a non-uniform degree of texture throughout the thickness of the film, and means for irradiating the textured precursor film from the back side of the film using a pulsed laser crystallization technique to re-orient the crystal grains to create a thin film having a uniform high degree of texture throughout the thin film.

[0027] In one or more embodiments, said pulsed laser crystallization technique includes flood irradiation wherein the crystal grains having a crystallographic orientation predominantly in one direction are not completely melted.

[0028] In one or more embodiments, said pulsed laser crystallization technique includes sequential lateral solidification wherein a portion of the crystal grains having a crystallographic orientation predominantly in one direction are completely melted and the melted portion laterally crystallizes on said crystallographically oriented crystals.

[0029] In one aspect, a method for making a textured thin film includes providing a textured precursor film comprising crystal grains having a crystallographic orientation predominantly in one direction on a substrate, wherein at least a portion of the substrate is transparent to laser irradiation; and irradiating the textured precursor film from the back side of the film using a pulsed laser crystallization technique, wherein crystal grains oriented in said crystallographic orientation are grown on said crystallographically oriented crystals.

BRIEF DESCRIPTION OF THE DRAWING

[0030] The foregoing and other features and advantages of certain embodiments described herein will be apparent from the following more particular description, as illustrated in the accompanying drawings.

[0031] FIG. 1A is an illustrative schematic of a back side laser irradiation method in accordance with one or more embodiments described herein.

[0032] FIG. 1B is an illustrative schematic of another back side laser irradiation method in accordance with one or more embodiments described herein.

[0033] FIG. 2 is a schematic illustration of a back side laser irradiation process in accordance with one or more embodiments described herein.

[0034] FIG. 3A is an illustrative schematic of a conventional textured film.

[0035] FIG 3B is an illustrative schematic of top side laser irradiation processes in accordance with the prior art.

[0036] FIG.'s 3C-D are illustrative schematics of back side laser irradiation processes in accordance with one or more embodiments described herein.

[0037] FIG. 4 is an illustrative schematic of a hybrid sequential lateral solidification (SLS) method in accordance with the prior art.

[0038] FIG. 5 is a schematic illustration of a conventional textured film in which texture quality varies throughout the film and has the highest degree of texture at the top surface of the film.

DETAILED DESCRIPTION

[0039] The disclosed subject matter relates to a method for creating a thin film which has a uniform degree of texture and in some preferred embodiments also a uniform microstructure. This is accomplished by irradiating a deposited textured thin film from the back side of the film prior to generating the required texture throughout the film, followed by optional crystallization of the film using a crystallization technique that preserves the texture of the film, e.g., sequential lateral solidification ("SLS").

[0040] As shown in Figure 4, previous methods of creating textured thin films involved two steps: (1) generating a textured precursor (102) and (2) generating the desired microstructure using SLS (104). This method is referred to herein as "hybrid SLS."

[0041] Textured films can generally be generated either directly through deposition, or involving a post-deposition crystallization procedure. While various crystallization procedures have been demonstrated to result in highly textured films, doing so requires an additional processing step commonly involving equipment that is distinct from the equipment that is used for creating the uniform microstructure. The use of textured films obtained via deposition would thus be preferable, as it combines the deposition and texturing processes and thereby eliminates a processing step. However, thin films created using deposition methods do not typically have a uniform degree of texture throughout the thickness of the film. For example, as shown in Figure 5, after deposition of the thin film 200 on a substrate according to step 102 in Figure 4, most deposited films have a high degree of texture towards the top of the film 201, e.g., at or near to the upper surface of the film, but have a low degree of texture towards the bottom of the film 202, e.g. at or near the substrate-film interface. Thus, the film shown in Figure 5 has a non-uniform degree of texture throughout the

thickness of the film. Because of heat absorption and heat-flow considerations, pulsed-laser crystallization processes typically are seeded from material that is at or near the bottom of the film, i.e., at or near the interface of the film with the underlying substrate. Therefore when SLS is performed on the "textured" thin film to create the desired microstructure (as shown in step 104 of Figure 4), the lateral solidification process is initiated from a seed grain that is located at or near the bottom of the film 202 and the ensuing growth from the seed grain propagates laterally and throughout the thickness of the remainder of the completely molten area of the film. As stated above, in this region the film has low texture and, as such, the laterally grown grains will likely have low texture as well.

[0042] As shown in Figure IA, in order to create a thin film from a deposited textured precursor with both a uniform high degree of texture and a good microstructure, the film may be pre-treated before the microstructure controlling step or the microstructure may be controlled in an alternative way. After generation of a textured precursor film (302), the film is either treated with back side laser irradiation (303) to improve texture throughout the film thickness before optionally generating a desired crystalline microstructure using laser crystallization (304), or it is treated with back side laser crystallization to induce controlled lateral growth to directly impose a desired microstructure in a way that preserves and expands the texture. The method disclosed in Figure IA is discussed in more detail below.

[0043] In 302 of the method described in Figure IA, a film precursor having a non-uniform degree of texture through the thickness of the film is produced or provided through deposition. A textured deposited film contains grains having predominantly the same crystallographic orientation in at least a single direction. For example, if one crystallographic axis of most crystallites in a thin polycrystalline film is oriented preferentially in a given direction or along a selected axis, we refer to the microstructure as having "uni-axial texture." For some embodiments described herein, the preferential direction of the uni-axial texture is a direction normal to the surface of the crystallites (or the top surface of the film). Thus, "texture" can refer to a uni-axial surface texture of the grains as used herein. The degree of texture can vary depending upon the particular application for the film. The "degree" of texture refers to the volume or percent of crystalline that are substantially oriented on the given direction. Films having at least 80%, or at least 90% of their surface oriented to within 20 degrees or within 10 degrees or within 5 degrees of the selected axis are considered to be highly surface textured. For example, a higher degree of texture may be preferable for a thin film transistor (TFT) being used for a driver circuit as opposed to a TFT that is used for a

switch circuit. In addition, a high degree of texture may be desired in a thin film seed layer used to epitaxially grow a thick silicon layer for solar applications.

[0044] In some instances, a textured film is obtained using conventional film deposition methods, but it was observed that the degree of the texturing varied throughout the thickness of the film. Notably, the thin film can have a differential in crystal texture between the upper and lower portions of the film. For example, the thin film can have a poorer texture at the lower region of the film that is closest to the substrate.

[0045] The thin film can be a metal or semiconductor film, with a thickness between about 50 nm to about 100 nm. The metals can include aluminum, copper, nickel, titanium, gold, and molybdenum. The semiconductor films can include conventional semiconductor materials, such as silicon, germanium, and silicon-germanium. Additional layers situated beneath or above the metal or semiconductor film are contemplated. The additional layers can be made of silicon oxide, silicon nitride and/or mixtures of oxide, nitride or other materials that are suitable, for example, for use as a thermal insulator to protect the substrate from overheating or as a diffusion barrier to inhibit diffusion of impurities from the substrate to the film. For the purposes of clarity, the laser technique is described with reference to silicon; however, it is apparent to those of skill in the art that the film can be a material susceptible to melt recrystallization.

[0046] Conventional methods of obtaining a precursor film are used in Figure IA (301), including direct deposition techniques (including chemical vapor deposition (CVD), sputtering, evaporation). Other methods for producing {100} textured films include CVD and low-pressure CVD. See, e.g., *J. Electrochem. Soc.* Vol. 134, NO. 134, pp. 2541-2545 (October, 1987); *J. Appl. Phys.*, Vol. 73, No. 12, pp. 8402-8411 (June, 1993); and *J. Math Sci. Lett.*, Vol. 7, pp. 247-250 (1988). It is envisioned that other texture-inducing methods can also be used in a similar way to generate the textured precursors. As noted above, such texturing techniques typically result in the highest degree of texture on the top surface of the film.

[0047] The deposited textured precursor film is supported on a substrate that is transparent to laser energy over at least a portion of its area. By 'transparent to laser energy', it is meant that laser energy used in the treatment of the films described herein is not substantially absorbed by the substrate (e.g., the thickness of the substrate is significantly less than the absorption length therein). Thus, laser energy is selectively absorbed by the film, with concomitant heating and melting of at least a portion of the film. Optionally, a capping layer can be used on the upper surface of the thin film to be crystallized. The capping layer

can be made of a material, in particular, it can be made using materials that are inert to the textured precursor film (i.e., materials that do not interact or react with the textured precursor film), are thermally stable and/or can be readily removed after completion of the crystallization process, e.g., using hydrogen fluoride ("HF") removal. Inorganic materials such as silicon oxynitride and silicon nitride are suitable for use as capping materials. Conventional capping materials and deposition and removal techniques can be used in this process. The use of capping layers can avoid complications arising from reductions in the film's integrity during the irradiation process. For example, using irradiation, the film can become discontinuous due to fluid flow, i.e., melting.

[0048] It has been observed that both capped and uncapped thin films can remain intact during back side irradiation procedures. The film stays largely intact even in the absence of a cap layer during irradiation. It is speculated that in uncapped samples, a thin native oxide layer can form or exist that is sufficiently strong and/or robust to support the film during laser-induced melting. In some other embodiments, the capping layer can serve as a supersubstrate that serves to reverse the direction of heat flow in the film away from the substrate, which can further help equalize the texture gradient as is discussed in greater detail below.

[0049] Formation of textured films has been previously described in an application by James Im, United States Ser. No. 10/994,205, filed November 18, 2004 and entitled "System and Methods for Creating Crystallographic Controlled Orientation Controlled PolySilicon Films," the contents of which are incorporated herein in its entirety by reference. In that process, a film was pretreated to introduce a desired texture into the film and then crystallized using SLS laser irradiation to form the enhanced crystal growth that is typical of SLS.

[0050] However, a film that is deposited according to conventional methods, does not have a uniform degree of texture, and further lacks a uniform microstructure, i.e., the grains are randomly located on the surface and are of no particular size. As shown in Figure IA, the next step of the method, back side irradiation (Step 303), creates the uniform degree of texture throughout the thickness of the thin film. The laser therefore first passes through the substrate (or a transparent portion of the substrate) before entering the thin film. Back side irradiation takes advantage of the location of the higher texture quality generated at the top surface of the film. During back side irradiation, heat-flow considerations suggest that the lateral growth will proceed from the top side of the film, which will have the highest degree of texture.

[0051] Figure 2 is a schematic illustration of a method of back side irradiation in one or more embodiments as substantially described herein. In Figure 2, a laser 400 irradiates a back side 402 of a solid film 404, for example, silicon. As discussed previously, the top of the film 406 has a high degree of texture—having a uniform distribution and orientation of {100} crystals—while the back side of the film 402 has weak or no texture. The laser 400 melts the solid silicon in the film 404 to create a liquid 408. The silicon regrows from the melt with the highly textured {100} top of the film 406 serving as the seed layer for the grains. Therefore, the entire film, when cooled, has a high degree of texture, instead of just the top of the film 406.

Flood Irradiation

[0052] In one embodiment, the back side irradiation of the film can be flood irradiation. Flood Irradiation is an irradiation method in which a large area of the film, preferably larger than the heat diffusion length of the film, is irradiated with a uniform beam of light. This process can be used to induce melting in the film. Flood Irradiation is carried out from the back or the bottom side of the device through the substrate such that the lower portions of the thin film are irradiated first. As the substrate is transparent to the laser energy, it remains cool and unheated in this radiation process. The energy of the Flood Irradiation is selected to partially or nearly-completely melt the thickness of the deposited and textured film to induce regrowth of the film on the {100} oriented crystals only. Recall that the upper surfaces of the textured films are of the highest quality. Therefore, by partially and preferentially melting the lower portion of the thin film, a liquid/solid front is formed at a boundary of more highly textured material. As the molten silicon cools down and re-crystallizes from the upper surface down towards the substrate, the {100} texture will extend throughout the substrate. These films have much higher quality texture and can be used in subsequent applications, e.g., in an optional pulsed laser lateral growth process, to provide the desired large grain and grain boundary location controlled films. Then these films can be used as a textured layer in devices or other subsequent applications.

[0053] In some embodiments, the flood irradiation can be performed using systems similar to those used in the SLS process, which is discussed in more detail below. These SLS systems are described in the following patents and applications: U.S. Patent No. 6,322,625, entitled "Crystallization Processing of Semiconductor Film Regions on a Substrate, and Devices Made Therewith," as filed on November 27, 1998; U.S. Patent No. 6,368,945, entitled "Method and System for Providing a Continuous Motion Sequential Lateral

Solidification," as filed on March 16, 2000; U.S. Patent No. 6,555,449, entitled "Methods for Providing Uniform Large-Grained and Grain Boundary Location Manipulated Polycrystalline Thin Film Semiconductors Using Sequential Lateral Solidification," as filed on September 3, 1999; and U.S. Patent No. 6,573,531, entitled "Systems and Methods Using Sequential Lateral Solidification for Producing Single or Polycrystalline Silicon Thin Films at Low Temperatures," as filed on September 3, 1999, and U.S. Patent Application No. 12/063,810, entitled "High Throughput Crystallization of Thin Films," filed on February 14, 2008, the entire disclosures of each are incorporated by reference.) For example, the flood irradiation can be performed using a SLS system, but instead of front side irradiating the film, the film is irradiated from the back side. Further if a mask is used in a two-dimensional projection SLS system, i.e., the beam has a two dimensional character, the mask can be removed for the flood irradiation process. In this way, an SLS system can be used to perform the flood irradiation.

[0054] Additionally, the flood irradiation can be performed using one dimensional beam in ELA mode line scan systems. Such systems are discussed in more detail in (U.S. Patent Application No. 11/293,655, entitled "Line Scan Sequential Lateral Solidification of Thin Films," as filed December 2, 2005; U.S. Patent Application No. 12/063,810, entitled "High Throughput Crystallization of Thin Films," as filed on February 14, 2008; and U.S. Patent Application No. 11/373,772, entitled "Processes and Systems for Laser Crystallization Processing of Film Regions on a Substrate Utilizing a Line-type Beam and Structures of Such Film Regions," as filed on March 9, 2006, the entire disclosure of each are incorporated by reference). By operating in ELA mode, it is meant that beam need not be sharpened to create a more uniform energy density across the beam profile.

[0055] If either of the SLS or ELA systems are used, the fluence of the respective laser beams can be adjusted to be sufficient for only the partial melting of the film. Alternatively, the beam produced by SLS or ELA systems can be redirected through various types of optics to create a flood irradiation optimized beam to be delivered to the film.

[0056] Once a thin film with a uniform high degree of texture has been created, a uniform microstructure may be created in the thin film as shown in the Figure IA (304). This microstructure can be created using a variety of controlled lateral growth methods or methods based on such, such as SLS, that offer control of the lateral growth over a length not exceeding that at which defects may be formed for example through sub-boundary formation or twinning. The lateral crystallization using controlled lateral growth or SLS results in "location-controlled growth" of grain boundaries and elongated crystals of a desired

crystallographic orientation. Location-controlled growth referred to herein is defined as the controlled location of grains and grain boundaries using particular beam patterns and masks such as, for example, dot-patterned masks.

[0057] The process of sequential lateral solidification (SLS) generally includes the following: generating a plurality of laser beam pulses; directing the plurality of laser beam pulses through a mask to generate a plurality of patterned laser beams; irradiating a portion of a selected region of a film with one of the plurality of patterned beams, the beam having an intensity that is sufficient to melt throughout the entire thickness the irradiated portion of the film, where the irradiated portion of the film laterally crystallizes upon cooling. The process further includes repositioning the film to irradiate a subsequent portion of the selected region with patterned beams, such that the subsequent position overlaps with the previously irradiated portion, permitting further lateral re-growth of the crystal grains. In one embodiment, successive portions of the selected region are irradiated such that the film is substantially crystallized in a single traversal of the patterned beams over the selected region of the film.

[0058] These SLS systems and processes are described in U.S. Patent No. 6,322,625, entitled "Crystallization Processing of Semiconductor Film Regions on a Substrate, and Devices Made Therewith," issued November 27, 2001; U.S. Patent No. 6,368,945, entitled "Method and System for Providing a Continuous Motion Sequential Lateral Solidification Issued," issued April 9, 2002; U.S. Patent No. 6,555,449, entitled "Methods for Producing Uniform Large-Grained and Grain Boundary Location Manipulated Polycrystalline Thin Film Semiconductors Using Sequential Lateral Solidification," issued April 29, 2003; and U.S. Patent No. 6,573,531, entitled "Systems and Methods Using Sequential Lateral Solidification for Producing Single or Polycrystalline Silicon Thin Films at Low Temperatures," issued June 3, 2002, issued to Dr. James Im, the entire disclosures of which are incorporated herein by reference, and which are assigned to the common assignee of the present application.

[0059] An alternate SLS method is used in different embodiments and is referred to herein as the dot-patterned SLS process. This process uses a mask incorporating a dot pattern. The dot mask is an inverted mask, where the dots correspond to masked regions and the remainder of the mask is transparent. In order to fabricate large silicon crystals, the dot pattern can be sequentially translated about the points on the sample where such crystals are desired. For example, the dot mask can be translated a short distance in the positive Y direction after a first laser pulse, a short distance in the negative X direction after a second

laser pulse, and a short distance in the negative Y direction after a third laser pulse to induce the formation of large crystals. If the separation distance between dots is greater than two times the lateral growth distance, a crystalline structure where crystals separated by small grained polycrystalline silicon regions can be generated. If the separation distance is less or equal to two times the lateral growth distance so as to avoid nucleation, a crystalline structure where crystals are generated. Further details about this SLS method are described in U.S. Patent No. 6,555,449, entitled "Methods for Producing Uniform Large-Grained and Grain Boundary Location Manipulated Polycrystalline Thin Film Semiconductors Using Sequential Lateral Solidification," as filed September 3, 1999, the entire teachings of which are incorporated herein by reference.

[0060] In still other embodiments, the SLS process can employ a laser line beam that can be shaped with laser optics into a long aspected beam with or without the use of a mask to shape the laser beam. Further details about the SLS line beam method are found in A. Limanov and V. Borisov, Mat. Res. Soc. Symposium, Proc. Vol. 685E, DIO. 1.1 (2001); and U.S. Application Publication No. 2006/0254500, entitled Line Scan Sequential Lateral Solidification of Thin Films, published on November 16, 2006, the contents of which are incorporated in their entirety by reference.

[0061] During the SLS process, the lower regions of the film crystallize first because the heating through beam absorption is typically in the top regions of the film and because they are adjacent to the substrate, which can act as a heat sink. This allows the onset of the solidification to be initiated from the lower side of the film. Thus, performing SLS on a deposited precursor, i.e., lacking the back side flood irradiation step described herein, produces a thin film having a relatively low degree of texture.

[0062] Thus, it has been discovered that differences in the degree of the texture between the base and the top of the film (pre-SLS) has a dramatic effect on the quality and degree of the texture in the final SLS-processed film. The methods and processes developed herein address this problem by creating a uniform degree of texture prior to performing SLS.

Back side SLS

[0063] The irradiation on the back side of the thin film also can be SLS irradiation. Because laterally grown grain adopts the orientation of the seed, by selecting seed crystals of similar crystallographic orientation (texture), it is possible to grow large location-controlled (microstructure) grains of similar crystallographic orientation. The embodiments of the

disclosed subject matter are directed to particular combinations of a texture-developing technology and the SLS process, discussed in detail above.

[0064] As shown in Figure 1B, the method includes (1) providing a textured precursor film (306) and (2) back side SLS irradiation to improve microstructure and texture throughout the film thickness (308). The textured film 320, as shown in Figure 3A, is provided according to the embodiments disclosed above. Note that there are regions of low texture, 330 near the bottom of the textured film, towards the substrate 325, and regions of high texture 340 near the top of the textured film 320. The back side SLS is performed in a similar manner as the front side SLS disclosed above and shown in Figure 3B except that the SLS is performed through the substrate 325 on the back side of the film, 320 shown in Figure 3C.

[0065] In this process, the reverse effect is observed as is disclosed in the prior art crystallization techniques. Recall the previous discussion that texture was poorer in samples that were top irradiated, because lateral growth was seeded by grains located at or near the bottom interface of the film, as shown in Figure 3B (where the radiation from the front side of the thin film favors the lateral growth of poorly textured crystals 330 due to more rapid cooling at the substrate interface because of heat loss through the substrate 325). By irradiating from the back side of the film 320, the opposite occurs. Initially, the irradiation creates a heat gradient in which the melted silicon 335 is hotter at the interface with the substrate because it is closest to the laser. Therefore, crystallization will be initiated at the cooler surface of the film layer, as is shown in Figure 2. When the laser shuts off, the substrate acts as a heat sink and quickly draws the heat away from the melted silicon 335 adjacent to the substrate. However, lateral growth has already set in before this happens and thus the texture of the crystallization is dominated by the top part of the film 340. As shown in Figure 3D, a capping layer 390, may further assist in maintaining the integrity of the film 320 as well as offering a heat sink at the top to maintain for a longer period of time the reversed temperature gradient, if needed.

[0066] While there have been shown and described examples of the disclosed subject matter, it will be readily apparent to those skilled in the art that various changes and modifications may be readily apparent to those skilled in the art that various changes and modifications may be made therein without departing from the scope of the disclosed subject matter as defined by the appended claims. Accordingly, the disclosed subject matter is limited only by the following claims and equivalents thereto.

[0067] What is claimed is:

CLAIMS

1. A method for making a textured thin film comprising:
providing a precursor film on a substrate, the film comprising crystal grains having a surface texture and a non-uniform degree of texture throughout the thickness of the film, wherein at least a portion of the this substrate is substantially transparent to laser irradiation; and
irradiating the textured precursor film through the substrate using a pulsed laser crystallization technique to at least partially melt the film wherein the irradiated film crystallizes upon cooling to form crystal grains having a uniform degree of texture.
2. The method of claim 1, wherein said pulsed laser crystallization technique comprises flood irradiation to partially melt the film leaving a thin portion of the film solid at the surface of the film, wherein the thin portion consists predominantly of crystal grains having a crystallographic orientation predominantly in one direction.
3. The method of claim 1, wherein said pulsed laser crystallization technique comprises sequential lateral solidification wherein a portion of the crystal grains having a crystallographic orientation predominantly in one direction are completely melted and the melted portion laterally crystallizes on said crystallographically oriented crystals.
4. The method of claim 3, wherein sequential lateral solidification crystallization comprises:
generating a plurality of laser beam pulses;
irradiating a selected region of a film with one of the plurality of laser beam pulses, said beam having an intensity that is sufficient to melt the irradiated portion of the film, wherein the irradiated portion of the film crystallizes upon cooling into a crystallographic orientation predominantly in one direction; and
irradiating successive portions of the selected region with the pulsed laser beams, to substantially crystallize the selected region of the film.
5. The method of claim 4, further comprising directing the plurality of laser beam pulses through a mask to generate a plurality of patterned laser beams.

6. The method of claim 5, wherein the mask comprises a dot-patterned mask.
7. The method according to claim 6, wherein the mask includes opaque array patterns which include at least one of dot-shaped areas, hexagonal-shaped areas and rectangular-shaped areas.
8. The method of claim 1, wherein the textured film is generated by direct deposition methods.
9. The method of claim 8, wherein the direct deposition methods comprise one of chemical vapor deposition, sputtering and evaporation.
10. The method of claim 8, wherein the pulsed laser crystallization methods comprise one of sequential lateral solidification and multiple-pulse excimer laser annealing processes.
11. The method according to claim 1, wherein the predominant crystallographic orientation is a {111} orientation.
12. The method according to claim 1, wherein the predominant crystallographic orientation is a {100} orientation.
13. A system for processing a film on a textured substrate, comprising:
 - at least one laser for generating a plurality of laser beam pulses;
 - a film support for positioning the textured film that is capable of movement in at least one direction, at least a portion of said film support transparent to laser irradiation;
 - optics for directing a first set of laser beam pulses through a first mask and through the transparent portion of the film support to generate a film having a uniform high degree of texture throughout the thickness of the film; and
 - a controller for controlling the movement of the film support in conjunction with frequency of the first set of and second set of laser beam pulses.
14. The system of claim 13 comprising a mask support.
15. The system of claim 13, wherein the textured film is generated by direct deposition methods.

16. The system of claim 15, wherein the direct deposition methods comprise one of chemical vapor deposition, sputtering, and evaporation.
17. The system of claim 13, wherein the pulsed laser crystallization methods comprise one of sequential lateral solidification and multiple-pulse excimer laser annealing processes.
18. A system for processing a film on a substrate comprising:
 - a substrate, wherein at least a portion of the this substrate is transparent to laser irradiation;
 - a precursor film on a substrate comprising crystal grains having a non-uniform degree of texture throughout the thickness of the film; and
 - means for irradiating the textured precursor film from the back side of the film using a pulsed laser crystallization technique to re-orient the crystal grains to create a thin film having a uniform high degree of texture throughout the thin film.
19. The system of claim 18, wherein said pulsed laser crystallization technique comprises flood irradiation wherein the crystal grains having a crystallographic orientation predominantly in one direction are not completely melted.
20. The system of claim 18, wherein said pulsed laser crystallization technique comprises sequential lateral solidification wherein a portion of the crystal grains having a crystallographic orientation predominantly in one direction are completely melted and the melted portion laterally crystallizes on said crystallographically oriented crystals.
