(54) Title: SYSTEMS AND METHODS FOR REMOTE MULTI-DIRECTIONAL BARK DETERRENCE

FIG. 8A

(57) Abstract: An apparatus is described that comprises a microphone array and a plurality of transducers. The microphone array and the plurality of transducers are communicatively coupled with at least one processor. The apparatus includes the microphone array for receiving at least one signal. Each transducer of the plurality of transducers is configured to deliver a correction signal along a transducer beam spread axis, wherein the plurality of transducers is positioned on the apparatus for providing a combined transducer beam spread coverage in the horizontal plane. One or more applications running on the at least one processor use information of the at least one signal to detect a sound event. The detecting the sound event includes selecting transducers from the plurality of transducers and instructing the selected transducers to deliver a correction signal.

SYSTEMS AND METHODS FOR REMOTE MULTI-DIRECTIONAL BARK DETERRENCE

RELATED APPLICATIONS

This application claims the benefit of US Application No. 16/522,593, filed July 25, 2019.

TECHNICAL FIELD

The disclosure herein involves monitoring and deterring noise disturbances generated by an animal.

BACKGROUND

A dog may from time to time generate noise disturbances including barking episodes. Bark deterrence systems often use delivery of sound stimulus to deter this unwanted behavior.

INCORPORATION BY REFERENCE

Each patent, patent application, and/or publication mentioned in this specification is herein incorporated by reference in its entirety to the same extent as if each individual patent, patent application, and/or publication was specifically and individually indicated to be incorporated by reference.

DETAILED DESCRIPTION

Remote bark deterrent technology may incorporate a bark detect component responsible for detecting the occurrence of a dog bark and a correction component responsible for providing a stimulus to the dog when the bark detection component indicates an occurrence of a bark event. The stimulus discourages present and potentially future bark episodes. The bark detect and correction component may be combined into an integral bark detection and correction unit as further described herein.

The bark detect component may comprise a microphone (or microphone array) for analyzing one or more of audio frequency spectrum, sound pressure level (audio magnitude), and audio signature. These concepts are further described below.

An audio frequency or audible frequency is a periodic vibration whose frequency is in the band audible to the average human. The SI unit of audio frequency is the hertz (Hz). It is the property of sound that most determines pitch. The generally accepted standard range of audible frequencies for humans is 20 to 20,000 Hz, although the range of frequencies individuals hear is greatly influenced by environmental factors. In air at atmospheric pressure, these represent sound waves with wavelengths of 17 meters (56 ft) to 1.7 centimeters (0.67 in). Frequencies below 20

Hz are generally felt rather than heard, assuming the amplitude of the vibration is great enough. High frequencies are the first to be affected by hearing loss due to age or prolonged exposure to very loud noises.

Sound pressure or acoustic pressure is the local pressure deviation from the ambient (average or equilibrium) atmospheric pressure, caused by a sound wave. In air, sound pressure can be measured using a microphone. Sound pressure, like other kinds of pressure, is commonly measured in units of Pascals (Pa). The quietest sound that most people can hear has a sound pressure of 2×10^{-5} Pa, so this pressure is called the threshold of human hearing.

Sound pressure level (SPL) uses a logarithmic scale to represent the sound pressure of a sound relative to a reference pressure. The reference sound pressure is typically the threshold of human hearing: remember that it's 2×10^{-5} Pa. Sound pressure level is measured in units of decibels (dB) and is calculated using the following equation, where p is the sound pressure of the sound wave and p_0 is the reference sound pressure:

$$L_p = 20 \log_{10} \left(\frac{p}{p_0} \right) \text{dB}$$

An audio signature comprises characteristics of an audio signal that may be interpreted as a bark event. Bark detection may be as simple as detection of sound pressure level (dB) in certain frequency ranges. For example, the detection of energy within the frequency range of 140Hz and 2000Hz with a SPL above 60dB. An embodiment may add a time component to the combination of frequency and sound pressure level. Under this embodiment, a signature comprises a combination of frequency and signal pressure level analysis over a period of time. For example, the detection of energy within the frequency range of 140Hz and 2000Hz, with a SPL above 60dB, within at least three 16 millisecond periods within any ten contiguous 16 millisecond periods.

As indicated above, remote bark deterrent technology may incorporate a correction component responsible for providing a stimulus to the dog when the bark detect component indicates an occurrence of a bark event. The stimulus of course discourages present and potentially future bark episodes. The correction component typically involves a sound generation device, under an embodiment. The sound may be generated in the audible region via audio circuitry connected to a speaker or in the ultrasonic region via ultrasonic drive circuitry connected to an ultrasonic transducer.

Ultrasonic transducers convert alternating current (AC) into ultrasound, as well as the reverse. Ultrasonics typically refers to piezoelectric transducers or capacitive transducers. Piezoelectric crystals change size and shape when a voltage is applied: AC voltage makes them oscillate at the same frequency and produce ultrasonic sound. Capacitive transducers use electrostatic fields between a conductive diaphragm and a backing plate.

As indicated above, one type of ultrasonic transducer comprises the piezoelectric crystal, which converts an oscillating electric field applied to the crystal into a mechanical vibration. Piezoelectric crystals may include quartz, Rochelle salt, certain types of ceramic, etc. Piezoelectric transducers may be employed over the entire frequency range and at all output levels.

The sound generated by a correction component may be in the audible region or ultrasonic region. Some audible sounds are effective at distracting a barking dog such as white noise (white noise is a sound that contains every frequency within the range of human hearing; generally from 20 hertz to 20 kHz in equal amounts), the owner's voice, and/or the sound of coins shaking in a can. To obtain a response from a dog while not disturbing people, the ultrasonic region may be chosen, under an embodiment. The ultrasonic frequencies are heard by dogs but not typically heard by humans. The frequencies chosen are under one embodiment in the 20kHz to 27kHz range. Also, frequencies up to 50kHz may be heard by dogs and may be utilized. Sound pressure level increases as amplitude of the ultrasonic signal increases. Under one embodiment acoustic power is maximized for efficacy but only to the point where the maximum sound pressure level at the dog's ears is less than or equal a value determined to be safe for the dog and any human that is within the field of the ultrasonic field. Ultrasonic frequencies and power levels are chosen under one embodiment based on the frequencies/power levels determined to be effective for a specific dog or event type. They may be determined based on a logging/learning methodology and/or based on repeat occurrences of a behavior following an ultrasonic correction. At the ear on the animal, 115dBA may be tolerated for 15 minutes, under an embodiment. However, the scale may slide all the way to 160dBA for 1 second. Typically correction tones are 2 seconds or less. Source sound pressure level at the face of the transducer under an embodiment is typically no more than 130dBA. As long as the ear of a target animal is 1 meter away, this animal would experience levels significantly below 115dBA. This also ensures safety of humans within the field of the ultrasonic signals.

The higher the frequency of the correction sound, the narrower the beam spread. (Note that beam spread is a measure of the whole angle from side to side of the main sound beam in the far field. Beam divergence is a measure of the angle from one side of the sound beam to the central axis of the beam in the far field). Therefore, the higher the frequency, the more aligned the dog must be with the correction speaker or transducer to receive a sufficient sound pressure level to distract a dog from a barking episode.

The ultrasonic frequencies especially suffer from this phenomena. The maximum sound pressure level for the ultrasonic frequencies is found along the centerline (i.e., axis) of the transducer signal and then diminishes significantly as the angle from centerline increases.

The audible frequency bark itself has a wide, audible frequency, beam spread, and thus, the bark is detected by the bark detection circuitry from a wide angle in the horizontal plane. This angle is under one embodiment wider than the correction sound, especially if the correction sound is in the ultrasonic range.

In order to effectively interrupt an unwanted behavior exhibited by the dog, the sound pressure level, i.e. the correction signal, must be of a significant enough level when it reaches the dog's ears. The dog may not necessarily be aligned with the front of the speaker or transducer when the barking is detected. In other words, the bark detection component may detect a bark event but the animal may be outside the beam spread of the correction signal. The signal reaching the dog's ears may be significantly attenuated, possibly even below perception levels.

Carrying this concept to the next level, if a single bark deterrent system covers a wide region, a single fixed speaker or transducer may likely not generate enough sound pressure at every spot in the yard or indoor room to deter the barking behavior.

As indicated above, a bark detection and correction unit may comprise a bark detect component responsible for detecting the occurrence of a dog bark and a correction component for transmitting a bark correction signal. The bark correction (or deterrent) component may cover a wider angular region of the horizontal plane in order to optimize delivery of sound pressure levels to animals upon detection of a bark event. In other words, a wider angular correction region increases the chances of delivering sufficient sound energy, i.e. sound pressure level, to a dog's ears. The bark detection component may detect a direction of an incoming bark event and provide information to the bark correction component for activating a plurality of transducers that emit signals covering wide angular regions, for selecting a specific transducer that transmits

a bark deterrent signal in the direction of the animal, and/or for rotating one or more transducers to direct their beam spread regions in a direction of the animal.

Figure 1 shows a bark detection and correction unit 110. The unit comprises an ultrasonic transducer 185 that emits an ultrasonic signal. Figure 1 shows the ultrasonic beam spread. The beam spread comprises regions 130, 140, 150, 160, 170. Note that sound pressure level is greatest along the central axis 180 of a beam spread and dissipates as the angle 190 from central axis 180 increases. Therefore the beam spread comprises the following regions: strongest perception region 150; weaker perception regions 140, 160; and lowest perception regions 130, 170. The correction signal is more likely to reach and deter the barking behavior of an animal in region 150 version region 170.

Figure 2 shows a bark detection and correction unit 200. The unit comprises an ultrasonic transducer 210 that emits an ultrasonic signal. The unit also comprises a bark detection sensor 212 (which may be located at any position on the unit for detecting audible sound in the broadest possible range around the unit). Under one embodiment, the transducer and sensor may comprise a common component.

The sensor may comprise a microphone which is itself a transducer that converts sound into an electrical signal. Several different types of microphone may be used for implementing bark sensing methods described herein. The different types of microphone employ different methods for converting the air pressure variations of a sound wave to an electrical signal.

Under one embodiment, a detection sensor microphone comprises a MEMS (MicroElectrical-Mechanical System) microphone (also called a microphone chip or silicon microphone). A pressure-sensitive diaphragm is etched directly into a silicon wafer by MEMS processing techniques, and is usually accompanied with integrated preamplifier. Most MEMS microphones are variants of a condenser microphone design. Under an embodiment, digital MEMS microphones have built in analog-to-digital converter (ADC) circuits on the same CMOS chip making the chip a digital microphone and so more readily integrated with modern digital products.

Under one embodiment, a detection sensor microphone comprises a piezoelectric ultrasonic transducer for detecting the vibration of the bark. A piezoelectric sensor is a device that uses the piezoelectric effect to measure changes in pressure by converting them to an electrical charge.

With continued reference to Figure 2, the bark detection sensor detects sound waves 230 of a bark event. In response, the transducer emits an ultrasonic signal with beam spread 240. As the dog 250 is located directly in the path of the beam spread, the sound pressure level of the ultrasonic correction sound is likely sufficient to command attention of the animal and deter barking.

Figure 3 shows a bark detection and correction unit 300. The unit comprises an ultrasonic transducer 310. The unit also comprises a bark detection sensor 312 (which may be located at any position on the unit for detecting audible sound in the broadest possible range around the unit). Under one embodiment, the transducer and sensor may comprise a common component. The bark detection sensor detects sound waves of a bark event. In response, the transducer emits an ultrasonic signal with beam spread 340. As the dog 350 is located outside the path of the beam spread 340, the sound pressure reaching the animal is very low and very unlikely to influence animal behavior.

Figure 4 shows a bark detection and correction unit 400. The unit comprises ultrasonic transducers 410, 412, 420. The unit also comprises bark detection sensors 416, 418, 414. The transducer / sensor pairs (as seen in Figure 4) may comprise combined transducer / sensor components or discrete components paired at common locations of the bark detection and correction unit 400. (Under an embodiment, the detection sensors may be located at any position on the unit for detecting audible sound in the broadest possible range around the unit). One or more of the bark detection sensors detects sound waves 430 of a bark event. In response, the transducers 410, 412, 420 emit an ultrasonic signal with corresponding beam spread regions 440, 450, 460. As the dog 470 is located directly in the path of the beam spread 460, the sound pressure level of the ultrasonic correction sound is likely sufficient to command attention of the animal and deter barking.

The embodiment of Figure 4 effectively monitors approximately a 180 degree range comprising beam spread regions 440, 450, 460. Irrespective of the animal's location in this 180 degree region, one or more of the bark sensors detect a bark event. For example, the animal 470 may be located in region 440 in close proximity to region 450. As the animal approaches region 450 (but while still located in region 440), the animal may begin barking. As long as the bark event is detectable by at least one of the sensors 416, 418, 414, detection then triggers operation of all transducers 410, 412, 414. Assume that the bark event is only detected by microphone 416.

Nevertheless, all transducers operate simultaneously to produce overlapping beam spread regions that span approximately 180 degrees. Even if the animal accelerated into region 450 and then region 460, an effective ultrasonic signal reaches the animal.

Figure 5 shows a bark detection and correction unit 500. The unit 500 comprises eight correction units 512, 514, 516, 518, 520, 522, 524, 526. Each correction unit comprises an ultrasonic transducer. The correction units may include detection sensors for detecting bark events. Alternatively, one or more detection sensors may be placed at any other location on bark detection and correction unit 500 for detecting audible sound in the broadest possible range around the unit. As just one example, a sensor 540 may be located at a highest point (or other location) enabling detection of bark events from any direction. The combined beam spread of the transducers covers a 360 degree range around the unit 500. One or more sensors may detect a bark event anywhere in the detection region and trigger operation of all transducers. The resulting signal is then directed toward the animal irrespective of its position. Of course, fewer than eight transducers may be used to cover the 360 degree range correction region.

Figure 6 shows four microphone sensors 610, 612, 614, 616 configured as a microphone array 600 for use in detecting bark events. Assuming a Cartesian coordinate system imposed on the microphone array as seen in Figure 6, microphone 612 is located in region I, microphone 610 is located in region II, microphone 614 is located in region III, and microphone 616 is located in region IV. The microphone array may be placed on a bark detection and correction unit as seen in Figure 7. The microphones illustrated in Figure 6 detect sound waves 630 of animal 620. The microphone array is coupled to an analog to digital converter 670 which is further coupled to at least one processor 680. The microphone array, analog to digital converter, and processor are also communicatively coupled with transducers located on a bark detection and correction unit under an embodiment. The microphones receive information of the audible bark event including arrival time, phase, and magnitude at the respective microphone. This information is passed through the analog to digital converter 670 to processor 680. (As indicated above, one or more microphones may include analog-to-digital converter (ADC) circuits). Based on arrival time, phase difference, and/or signal magnitude, the processor determines the bearing to the dog relative to the position of the microphone array and therefore relative to a bark detection and correction unit using the array for detection purposes. Methods for determining the bearing from a microphone array to a sound source are further described below. The processor also uses

information of the audible bark event to confirm that the audible event is in fact a bark. Methods for detecting bark events are also further described below.

Once the bark sound is confirmed to be valid, and bearing from the unit to the pet is known, the processor 680 can easily determine, via lookup table, the proper single or multiple transducers to utilize in directing the maximum SPL to the bearing angle. The detected bearing angle may comprise a positive rotation from a zero degree reference line (as further described below). The lookup table may include bearing information for each transducer, i.e. bearing information for each respective beam axis relative to such zero degree reference line. Upon detecting a bearing to a barking animal, the lookup table may be used to select one or more transducer(s) most aligned (plus or minus a threshold degree range) with the detected bearing.

Figure 7 shows a bark detection and correction unit 700, under an embodiment. The unit includes a microphone array 600 (as seen in Figure 6) on a top surface of the unit. The microphone array is also coupled to an analog to digital converter 670 which is also coupled to a processor 680 (also shown in Figure 6). The unit 700 includes a plurality of ultrasonic transducers 710, 712, 714, 716, 718, 728 and corresponding beam spread regions. Figure 7 illustrates additional beam spread regions 720, 722, 724, 726 emanating from additional ultrasonic transducers (not shown) surrounding the bark detection and correction unit 700. An animal within a monitored region corresponding to the combined span of the beam spread regions seen in Figure 7 may bark producing sound waves that arrive at the microphone array. Under an embodiment, the microphone array may detect signals corresponding to the bark event and determine a location of the animal relative to the microphone array and relative to the ultrasonic transducers positioned around the upper periphery of the bark detection and correction unit 700.

As indicated, the microphone array 600 and processor 680 determine location of the animal relative to the unit using one or more location methods (further described below). The processor then uses information of the location and a lookup table to select the transducer or transducers (and corresponding beam spread coverage) most aligned with the bearing of the animal, i.e. to select the transducer(s) capable of delivering maximum sound pressure level to the source. Under one embodiment, the unit 700 may then identify an additional transducer or transducers on either side of the previously selected transducer(s). The bark detection and correction unit 700 then transmits a correction signal using the selected transducer and any

additional transducers. Under an embodiment, bark detection may continue during the correction phase. If a new bearing of the animal is determined, the processor may identify transducers for delivery of a correction signal in the same manner as described above. If the newly identified transducers are the same as the previously identified transducers, then the detection and correction unit may simply continue the correction signal. If the newly identified set of transducers is entirely different than previously identified set, then detection and correction unit may use the new set to deliver a correction signal. If the newly identified set of transducers partially overlaps with the previously identified set, then the detection and correction unit may simply initiate use of the additionally identified transducers (cumulative of operational transducers) in delivering a correction signal.

Figure 8A provides the same bark detection and correction unit as displayed in Figure 7 and already described above. An animal in a proximity to the bark detection and correction unit may begin barking producing a sound wave which approaches microphone array 600. The microphone array 600 and processor 680 determine location of the animal relative to the unit using one or more of the location methods further described below. The processor may determine a bearing of 225 degrees. In other words, the animal is positioned along a line corresponding to a 225 degree positive rotation from a zero degree reference line. (Figure 8B shows the bearing according the geometry of the microphone array described in Figure 6). The processor then uses information of the location and a lookup table to select the transducer or transducers (and corresponding beam spread coverage) most aligned with the bearing of the animal, i.e. to select the transducer(s) capable of delivering maximum sound pressure level to the source. In the example of Figure 8A, the processor selects transducers 710, 712 for delivering a correction signal.

Figure 9 shows a bark detection and correction unit 900, under an embodiment. The embodiment of Figure 9 features a rectangular prism. The unit includes a microphone array 600 (as seen in Figure 6) on a top surface of the unit. The microphone array is also coupled to an analog to digital converter 670 which is also coupled to a processor 680 (also shown in Figure 6). A front of the rectangular prism features an ultrasonic linear phased 1x5 array. In the event of a nearby bark, the microphone array and processor determine a bearing of the animal. Under the embodiment of Figure 9, the bearing is determined to be 225 degrees (using location methods

further described below). Utilizing beam forming from the multiple transducers, the correction sound is directed along the 225 degree bearing.

Under one embodiment a linear phased array as shown in Figure 9 may deliver a correction signal. The linear phased array comprises a number of transducer elements positioned in a physical linear array. The elements are fired sequentially from one side to the other, all within a single cycle time of the driven correction signal frequency, allowing constructive interference to focus the beam along a specified bearing. Note that waves generally do not reflect when they strike other waves. Instead, they combine. If the amplitudes of two waves have the same sign (either both positive or both negative), they will add together to form a wave with a larger amplitude. This is called constructive interference. The distance between transducers, and the phase relationship of the signals driven by each transducer determine direction of the sound beam. Further, note that the linear phased array may comprise greater than or less than the five transducers shown in Figure 9.

Figure 10 shows a bark detection and correction unit 1000, under an embodiment. The embodiment of Figure 10 features a unit in the shape of a conical tower. The unit includes a microphone array 600 (as seen in Figure 6) on a top surface of the unit. The microphone array is also coupled to an analog to digital converter 670 which is also coupled to a processor 680 (also shown in Figure 6). A top portion 1010 of the detection and correction unit is rotatably coupled to a lower portion 1020. A rotation of the top portion also rotates a position of an ultrasonic transducer 1040 around the periphery of the unit. The transducer may be rotated to any position along a 360 degree path around the exterior of the unit. Under one embodiment, the bearing of a barking animal is determined to be 225 degrees (using location methods described below). The transducer is then rotated to deliver an ultrasonic signal with a beam spread axis aligned along the 225 degree bearing. Note that the embodiment of Figure 10 may comprise multiple transducers. As one example, multiple transducers may be equally spaced around a periphery of the unit. The processor 680 may use information of the bearing and information of transducer location (available via lookup table) to rotate the transducers in a direction (clockwise or counterclockwise) that positions a transducer (or transducers) for operation with the least amount of rotation.

One or more applications may run on the processor described above for (i) determining effectiveness of a driven correction sound based on time between barking episodes; (ii) changing

the correction sound when a driven correction sound is determined to be ineffective, i.e. the dog continues to bark; and/or (iii) improving detection of bark sounds and rejection of non-bark sounds.

The processor monitors and analyzes the bark events, under an embodiment. Based on the bark (or even bark type as further described below) and repeat episode timing or sequence, the correction sound can be found to be effective or ineffective.

An example is as follows:

A. Detect bark.

B. Drive a frequency range with a specific on/off pattern as a deterrent for a period of time. Under an embodiment ultrasonic products drive fixed-amplitude chirps or signals from about 22kHz to 27kHz at varying time intervals including time intervals ranging from 600 milliseconds to 4 seconds. These fixed amplitude chirps / signals may under an embodiment start at 22kHz and rise to 27kHz within the correction period. Under an alternative embodiment, these fixed amplitude chirps / signals may start at 37kHz and rise to 42kHz within the correction period.

C. Monitor for a repeat bark event for a period of time.

D. If the period of time shows a continuation of the same barking episode (i.e. repeats within 5 seconds), the chosen frequency range and specific on/off pattern can be repeated.

E. If A-D occurs more than a pre-determined number of times a new frequency range and specific on/off pattern can be driven.

Repeating A to E.

Systems and methods for detecting bark events are set forth in United States Patent Application No. 15/871,846, filed January 15, 2018, which application is incorporated herein by reference as if set forth herein in its entirety. Bark detection methods of a bark detection and correction unit are further described below.

Note that the microphone array of a bark detection and correction unit may be coupled to a front end filter controlled by firmware running on one or more processors as further described below. Further, the bark detection methods described below incorporate power saving functionality by scheduling detection tests to terminate a detection process early when the sound event clearly fails to qualify as a bark.

The electrical signals provided by a microphone array's detection of a nearby sound event is processed through a series of three analog operational amplifier stages. Stage one provides buffering and a ~160Hz high pass filter. The filter eliminates low frequency content of the signals that are primarily created from (non-bark) activity. Stage two provides unity gain with variable attenuation that is updated and controlled by the bark detection algorithm firmware. If the signal is found to be very large in magnitude (using most of the dynamic range of the ADC (Analog to Digital Converter)) the signal is attenuated in the second stage in an attempt to prevent clipping of the signal (a condition in which the input signal exceeds the dynamic range of the ADC). The third stage is a fixed gain stage to increase the overall signal to optimally conform to the electrical limits of the ADC with no attenuation from stage 2. The overall set point for the gain is a function of both the mechanical and electrical characteristics of the entire system. Finally, the conditioned signals from the three stage operational amplifier AFE (analog front end) are converted to a digital equivalent by using an ADC which is used by a bark detection algorithm for bark event detection, under one embodiment. The bark detection algorithm runs on a processor as shown in Figure 6 above.

The algorithm for bark detection analyzes the whole waveform of a sound event to accept or reject the sound event as a bark. This improves both bark detection and false (non-bark) rejection.

The bark detection algorithm samples the signals from the ADC. A number of criteria are included as part of this method of discrimination. The algorithm works to positively detect a bark event on the basis of not being rejected by the following criteria:

Too Few Timeslots - This indicates a short duration event such as a strike, a bump, or a quick scratch or scrape. The bark detection algorithm identifies these events and aborts as quickly as possible in order to conserve battery. On the other hand, if an early abort does not occur due to a short duration event, then a single trigger event can cause an increment of more than one (possibly several) of the abort causes listed below. That is, a possible bark can fail the bark validation for more than one reason.

Abort Unsaturated Timeslots - This means that the signal amplitude was too high. Too many time slots were saturated; meaning there were too few unsaturated timeslots to properly analyze the signal for a bark. When used in conjunction with the hardware attenuation (stage 2)

automatic gain control very few of these aborts should occur since it results in a decrease in the overall gain.

Abort Amplitude - This means that too few timeslots met the minimum amplitude requirement.

Abort Minimum Ratio and Abort Median Ratio - These indicate that the signal had features that made it look more like a scratch or a scrape than a real bark. These tests look at the ratio of the signal's absolute average voltage to its peak-to-peak voltage in each timeslot. Under one embodiment a single finding of a low ratio in one timeslot is enough to categorize the signal as a non-bark event. Real barks tend to have a higher ratio than scrapes and scratches

Abort Low Pass Minimum Ratio and Abort Low Pass Median Ratio - These are very similar to the Abort Minimum Ratio and Abort Median Ratio, except that we first low pass filter the signal in firmware before we calculate the ratio of the absolute average voltage to the peak-to-peak voltage.

Abort Spike Ratio - This indicates that the peak-to-peak amplitude of the signal in one or more timeslots exceeded the average peak-to-peak amplitude of its two neighboring timeslots by a factor of > 1.75 . That means that there was at least one spike in the data, and spikes of that high an amplitude are uncharacteristic of a real bark. (Real barks usually score below 1.30).

Abort Absolute Spike Ratio - This indicates that the absolute average amplitude of the signal in one or more timeslots exceeded the absolute average amplitude of its two neighboring timeslots by a factor of > 1.75 . That means that there was at least one spike in the data, and spikes of that high an amplitude are uncharacteristic of a real bark. (Real barks usually score below 1.30).

Historically, bark detection has used positive logic. That is, software (implementing audio signal processing through analog or digital signal processing methods) would test an arbitrary waveform and if the criteria by which the waveform is evaluated is met (was true), a correction would be invoked, with the implication that the event is a bark.

The new approach for detection described herein uses negative logic. Each waveform is evaluated by a series of “tests” to prove that the waveform is not a bark. Furthermore, multiple tests have been created to allow greater discrimination of an arbitrary waveform. If the first test is true (i.e., if first test criteria are met indicating that the waveform is not a bark) then the negative logic process may abort. However, if the first test criteria are not met, then negative

logic suggests that the waveform may be a bark. Then the second test is applied. If the second test is true (i.e., if second test criteria are met indicating that the waveform is not a bark) then the negative logic process may abort. The waveform is then reevaluated by the next negative logic test. If the waveform passes through all of the tests (i.e. failing to meet test criteria), the implication is that the event was a bark. These additional tests allow greater discrimination of an event from previous designs to improve the confidence in the waveform identification since each additional test reinforces the negative logic and thus further provides that the waveform is a bark at the conclusion of all waveform test criteria.

In addition to the improved confidence in the detection algorithm, negative logic minimizes power. The order of the negative logic test criteria was chosen in such a way such that the most frequently created non-bark waveforms (those created by bumps, strikes, impacts, etc.) would be detected first (aborting any further checks for that waveform) and the unit quickly returns to a low power state.

The bark detection unit may include user selectable sensitivity ranges. The different sensitivity settings change the levels of specific negative logic tests which in turn, result in either a broader range of waveforms in which a correction will be triggered or a narrower range.

The bark detection unit can identify other dog vocalizations (whining, whimpering, moaning) to be detected/corrected in addition to barks.

The ratios and tests set forth above are applied to a waveform (potential bark event) using negative logic. The application of such method allows for multiple testing criteria to be conducted and sequenced in such a way so as to maximize battery life.

The use of ratios and tests as set forth above allows for fixed limits to be set while using a variable gain system. Without the use of ratios the limits would need to be modified every time the gain of the AFE (Acoustic Front End) is changed.

As for improving detection of bark sounds and rejection of non-bark sounds, an embodiment of the bark detection and correction unit may implement machine learning. Under an embodiment detected audio samples are compared to stored library samples. This approach allows library growth as additional audio samples (corresponding to bark events) are encountered. The library may encompass the many bark types of many different breeds. The library may include samples corresponding to “types” of bark. Using such library, bark detection may discount some bark types (i.e. a bark indicating stranger on premises) as a non-event while

detecting and discouraging other bark types (i.e. a bark indicating boredom). The library may include sufficient samples from a single animal to detect whether a bark event corresponds to that animal. The library may also include samples corresponding to common sounds occurring within detection range of a bark detection and correction unit such that common sounds may be filtered.

Methods for determining the bearing from a microphone array to a sound source are referenced above. The most basic approach to determine the bearing from a microphone array to a sound source is to determine the time difference of arrival of the sound as it arrives at each pair of microphones in a fixed array. Figure 11 shows microphone array 1100 comprising microphone_i and microphone_j. Of course, the array may include a greater number of microphones. Figure 11 also illustrates arriving sound waves 1110. Once the time difference of arrival (T) is known for a microphone pair, the angle (q) to the sound source from each set of microphones can be calculated as follows:

$T = \text{Arrival time difference}$

$c = \text{Speed of sound}$

$D = \text{distance between microphones}$

$$q = \cos^{-1} \frac{cT}{D}$$

The time difference of arrival method described above can be more accurately implemented using an XCORR Cross Correlation method if the form factor of a detection and correction unit allows sufficient spacing between microphones to determine the required resolution. Figure 12 shows microphone array 1200 comprising microphone_i and microphone_j. Of course, the array may include a greater number of microphones. Figure 12 also illustrates arriving sound waves 1210. To determine the time delay between microphone sets, the XCORR Cross correlation method determines the time delay utilizing the cross correlation between the received signals at the microphones. The signals from each microphone are first sampled at a sampling frequency (F_s) sufficient to yield the resolution required of the system. The sampled signals, i.e. the resulting digital signals $S_i(n)$ and $S_j(n)$, are then fed to a cross correlator 1220. The cross correlator output is typically then fed to a peak detector 1240. The delay time in reaching the correlation peak (signal match) determines the time difference of arrival of the

sound arriving at the two microphones. This time difference is then used to determine the bearing angle (q) as follows:

T = Number of samples to reach correlation peak

c = Speed of sound

D = Distance between microphones

F_s = Sampling frequency

$$q = \cos^{-1} \frac{cT/F_s}{D}$$

The GCC-PHAT algorithm may under an embodiment be used to determine bearing from a microphone array to a sound source. It can be implemented in either the time or frequency domain. The approach also allows for microphone arrays at all spacing intervals.

The generalized cross correlation (GCC) can estimate the time delay between two microphone inputs by obtaining the inverse Fast Fourier Transform (I-FFT) of the cross-spectrum of the signals.

The phase amplitude transform (PHAT) attempts to improve the correlation by using a weighting function to obtain a unity gain for all frequency components while not affecting the phase information. The phase information yields the sound delay information. The result is a cross correlation with reduced noise.

Many other techniques may be employed to determine the bearing to an animal based on the bark sound arriving at a microphone array.

An apparatus is describe herein comprising a microphone array and a plurality of transducers, the microphone array and the plurality of transducers communicatively coupled with at least one processor, the at least one processor communicatively coupled with a memory. The microphone array is configured to receive at least one signal. Each transducer of the plurality of transducers is configured to deliver a correction signal along a transducer beam spread axis, wherein the plurality of transducers is positioned on the apparatus for providing a combined transducer beam spread coverage in the horizontal plane. One or more applications running on the at least one processor use information of the at least one signal to detect a sound event, the detecting the sound event including selecting transducers from the plurality of transducers, the detecting the sound event including instructing the selected transducers to deliver a correction signal.

The detecting the sound event includes determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event, under an embodiment.

The determining the sound event bearing comprises using time difference of arrival of the sound event at two or more microphones of the microphone array, under an embodiment.

The determining the sound event bearing comprises cross correlating signals corresponding to the sound event received by at least two microphones of the microphone array, under an embodiment.

The determining the sound event bearing comprises using a generalized cross correlation and phase amplitude transform applied to signals corresponding to the sound event received by at least two microphones of the microphone array, under an embodiment.

The selecting the transducers from the plurality of transducers includes comparing the sound event bearing with transducer bearings of the plurality of transducers, wherein a transducer bearing comprises an angle from a respective transducer beam spread axis to the reference line, wherein the memory comprises the transducer bearings, under an embodiment.

The selecting the transducers from the plurality of transducers includes selecting the transducers when an absolute difference between the sound event bearing and respective transducer bearing is below a threshold value, under an embodiment.

The combined transducer beam spread coverage of an embodiment spans ninety (90) degrees or less.

The combined transducer beam spread coverage of an embodiment is greater than ninety (90) degrees.

The selecting the transducers from the plurality of transducers includes selecting one or more additional transducers, under an embodiment.

The one or more additional transducers of an embodiment comprise a respective beam spread axis adjacent a beam spread axis of the selected one or more transducers in the horizontal plane, wherein the selected one or more transducers comprise the one or more additional transducers.

The sound event of an embodiment comprises barking of a dog.

The plurality of transducers comprise an ultrasonic transducer, wherein the correction signal comprises an ultrasonic signal, under an embodiment.

The ultrasonic signal of an embodiment comprises a frequency range between 20kHz and 50kHz.

The ultrasonic signal of an embodiment comprises a sound pressure level between 70dBA and 130dBA measured 0.3 meters from the face of the transducer.

The reference line of an embodiment forms a fixed angle with a line connecting two microphones of the microphone array.

The reference line of an embodiment comprises magnetic north.

An apparatus is described herein comprising a microphone array and at least one transducer, the microphone array and the at least one transducer communicatively coupled with at least one processor, the at least one processor communicatively coupled with a memory. The apparatus include the microphone array for receiving at least one signal. Each transducer of the at least one transducer is configured to deliver a correction signal along a transducer beam spread axis. Each transducer of the at least one transducer is configured to rotate. One or more applications running on the at least one processor use information of the at least one signal to detect a sound event, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event, the detecting the sound event including using the sound event bearing and transducer bearing information of the at least one transducer to rotate the at least one transducer, the rotating including adjusting a transducer beam spread axis of the at least one transducer to align with the sound event bearing, the detecting the sound event including instructing the at least one transducer to deliver a correction signal.

The rotating comprises rotating around a longitudinal axis of the apparatus, wherein the longitudinal axis is orthogonal to a horizontal plane, under an embodiment.

A method is described that includes under an embodiment receiving at least one signal through a microphone array. The method includes using information of the at least one signal to detect a sound event, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event. The method includes selecting one or more transducers using the sound event bearing and transducer bearing information of the one or more transducers, wherein each

transducer of the one or more transducers is configured to deliver a correction signal along an axis. The method includes instructing the selected one or more transducers to deliver a correction signal.

The axis of an embodiment comprises a transducer beam spread axis.

The memory of an embodiment comprises the transducer bearing information, wherein the transducer bearing information includes a transducer bearing for each transducer of the one or more transducers, wherein a transducer bearing comprises an angle from a transducer beam spread axis to the reference line.

The selecting one or more transducers includes using the transducer bearing information to compare the sound event bearing with transducer bearings of the one or more transducers, under an embodiment.

The selecting one or more transducers includes selecting the one or more transducers when an absolute difference between the sound event bearing and respective transducer bearing is below a threshold value, under an embodiment.

An apparatus is described herein that comprises a microphone array and a plurality of transducers, the microphone array and the plurality of transducers communicatively coupled with at least one processor. The apparatus includes the microphone array for receiving at least one signal. The plurality of transducers are configured to deliver a correction signal. One or more applications running on the at least one processor use information of the at least one signal to detect a sound event, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event, the detecting the sound event including instructing the plurality of transducers to direct a correction signal in a direction of the sound event bearing.

The plurality of transducers comprise a linear phased array of transducers, wherein the instructing the plurality of transducers to deliver the correction signal comprises selecting a correction signal phase difference between the transducers of the linear phased array to direct a majority of the corrections signal's sound energy along the sound event bearing, under an embodiment.

Computer networks suitable for use with the embodiments described herein include local area networks (LAN), wide area networks (WAN), Internet, or other connection services and network variations such as the world wide web, the public internet, a private internet, a private

computer network, a public network, a mobile network, a cellular network, a value-added network, and the like. Computing devices coupled or connected to the network may be any microprocessor controlled device that permits access to the network, including terminal devices, such as personal computers, workstations, servers, mini computers, main-frame computers, laptop computers, mobile computers, palm top computers, hand held computers, mobile phones, TV set-top boxes, or combinations thereof. The computer network may include one of more LANs, WANs, Internets, and computers. The computers may serve as servers, clients, or a combination thereof.

The systems and methods for remote multi-directional bark deterrence can be a component of a single system, multiple systems, and/or geographically separate systems. The systems and methods for remote multi-directional bark deterrence can also be a subcomponent or subsystem of a single system, multiple systems, and/or geographically separate systems. The components of systems and methods for remote multi-directional bark deterrence can be coupled to one or more other components (not shown) of a host system or a system coupled to the host system.

One or more components of the systems and methods for remote multi-directional bark deterrence and/or a corresponding interface, system or application to which the systems and methods for remote multi-directional bark deterrence is coupled or connected includes and/or runs under and/or in association with a processing system. The processing system includes any collection of processor-based devices or computing devices operating together, or components of processing systems or devices, as is known in the art. For example, the processing system can include one or more of a portable computer, portable communication device operating in a communication network, and/or a network server. The portable computer can be any of a number and/or combination of devices selected from among personal computers, personal digital assistants, portable computing devices, and portable communication devices, but is not so limited. The processing system can include components within a larger computer system.

The processing system of an embodiment includes at least one processor and at least one memory device or subsystem. The processing system can also include or be coupled to at least one database. The term “processor” as generally used herein refers to any logic processing unit, such as one or more central processing units (CPUs), digital signal processors (DSPs), application-specific integrated circuits (ASIC), etc. The processor and memory can be

monolithically integrated onto a single chip, distributed among a number of chips or components, and/or provided by some combination of algorithms. The methods described herein can be implemented in one or more of software algorithm(s), programs, firmware, hardware, components, circuitry, in any combination.

The components of any system that include systems and methods for remote multi-directional bark deterrence can be located together or in separate locations. Communication paths couple the components and include any medium for communicating or transferring files among the components. The communication paths include wireless connections, wired connections, and hybrid wireless/wired connections. The communication paths also include couplings or connections to networks including local area networks (LANs), metropolitan area networks (MANs), wide area networks (WANs), proprietary networks, interoffice or backend networks, and the Internet. Furthermore, the communication paths include removable fixed mediums like floppy disks, hard disk drives, and CD-ROM disks, as well as flash RAM, Universal Serial Bus (USB) connections, RS-232 connections, telephone lines, buses, and electronic mail messages.

Aspects of the systems and methods for remote multi-directional bark deterrence and corresponding systems and methods described herein may be implemented as functionality programmed into any of a variety of circuitry, including programmable logic devices (PLDs), such as field programmable gate arrays (FPGAs), programmable array logic (PAL) devices, electrically programmable logic and memory devices and standard cell-based devices, as well as application specific integrated circuits (ASICs). Some other possibilities for implementing aspects of the systems and methods for remote multi-directional bark deterrence and corresponding systems and methods include: microcontrollers with memory (such as electronically erasable programmable read only memory (EEPROM)), embedded microprocessors, firmware, software, etc. Furthermore, aspects of the systems and methods for remote multi-directional bark deterrence and corresponding systems and methods may be embodied in microprocessors having software-based circuit emulation, discrete logic (sequential and combinatorial), custom devices, fuzzy (neural) logic, quantum devices, and hybrids of any of the above device types. Of course the underlying device technologies may be provided in a variety of component types, e.g., metal-oxide semiconductor field-effect transistor (MOSFET) technologies like complementary metal-oxide semiconductor (CMOS), bipolar technologies like

emitter-coupled logic (ECL), polymer technologies (e.g., silicon-conjugated polymer and metal-conjugated polymer-metal structures), mixed analog and digital, etc.

It should be noted that any system, method, and/or other components disclosed herein may be described using computer aided design tools and expressed (or represented), as data and/or instructions embodied in various computer-readable media, in terms of their behavioral, register transfer, logic component, transistor, layout geometries, and/or other characteristics. Computer-readable media in which such formatted data and/or instructions may be embodied include, but are not limited to, non-volatile storage media in various forms (e.g., optical, magnetic or semiconductor storage media) and carrier waves that may be used to transfer such formatted data and/or instructions through wireless, optical, or wired signaling media or any combination thereof. Examples of transfers of such formatted data and/or instructions by carrier waves include, but are not limited to, transfers (uploads, downloads, e-mail, etc.) over the Internet and/or other computer networks via one or more data transfer protocols (e.g., HTTP, FTP, SMTP, etc.). When received within a computer system via one or more computer-readable media, such data and/or instruction-based expressions of the above described components may be processed by a processing entity (e.g., one or more processors) within the computer system in conjunction with execution of one or more other computer programs.

Unless the context clearly requires otherwise, throughout the description and the claims, the words “comprise,” “comprising,” and the like are to be construed in an inclusive sense as opposed to an exclusive or exhaustive sense; that is to say, in a sense of “including, but not limited to.” Words using the singular or plural number also include the plural or singular number respectively. Additionally, the words “herein,” “hereunder,” “above,” “below,” and words of similar import, when used in this application, refer to this application as a whole and not to any particular portions of this application. When the word “or” is used in reference to a list of two or more items, that word covers all of the following interpretations of the word: any of the items in the list, all of the items in the list and any combination of the items in the list.

The above description of embodiments of the systems and methods for remote multi-directional bark deterrence is not intended to be exhaustive or to limit the systems and methods to the precise forms disclosed. While specific embodiments of, and examples for, the systems and methods for remote multi-directional bark deterrence and corresponding systems and methods are described herein for illustrative purposes, various equivalent modifications are

possible within the scope of the systems and methods, as those skilled in the relevant art will recognize. The teachings of the systems and methods for remote multi-directional bark deterrence and corresponding systems and methods provided herein can be applied to other systems and methods, not only for the systems and methods described above.

The elements and acts of the various embodiments described above can be combined to provide further embodiments. These and other changes can be made to the systems and methods for remote multi-directional bark deterrence and corresponding systems and methods in light of the above detailed description.

CLAIMS

What is claimed is:

1. An apparatus comprising,
a microphone array and a plurality of transducers, the microphone array and the plurality of transducers communicatively coupled with at least one processor, the at least one processor communicatively coupled with a memory;
the microphone array for receiving at least one signal;
each transducer of the plurality of transducers configured to deliver a correction signal along a transducer beam spread axis, wherein the plurality of transducers is positioned on the apparatus for providing a combined transducer beam spread coverage in the horizontal plane;
one or more applications running on the at least one processor for using information of the at least one signal to detect a sound event, the detecting the sound event including selecting transducers from the plurality of transducers, the detecting the sound event including instructing the selected transducers to deliver a correction signal.
2. The apparatus of claim 1, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event.
3. The apparatus of claim 2, the determining the sound event bearing comprising using time difference of arrival of the sound event at two or more microphones of the microphone array.
4. The apparatus of claim 2, the determining the sound event bearing comprising cross correlating signals corresponding to the sound event received by at least two microphones of the microphone array.
5. The apparatus of claim 2, the determining the sound event bearing comprising using a generalized cross correlation and phase amplitude transform applied to signals corresponding to the sound event received by at least two microphones of the microphone array.

6. The apparatus of claim 2, the selecting the transducers from the plurality of transducers including comparing the sound event bearing with transducer bearings of the plurality of transducers, wherein a transducer bearing comprises an angle from a respective transducer beam spread axis to the reference line, wherein the memory comprises the transducer bearings.
7. The apparatus of claim 6, the selecting the transducers from the plurality of transducers including selecting the transducers when an absolute difference between the sound event bearing and respective transducer bearing is below a threshold value.
8. The apparatus of claim 1, wherein the combined transducer beam spread coverage spans ninety (90) degrees or less.
9. The apparatus of claim 1, wherein the combined transducer beam spread coverage is greater than ninety (90) degrees.
10. The apparatus of claim 1, the selecting the transducers from the plurality of transducers including selecting one or more additional transducers.
11. The apparatus of claim 10, wherein the one or more additional transducers comprise a respective beam spread axis adjacent a beam spread axis of the selected one or more transducers in the horizontal plane, wherein the selected one or more transducers comprise the one or more additional transducers.
12. The apparatus of claim 1, wherein the sound event comprises barking of a dog.
13. The apparatus of claim 1, wherein the plurality of transducers comprise an ultrasonic transducer, wherein the correction signal comprises an ultrasonic signal.
14. The apparatus of claim 13, wherein the ultrasonic signal comprises a frequency range between 20kHz and 50kHz.

15. The apparatus of claim 13, wherein the ultrasonic signal comprises a sound pressure level between 70dBA and 130dBA measured 0.3 meters from the face of the transducer.
16. The apparatus of claim 1, wherein the reference line forms a fixed angle with a line connecting two microphones of the microphone array.
17. The apparatus of claim 1, wherein the reference line comprises magnetic north.
18. An apparatus comprising,
a microphone array and at least one transducer, the microphone array and the at least one transducer communicatively coupled with at least one processor, the at least one processor communicatively coupled with a memory;
the microphone array for receiving at least one signal;
each transducer of the at least one transducer configured to deliver a correction signal along a transducer beam spread axis;
each transducer of the at least one transducer configured to rotate;
one or more applications running on the at least one processor for using information of the at least one signal to detect a sound event, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event, the detecting the sound event including using the sound event bearing and transducer bearing information of the at least one transducer to rotate the at least one transducer, the rotating including adjusting a transducer beam spread axis of the at least one transducer to align with the sound event bearing, the detecting the sound event including instructing the at least one transducer to deliver a correction signal.
19. The apparatus of claim 18, wherein the rotating comprises rotating around a longitudinal axis of the apparatus, wherein the longitudinal axis is orthogonal to a horizontal plane.
20. A method comprising,
one or more applications running on at least one processor for providing,
receiving at least one signal through a microphone array;

using information of the at least one signal to detect a sound event, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a reference line to a direction of the sound event;

selecting one or more transducers using the sound event bearing and transducer bearing information of the one or more transducers, wherein each transducer of the one or more transducers is configured to deliver a correction signal along an axis;

instructing the selected one or more transducers to deliver a correction signal.

21. The method of claim 20, wherein the axis comprises a transducer beam spread axis.

22. The method of claim 21, the memory comprising the transducer bearing information, wherein the transducer bearing information includes a transducer bearing for each transducer of the one or more transducers, wherein a transducer bearing comprises an angle from a transducer beam spread axis to the reference line.

23. The method of claim 22, the selecting one or more transducers including using the transducer bearing information to compare the sound event bearing with transducer bearings of the one or more transducers.

24. The method of claim 23, the selecting one or more transducers including selecting the one or more transducers when an absolute difference between the sound event bearing and respective transducer bearing is below a threshold value.

25. An apparatus comprising,
a microphone array and a plurality of transducers, the microphone array and the plurality of transducers communicatively coupled with at least one processor;
the microphone array for receiving at least one signal;
the plurality of transducers configured to deliver a correction signal;
one or more applications running on the at least one processor for using information of the at least one signal to detect a sound event, the detecting the sound event including determining a sound event bearing, wherein the sound event bearing comprises an angle from a

reference line to a direction of the sound event, the detecting the sound event including instructing the plurality of transducers to direct a correction signal in a direction of the sound event bearing.

26. The apparatus of claim 25, wherein the plurality of transducers comprises a linear phased array of transducers, wherein the instructing the plurality of transducers to deliver the correction signal comprises selecting a correction signal phase difference between the transducers of the linear phased array to direct a majority of the corrections signal's sound energy along the sound event bearing.
