populations, in combination with a supply of in-situ generated water-dissolved oxygen and hydrogen. Water electrolysis is used to produce water-dissolved oxygen and hydrogen. The immediate advantage of using H₂ from the electrolysis, is to provide electron donors to methanogens to reductively dechlorinate the chloroaliphatics, and to reduce the water carbonates and generate methane which is used as energy and carbon source for the methanotrophic bacteria. Oxygen is used as electron acceptor by the aerobic bacteria, including the methanotrophs. The addition of an organic carbon source can be minimized or even eliminated, so as to diminish the competition between methanotrophic bacteria and heterotrophic bacteria for oxygen.

ABSTRACT

The invention disclosure is a method of bioremediation of wastewater, particularly groundwater, by utilizing coupled anaerobic and aerobic biological treatment, more specifically, methanogenic (strictly anaerobic) and methanotrophic (strictly aerobic) microbial populations, in combination with a supply of in-situ generated water-dissolved oxygen and hydrogen. Water electrolysis is used to produce water-dissolved oxygen and hydrogen. The immediate advantage of using H_2 from the electrolysis, is to provide electron donors to methanogens to reductively dechlorinate the chloroaliphatics, and to reduce the water carbonates and generate methane which is used as energy and carbon source for the methanotrophic bacteria. Oxygen is used as electron acceptor by the aerobic bacteria, including the methanotrophs. The addition of an organic carbon source can be minimized or even eliminated, so as to diminish the competition between methanotrophic bacteria and heterotrophic bacteria for oxygen.

Bioelectrolytical Methanogenic/Methanotrophic Coupling For Bioremediation of Ground Water

BACKGROUND OF THE INVENTION

(01) This invention relates to the remediation of contaminated aquifers (groundwater). Chlorinated aliphatics such as tetrachloroethylene or perchloroethylene (PCE), trichloroethylene (TCE), trichloroethane (TCA) and dichloroethylene (DCE) have become common pollutants of soil and groundwater in North America. In the case of TCE this was due to its extensive use as a solvent and degreasing agent in industry, and to spills caused by mishandling, accidental or otherwise. The removal of PCE and TCE from soils and groundwater is an important environmental issue, especially since PCE, TCE and derivatives are potentially toxic to human beings and other life-forms. The invention relates also to other emergent contaminants, such as chloropropanes, namely 1,2,3-trichloropropane (TCP).

(02) Currently, there are several approaches for the biodegradation of chlorinated compounds.

(03) Biodegradation of chlorinated compounds can be accomplished by aerobic microorganisms, namely by methanotrophs or other microorganisms possessing mono-oxygenases with broad selectivity. Aerobic microorganisms (in particular methanotrophs) are capable of efficient mineralization of low chlorinated compounds, while the biodegradation rates of highly chlorinated compounds under aerobic conditions are lower. Moreover, most highly chlorinated chemicals are refractory to conventional aerobic conditions. Polychlorobiphenyls (PCB) such as pentachlorobiphenyl, highly chlorinated monoaromatics such as hexachlorobenzene and 1,2,4,5-tetrachlorobenzene, chlorinated aliphatics such as hexachlorobutadiene, PCE and carbon tetrachloride (CCl_4), hetero-substituted aromatics such as 4-chloro-2-nitrophenol (CNP) are not appreciably or not degraded at all under conventional aerobic conditions (Brown *et al.* 1987; Janssen *et al.* 1991; Zitomer and Speece 1993; Galli and McCarty 1989; Beunink and Rehm 1990; Field *et al.* 1995).

(04) Biodegradation of chlorinated compounds can also be accomplished by reductive dechlorination i.e. by anaerobic bacteria e.g. methanogens, which

chlorinated compounds. Although the rate of dechlorination of the contaminant itself could be sufficiently high, it decreases with decreasing extent of halogenation (Mohn and Tiedje 1992). Consequently, anaerobic degradation of chlorinated compounds often is incomplete and results in the production of less chlorinated intermediates. These intermediates can be even more toxic than the initial compound. For instance reductive dechlorination of PCE stalls at *cis*-dichloroethene (cDCE). To date, only one microorganism, *Dehalococcoides ethenogenes*, has been shown to dechlorinate PCE, TCE or DCE to ethene (Major *et al.* 2003).

(05) Accordingly, complete biodegradation of these compounds often requires a combination of anaerobic and aerobic conditions. Sequential anaerobic and aerobic biodegradation carried out in two reactors has been demonstrated. It provides complete mineralization of the initial compound. However, the existence of two bioreactor systems (anaerobic and aerobic) increases the cost. As well, a supply of methane is required if the aerobic part is based on methanotrophic activity.

(06) For groundwater applications, reductive dechlorination of PCE or TCE tends to be incomplete while aerobic degradation of TCE occurs in narrow ecological zones due to its specific requirements. In general, anaerobic activity is confined to the centers of contaminant plumes which are usually anaerobic, and aerobic activity occurs at the edges of the plumes where oxygen is present.

(07) Moreover, in view of the low solubility in water of methane (which is required as a carbon source for the methanotrophs), it is difficult to inject enough methane into the system to support sufficient metabolism of the methanotrophs.

(08) An example of a prior art approach is found in US 6,391,184. This patent reports methods for in-situ decontamination of groundwater by producing high amounts of dissolved oxygen and reactive initiators such as hydroxyl radicals. An electrolysis apparatus is described such as to effect the water electrolysis at given depth in screened wells. The apparatus essentially is a probe incorporating a submersible pump, an electrolysis cell, a chlorine filter and distribution chamber. The probe can be introduced into and removed from the well. The incorporation of

a pumping device at the probe tip allows for turning the well into a reactive well. The method also includes a protocol to position the wells given the hydrogeology of the site and the extension of its contamination, as well as an on-line control strategy to properly command the pumping and electrolysis operation.

(09) However, there is no use that is recognized for hydrogen. The method is essentially an alternative to air sparging, with much higher efficiency in terms of oxygen transfer to the liquid phase (resulting in higher dissolved oxygen concentration and better diffusion), and with the additional benefit of hydroxyl radicals generation. The outcomes expected are an initiation of chemical oxidation and a stimulation of aerobic indigenous microbial populations (oxidative pathways).

(010) In another prior art, US 5,919,351, the patent uses in-situ electrolysis with two flat screened electrodes placed perpendicular to the water flow direction, and crossed by the water path. First electrode is negative (cathode) and generates hydrogen; second one is positive (anode) and generates oxygen. This creates two zones, anaerobic and aerobic, so that the treatment is sequential rather than simultaneous coupling due to the oxygen gradient across the biofilm. In addition, the distance between the electrodes is relatively large, in the meter range, so that high voltage has to be applied for enough current to be generated. In addition, water has to flow across the flat screened electrode, requiring large electrode areas, and a risk of electrode clogging, i.e. loss of electrolytical efficacy and permeability. Those characteristics jeopardize the cost-effectiveness of the system, further to the fact that this method is limited to shallow aquifers.

(011) An integrated anaerobic and aerobic system for bioremediation of groundwater is described in our previous US patent no. 5,599,451, the disclosure of which is incorporated herein by reference (Guiot 1997a). Although this system has been found to be quite useful for a variety of applications and compounds (Guiot 1997b, Tartakovsky et al. 2001), the low solubility of oxygen in water and low density of biomass granules cause certain problems.

SUMMARY OF THE INVENTION

(012) According to the present invention, a bioremediation method and apparatus is provided, which involves a combination of anaerobic and aerobic metabolisms, fueled by water electrolysis, with an intrinsic source of carbon source (water dissolved methane) for the methanotrophs.

(013) According to one aspect of the invention, it is proposed to combine the advantages of reductive/oxidative degradation mechanisms using anaerobic and aerobic coupling, more precisely methanogenic/methanotrophic coupling (MAMOC), in a single biofilm system (Figure 1a, 2a and 4).

(014) According to another aspect of the invention, a solution for the oxygen supply problem is provided, by using water electrolysis. In an embodiment, by using an electrolytic cell for the oxygenation of the contaminated liquid to be treated, one can also benefit from the hydrogen produced at the same time. The electrolytic cell is placed in the system recirculation line. The circulating contaminated liquid flows through the electrolytic cell which is thus continuously enriched in both H_2 and O_2 . This results in a fully integrated (or single-stage) bioelectrolytic methanogenic/methanotrophic coupled (eMAMOC) system.

(015) An immediate advantage of using intrinsic H_2 from the electrolysis, is not to depend on an organic carbon-source for the methanotrophs, and for the electron donors for both reductive dechlorination and methane production from carbonates (providing the medium is carbonated enough) by methanogens. Methane is then used as energy and carbon-source by methanotrophic bacteria, and oxygen from the electrolysis, is also used by methanotrophic bacteria as electron acceptor. Methanotrophs can also complete the degradation by oxidizing the intermediates partially reductively dechlorinated by methanogens. This forms thus, a system made of biological components in synergism (mutualism).

(016) In another embodiment of the invention, an alternative scheme for implementing the bioelectrolytic methanogenic/ methanotrophic coupling (eMAMOC) is proposed. This scheme considers a different bioreactor configuration (Figure 1b and 2b). The methanogenic zone is in the lower part of

the biosystem, and the methanotrophic zone, in the upper part of the system, i.e. a dual system is used. As the methanotrophic zone superimposes the methanogenic zone and because of the fluid continuity between the two compartments, the methane produced in the methanogenic compartment is allowed to rise and freely pass to and feed the methanotrophic compartment. Simultaneously, compounds partially dechlorinated in the methanogenic compartment are transported by the liquid upward flow to the methanotrophic compartment. The H₂- and O₂-enriched liquid fluxes are dissociated accordingly, by duplicating the liquid recirculation lines out of the electrolytic cell i.e. to separately provide H₂ to the methanogenic compartment, an O₂ to the methanotrophic compartment. The spatial distance between the methanogenic and methanotrophic populations does not allow the close synergism that we have in the single-stage system. However this is a more straightforward method for facilitating the methanotrophs proliferation.

(017) It will be apparent to those skilled in the art that the electrolytic integrated methanogenic/methanotrophic coupled biosystem for biotreatment of contaminated liquid (water) may have several fields of application. Although applicable to chlorinated aliphatics contamination in groundwater (through either ex situ or in situ treatment), it will be appreciated that such biosystem concept could also be applied to any contaminant requiring reductive and oxidative steps for its biodegradation. This may include contaminants in groundwater and wastewater such as polychlorinated aromatics (chlorophenols, chlorobenzenes, polychlorinated phenyls, chloro-lignins,), compounds substituted with nitro-groups (TNT, nitrocellulose, RDX, HMX, NDMA,), azo-organic compounds such azo-dyes, ... Technologies based on such concept could also be applied to nitrification-denitrification of effluents and groundwater, considering electrolytic oxygen would be used for the nitrification step, while the electrolytic hydrogen would be used for the denitrification steps, as the electron donor for reducing nitrate and nitrite into nitrogen. In some of those applications, this means that, if the methanotrophic activities might not be instrumental and required, they should be substituted with other aerobic activity, for instance in the treatment of nitrogen pollution, aerobic populations would be ammonium-oxidizing bacteria.

(018) According to one aspect of the invention, a method is provided for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) providing a bioreactor containing a coupled single phase anaerobic (methanogenic) aerobic (methanotrophic) biofilm, said biofilm comprising an anaerobic (methanogenic) zone located at a central core area of the biofilm, and a juxtaposed aerobic (methanotrophic) zone at a surrounding peripheral area of the biofilm, in fluid communication with the anaerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic (methanotrophic) zone to the anaerobic (methanogenic) zone toward the core area, and an electrolytic cell for hydrolyzing water, in fluid communication with the bioreactor,

(b) circulating the contaminated liquid through the electrolytic cell to together introduce a controlled amount of dissolved oxygen and hydrogen into the contaminated liquid, and

(c) continuously cycling the oxygenated and hydrogenated contaminated liquid through the bioreactor, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria including methanogens and dissolved oxygen is used as an electron acceptor by aerobic including methanotrophic bacteria, and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

(019) According to another aspect of the invention, a method is provided for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) providing a bioreactor containing a coupled dual phase anaerobic (methanogenic) aerobic/methanotrophic biofilm, said biofilm comprising an aerobic (methanotrophic) zone in fluid communication with and superimposing

an anerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic (methanotrophic) zone to the anaerobic (methanogenic) zone, and an electrolytic cell for hydrolyzing water, in fluid communication with the bioreactor,

(b) circulating the contaminated liquid through the electrolytic cell to separately introduce a controlled amount of dissolved oxygen and hydrogen into the contaminated liquid, and providing dissolved oxygen to the aerobic (methanotrophic) zone and dissolved hydrogen to the anerobic (methanogenic) zone, and

(c) continuously cycling the oxygenated and hydrogenated contaminated liquid through the bioreactor, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria including methanogens; and dissolved oxygen is used as an electron acceptor by aerobic, including methanotrophic bacteria, and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

(020) According to yet another aspect of the invention, an apparatus is provided for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) a bioreactor containing a coupled single phase anerobic (methanogenic)/aerobic (methanotrophic) biofilm, said biofilm comprising an anaerobic (methanogenic) zone located at a central core area of the biofilm, and a juxtaposed aerobic (methanotrophic) zone at a surrounding peripheral area of the biofilm, in fluid communication with the anaerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic (methanotrophic) zone to the anaerobic (methanogenic) zone toward the core area,

(b) inlet means in said bioreactor for influent contaminated liquid,

- (c) first outlet means in said bioreactor for effluent treated liquid,
- (d) second outlet means in said bioreactor for effluent gas,
- (e) conduit means outside of said bioreactor for connecting said inlet and said first outlet means to define a closed loop including said bioreactor,
- (f) an electrolytic cell for hydrolyzing water associated with said conduit means for together introducing oxygen and hydrogen into said conduit means, whereby a controlled amount of oxygen and hydrogen is dissolved in said liquid outside of said bioreactor, and
- (g) pump means for continuously cycling contaminated liquid through the apparatus, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria, including methanogens; and dissolved oxygen is used as an electron acceptor by aerobic, including methanotrophic bacteria, and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

(021) According to a further aspect of the invention, an apparatus is provided for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

- (a) a bioreactor containing a coupled dual phase anaerobic (methanogenic)/aerobic (methanotrophic) biofilm, said biofilm comprising an aerobic (methanotrophic) zone in fluid communication with and superimposing an anaerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic (methanotrophic) zone to the anaerobic (methanogenic) zone,
- (b) inlet means in said bioreactor for influent contaminated liquid,
- (c) first outlet means in said bioreactor for effluent treated liquid,

- (d) second outlet means in said bioreactor for effluent gas,
- (e) conduit means outside of said bioreactor for connecting said inlet and said first outlet means to define a closed loop including said bioreactor,
- (f) an electrolytic cell for hydrolyzing water associated with said conduit means for separately introducing oxygen and hydrogen into said conduit means, whereby a controlled amount of oxygen and hydrogen is dissolved in said liquid outside of said bioreactor, and
- (g) pump means for continuously cycling contaminated liquid through the bioreactor, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria including methanogens; and dissolved oxygen is used as an electron acceptor by methanotrophic bacteria, and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

DETAILED DESCRIPTION OF THE INVENTION

(035) According to the present invention, we propose a bioremediation method which couples activities of aerobic and anaerobic microorganisms for the biodegradation or mineralization of chlorinated organics, more specifically methanotrophic bacteria for the group of aerobic bacteria and methanogenic bacteria, for the group of anaerobic bacteria, by engineering methanogenic/methanotrophic biofilms (by methanotrophic selective enrichment of methanogenic nuclei, as seen in Figures 1a and 4, under accurate oxygenation control) and develop a single-stage bioprocess, capable of faster and more complete degradation of chlorinated contaminants (namely PCE, TCE, TCA, TCP), as compared to conventional systems. With respect to degradation of PCE and TCE, reductive conditions, provided by the methanogenic bacteria, allow for the first steps of transformation (dechlorination) which are non-specific and relatively fast. With respect to degradation of TCE and derivatives, methanotrophs are of prime importance as they possess the methane monooxygenase (MMO) enzyme. This enzyme catalyzes the first step in the methane metabolism of these bacteria, which is the oxidation of methane to methanol. The specificity of this enzyme is low and is capable of oxidizing compounds other than methane. In the case of TCE, MMO oxidizes TCE to form TCE epoxide and in the case of DCE, MMO oxidizes DCE to form DCE epoxide.

(036) Conditions for the growth and activity of the methanotrophic bacteria have to be provided to exploit their ability to degrade TCE, DCE, etc. Specifically, methane as a carbon source and oxygen as an electron acceptor must be readily available to the methanotrophs. In the prior art, both gases were supplied by injection into the bulk liquid phase of the system. However, the transfer of gaseous methane into the aqueous liquid phase is difficult due to its low solubility

therein. According to the invention, direct additions of oxygen and methane are avoided by providing methanogens in proximity to the methanotrophs, to produce methane in-situ, thus avoiding the problem of transfer of methane into the liquid phase. The needs of the methanogens must also be addressed. Methanogens are strict anaerobes, and have to survive while in the presence of oxygen in the bulk fluid.

(037) The carbon source is also used by the facultative and aerobic heterotrophic bacteria in the outermost layer of the biofilm, to reduce part of the oxygen and shield the inner strict anaerobes from oxygen. But at the same time, those heterotrophic bacteria are fiercely competing with methanotrophic bacteria for oxygen, and doing so, limiting the methanotrophs proliferation at a lower level than expected, as mentioned earlier. To resolve such a limiting antagonism, we propose according to one aspect of the invention, to use water electrolysis to generate hydrogen and as such, to supply electron donors to methanogens and reductive dechlorinators.

(038) Moreover, at the same time, a solution to the oxygen supply is also provided, since water electrolysis also generates oxygen (at half the volumetric rate of hydrogen) which is used as electron acceptors by aerobic bacteria (including methanotrophs)

(039) It is not new to combine electrolysis of water with a biological system, but to our knowledge, up to now only one of the two gas species produced by electrolysis was utilized. In some instances of bioremediation, oxygenation was effected by electrolysis, but O_2 alone was used (Franz *et al.* 2002). In another case, it was H_2 that was generated by electrolysis for supplying electron donors to denitrifying bacteria, but the oxygen was discarded and at a cost (Felekea & Sakakibarab 2002). One novel aspect of this invention is that both gas species are useful in a single biofilm system. Hydrogen is used both by strict anaerobes to reductively dechlorinate chloroaliphatics into intermediates, and by methanogens to reduce water carbonates into CH_4 ; while oxygen is used by methanotrophs to oxidize CH_4 , and to co-metabolically degrade the chlorinated intermediates. The immediate advantage of using electrolytic H_2 is not to depend on an organic carbon-source for the electron donors for both reductive dechlorination and

methane production (providing the medium is carbonated enough). Yet a minimal supply of a carbon-source for facultatives and heterotrophs may be necessary to make sure O_2 diffusion is limited into the biofilm matrix and anaerobic niches preserved. However the required organic carbon flux is expected to be minimal which should diminish the competition between methanotrophs and heterotrophs for oxygen.

(040) According to the invention as seen in figure 1a the basic apparatus for continuous electrolytic methanogenic/methanotrophic coupled (eMAMOC) biotreatment of contaminated water comprises a bioreactor 10 of the upflow (expanded or static) bed-type, although it will be appreciated that other forms may also be employed. Waste liquid influent inlet means 12 is provided at the lower end of the reactor, and waste liquid effluent outlet means 14 is provided at the upper end of the reactor. Effluent by-product gas (methane, carbon dioxide etc.) outlet 16 is also provided at the top of the reactor. Conduit means 18 connects the inlet and outlet means to define a closed loop for circulating the waste liquid through the apparatus. De-contaminated effluent liquid is lapped off from the liquid outlet conduit means. Oxygenating means is associated with the circulating closed loop conduit. Water electrolysis within an electrolytic cell 20a is used for oxygen supply. At the same time hydrogen is also produced by the water electrolysis. Power is provided by a DC power supply. The electrolytic cartridge (or cell, or chamber) may be designed as illustrated in Figure 2a. A set of two flat electrodes (one cathode 26, negative electrical charge, hydrogen generating, and one anode 28, positive, oxygen generating). The anode can be made of titanium coated with iridium-dioxide (DSA, dimensionally stable anode), and the cathode, of stainless steel 300-400, or graphite, although it will be appreciated that any other material suitable for electrode and stable electricity production may be employed. The anode and cathode are separated by a non-conductive porous or permeable separator 30, or by a liquid void volume used as a spacer. The electrolytic cell 20a is placed such as to be crossed upward by the system liquid recirculation flow; the cell inlet 32, placed at the cell bottom (or on one side), is thus connected at the pipe 18 coming from recirculation pump 34; the electrolytical chamber outlet 36, placed at the cell top (or on the other side), at the pipe going to the inlet 12 at the bottom of the bioreactor body. The circulating liquid flows through the electrolytic cell which is thus continuously enriched in both H_2 and O_2 .

The liquid flow rate is set such as to be sufficient to wash out the microbubbles generated at the surface of the electrodes. A thin and rectangular shape of the electrode chamber is preferred as it will maximize the liquid linear velocity in the chamber. Other shapes are also possible, as well as multiplication of the electrode sets (and surfaces), depending on the current intensity which is needed at a given voltage (Figure 3). The liquid might also travel transversally from one side to the opposite side, depending on the cartridge shape and the electrode arrangement. The length of the liquid conduit from the electrolytic chamber outlet 34 to the bottom of the bioreactor body and gas inlet 12 is fixed such as to optimize the gas species transfer from the bubbles to the liquid phase (dissolution): in such an arrangement, gas transfer might be readily above 50%. The amount of oxygen dissolved is controlled by conventional means (not shown), so that the amount of dissolved oxygen is kept below the rate of consumption by the bioreactor. It is noteworthy that the electrolytic cell is a closed vessel, and thus the stripping by the gas production at the electrodes does not result in loss of volatile compounds.

(041) A coupled anaerobic/ aerobic biofilm means 38 is suspended in the bioreactor between the inlet and outlet means. As best seen in figure 4, the biofilm 38 (of about between 1 and 3 mm of diameter or thickness) includes an outer surface area 40 (of maximum 200 μm of thickness) and an inner core area 42, and has a decreasing gradient of oxygen concentration toward the core area (see graph portion of figure 4) which is substantially oxygen-free. Predominantly, strict aerobic bacteria including methanotrophs are located at the outer surface area. Predominantly, strict anaerobic bacteria including methanogens are located at the core area. The core area may include inert microcarrier granules (ie. of a particle size of between 300 and 600 μm , that have a highly porous structure and high specific surface area, such as: perlite, puzzolane, pumice, Biolite[®]™ (or Argex[™], or any other expanded clay particles), vermiculite, diatomite, sepiolite, sintered glass, granulated activated carbon, styrene beads, reticulated polyurethane beads, peat moss, or any other suitable porous microparticle) which could nucleate the cell immobilization and stabilize the suspended biofilm. The biofilm could also be made of a fixed biofilm system, packed with fixed inert support to develop a fixed methanogenic/ methanotrophic biofilm. Pump means 34 is

associated with the conduit means to cycle the waste liquid through the electrolytic cell.

(042) According to another aspect of the invention, a method for the continuous methanogenic/methanotrophic coupled single-stage biotreatment of contaminated water is provided, comprising

- (a) providing a biosystem containing a coupled single-stage anaerobic (including methanogenic)/aerobic (including methanotrophic) biofilm;
- (b) cycling the liquid to be treated outside of said biosystem, within an electrolytic device to produce H_2 and O_2 and to introduce a controlled amount of dissolved oxygen and hydrogen into the said circulating liquid and
- (c) continuously cycling the oxygenated and hydrogenated liquid through said biosystem to remove said contaminants, by feeding with O_2 and H_2 as electron acceptor and donor respectively, wherein the biofilm comprising an outer surface area containing predominantly aerobic bacteria and an inner core area containing predominantly anaerobic bacteria, provides a decreasing gradient of oxygen concentration toward said core area, the core area being substantially oxygen-free, while hydrogen, not reacting in the aerobic environment of the periphery, can readily reach the said core, and effectively act as an electron donor.

(043) The rate of oxygen consumption by the biofilm is fixed (because limited) by the oxygen supply rate and the efficiency of transfer from the gas to the liquid phases. The oxygen supply rate is a function of the power applied to and the surface area of the electrodes. The oxygen transfer efficiency is a function of the liquid retention time within the recirculation line ie. the liquid recirculation rate through the apparatus (high ratio of effluent recirculation to influent flow), and the liquid turbulence.

(044) Thus, a system is formed of biological components in synergism (mutualism) at two levels:

- at the level of the electron donors: the H_2 will serve as electron donor for reductive dechlorination and for production of CH_4 by methanogenic bacteria, which will be then used as energy and carbon-source by methanotrophic bacteria;
- at the level of the degradation of the chlorinated compounds: first step of degradation (reductive dechlorination) by methanogens complemented by the methanotrophic mineralization.

(045) As another embodiment of the invention, we propose an alternative scheme for implementing the bioelectrolytic methanogenic/methanotrophic coupling, considering a different bioreactor configuration. Coupling is provided by a methanogenic zone 22 in a lower part of the biosystem, and a methanotrophic zone 24, in the upper part of the system, i.e. a dual system is used. As the methanotrophic zone superimposes the methanogenic zone and because of the fluid continuity between the two zones, the methane produced in the methanogenic zone is allowed to rise and freely pass to and feed the methanotrophic zone (Figure 1b). Simultaneously, compounds partially dechlorinated in the methanogenic zone 22 are transported to the methanotrophic zone 24. For such a dual zone system to be operable, the H_2 and O_2 fluxes are dissociated. This is done by duplicating the liquid recirculation lines 37, 37a out of the electrolytic cell. This means the electrolytic cell 20b contains two parallel chambers, one with the cathode 26, the other with the anode 28. A porous separator 30, permeable to liquid and electrolytes, is installed in the middle (Figure 2b). In that case, the recirculation pumps 34 are also duplicated and placed after the electrolytic cell, pulling the liquid out of the cell chambers. The design principles are the same as for the one-chamber cell. The high liquid linear velocity will drive the H_2 and O_2 microbubbles out the chambers respectively in the separate conduits 37, 37a such that O_2 is provided to the methanotropic zone 24 and H_2 to the methanogenic zone 22 via inlets 13 and 12 respectively, before they may migrate through the porous wall and mix. Within such a design, O_2 will mix with CH_4 only in the upper part of the biosystem, making it an area essentially methanotrophic, since the main carbon-source there would be CH_4 . Thus the competition of heterotrophs and methanotrophs for oxygen is virtually eliminated.

Also, in the bottom part 22, no exogenous carbon-source (other than CO₂) is necessary, since the electrolytic H₂ acts as the electron donors (for CH₄ generation and chloroorganics reductive dechlorination). In such a design, the methanogenic and methanotrophic populations are spatially distant, which is a shortage as compared to the close synergism between the two populations that we have in the single-stage system, which reduces the diffusion paths and avoids toxicity of intermediates. Yet this might be a more straightforward way for giving a selective advantage to the methanotrophs. And although the methanogenic and methanotrophic populations are spatially distant as said, the system still keeps some integration characteristics as there is a relatively high turnover (recirculation) of liquid.

(046) Furthermore even though anaerobic populations would not be that critical for the degradation first steps i.e. that methanotrophic degradation of the primary molecules would not be that limited, methanogenic populations in the coupled system yet are of utility as an effective source of indigenous CH₄ i.e. the anaerobic nuclei in the single stage embodiment or the anaerobic compartment in the dual-stage embodiment can be viewed as an intrinsic or *in situ* methane releasing component, avoiding the burden of methane injection or supply from an extraneous source, with limited transfer efficacy and additional cost.

(047) Such a system has the potential for long-term and continuous operation with minimum energy or labour input.

PRELIMINARY RESULTS

(048) Superiority of the methanogenic/methanotrophic coupled system over either aerobic or anaerobic process alone, or sequential systems, as coupling minimizes diffusion pathways and eliminates toxic intermediates. Assays with ¹⁴C-labeled TCE showed that the methanotropic activity induced in the coupled system was central in the completeness of the reactions (Figure 5). The TCE complete dechlorination specific rates from methanogenic/methanotrophic reactors is in a range of one order of magnitude larger than the mineralization specific rates under methanotrophic conditions alone. It is hypothesized the methanotroph-induced mineralization of TCE is more limited than the aggregate of

initial reductive dechlorination steps (fast) and methanotrophic mineralization of less chlorinated intermediates (assumed as fast also).

Preliminary evaluation as a single-stage system.

(049) A preliminary evaluation of the electrolytic methanogenic/methanotrophic coupled (eMaMoC) system for PCE treatment was carried out at the lab-scale in single-stage reactors inoculated with unadapted anaerobic sludge granules.

(050) *Setup and operational conditions.* The 5-L glass-made reactors (internal diameter, 10 cm) were operated in an upflow sludge bed (USB) mode with an effluent liquid recirculation flow rate such as to maintain the in-reactor liquid upflow velocity between 0.4 and 2 m/h. The reactor influent was introduced to the effluent recycling line in four sidestreams of dilution water (buffer), nutrient solution, trace metal solution, and PCE solution. The dilution water consisted of (mg/L): NaHCO_3 , 760; KHCO_3 , 990; $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 27; K_2HPO_4 , 2840. The nutrient solution contained (mg/L): KH_2PO_4 , 880; K_2HPO_4 , 1030; NH_4HCO_3 , 12450. The chloride-free trace metal solution contained (mg/L): $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 856; H_3BO_3 , 5; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 13; $\text{MnSO}_4 \cdot \text{H}_2\text{O}$, 60; $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, 33; $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$, 9; $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$, 273; $\text{AlK}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$, 2; $\text{Na}_2\text{-EDTA}$, 33; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 1630; Na_2SeO_4 , 2; $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$, 6; cystein, 320. The PCE solution was prepared in an SKC Quality sample bags (tedlar, SKC Inc, Eighty-Four, PA) at a concentration of 22-70 mg/L of PCE. Ethanol, which facilitated the dissolution of PCE, was adjusted so as to have an organic load of 250 mg chemical oxygen demand (COD)/liter of reactor (L_{rx})·d. The dilution water : trace metal solution : nutrient solution ratio in the feed was 375 : 1 : 1 (vol./vol.).

(051) The electrolytic cell, which was crossed upward by the liquid recirculation flow, was continuously enriching the reactor liquid in both H_2 and O_2 . The electrodes (5 cm x 10 cm) were made of titanium coated with iridium-dioxide (Magneto, Schiedam, Netherlands). The applied electrical power varied from 0.8 to 1.1 W: this generated oxygen at a rate varying between 240 and 440 mg O_2/L_{rx} ·d, 20-70% of which were estimated to be transferred into the aqueous

phase. Abiotic tests were carried out showing a maximum dechlorination of 5% by the electrolysis alone.

(052) The COD (Standard methods, APHA 1995), pH (model PHB-51, Omega, Stamford, CT), inorganic chloride (Cl^-) were monitored in the effluent throughout the experiment. PCE and other chlorinated compounds were analyzed both in solution and in the off gas. Dissolved O_2 (DO) was controlled both in the inlet and effluent liquid (polarographic probe, Cole Palmer Instruments, Chicago, IL) . Dissolved CH_4 was measured by adding 1.5 mL of liquid sample to 2 mL glass vials. The vials were sealed and vortexed for 5 min. A 300 μL sample of the headspace gas of the vials was taken and injected into a gas chromatograph (GC). The Henry's constant was used to calculate the CH_4 content in the liquid phase of the vial from the CH_4 percentage in the vial headspace. The two values were then summed and reported to the vial liquid volume for estimating the dissolved CH_4 concentration in the liquid.

(053) The first reactor was operated for 6 months at a hydraulic retention time (HRT) of 1 day and at a temperature of 25°C. A second reactor was operated for a 4 month period, at an average HRT of 6.3 days and a temperature of 22°C. The electrical power applied was 0.4 ± 0.2 W; oxygen was generated at a flow rate of 39 to 45 mg $\text{O}_2/\text{L}_\text{rx} \cdot \text{d}$, 95% of which were estimated to be transferred into the aqueous phase. The ethanol load was decreased at 50 mg COD/ $\text{L}_\text{rx} \cdot \text{d}$.

Analytical Methods.

(054) The inorganic chloride content of the influent and effluent was determined using a high-performance liquid chromatograph (HPLC, pump model 600, autosampler model 717 plus) equipped with a Dionex IonPac AS15 column (250 x 2mm) and a conductivity detector (Waters Millipore, Milford, MA). Liquid analysis of PCE and chlorinated metabolites was done by adding 10 mL of sample to 20 mL glass headspace vials. The vials were sealed and heated for 60 min in an 80°C water bath, and a 300 μL sample of the headspace of the bottles was taken and injected into an Agilent Technologies 6890N Network GC System System with a flame ionization detector (FID) (Hewlett-Packard, Wilmington, DE)

equipped with a 1.8 m Carbowax B/1% SP-1000 column (Supelco, Bellefonte, PA) and using helium as the carrier gas. The oven temperature was programmed at 50°C for 1.25 min, 60°C/min to 220°C which was maintained for 6 min. The concentrations of chloroethenes were calculated using standards curves constructed by GC analyses of solutions with known concentrations of each compound to be analyzed. The reactor gas content in chloroethenes and ethene was analyzed directly by injection of 300 µL of the reactor off gas into the GC as above. The concentrations were calculated using standards curves obtained with calibration gas mixes with known concentrations of each volatile compound, from Liquid carbonic (Praxair, Danbury, CT) and Scott Specialty Gases (Plumsteadville, PA). The reactor gas composition (O₂, H₂, CH₄, N₂) was measured by injecting 300 µL of the reactor off gas into a HP 6890 Series GC System (Hewlett-Packard, Wilmington, DE) equipped with a FID and a 11 m x 3.2 mm 60/80 mesh Chromosorb 102 column (Supelco, Bellefonte, PA) and using argon as the carrier gas. For analyses of methane and hydrogen, the column temperature was held at 50°C for 3.9 min isocratic. For analyses of oxygen and nitrogen, the column temperature was held at 35°C for 7.5 min, then programmed to 100°C at a rate of 75°C/min, and finally held at 100°C for 6 min. A 0.5 µL sample fortified 1:1 with internal standard (isobutyric acid) in 6% formic acid was directly injected onto a 1 m x 2 mm glass column containing Carbowax C (60-80 mesh) coated with 0.3% Carbowax 20M and 0.1% H₃PO₄. Ethanol measurement was made on a Hewlett Packard 6890 GC coupled to a FID. A 1 µL liquid sample was injected onto a 2 m x 0.03 mm Hayesep Q micropacked column from Supelco. The column is heated at 60°C one minute then raised to 240°C at a rate of 20°C/min. Helium is used as carrier gas.

(055) Results. Under anaerobic conditions (DO = 0), PCE was transformed into DCE which accumulated in the bioreactor, while under anaerobic/aerobic conditions, over 50% of the *cis*-DCE was mineralized (Table 1).

(056) Although the extent of PCE dechlorination and mineralization augmented as the conditions became more oxidative (indicated by DO increase at the inlet, resulting from a power increase in the electrolytic cell), DCE mineralization seemed to be intrinsically limited at a level of less than 60% for an HRT of 1 d. With an HRT of 6.3 days, a higher DCE mineralization efficiency could be obtained (Table 1), however, the maximum mineralization efficiency that could be reached was only 83%. Mineralization results were corroborated by the stoichiometric recovery of inorganic chlorine in the effluent. The mineralization efficiency limit was probably related to the DCE oxidative degradation kinetics and/or the DCE-oxidizing microorganisms content in the granular biofilm and the liquid medium.

Kinetics study of the eMaMoC system in the dual-stage mode.

Experimental Setup.

(057) For the sake of elucidating the functionality of the coupled biosystem, a 5-L glass-made reactor was set up as a two-stage assembly aimed at segregating methanogens and methanotrophs within the bottom and upper parts of the reactor, respectively. See figure 1b.

(058) The bottom methanogenic zone 22 was inoculated with unadapted industrial anaerobic granules, while the upper methanotrophic zone 24 was

packed with a porous support made of granulated perlite silicate, and inoculated with activated sludge. Accordingly the liquid recirculation was bifurcated out of a two-chamber electrolytic cell 20b: a line 37 from the cathodic chamber carried H₂-enriched liquid to the bottom inlet 12 of the reactor 12, and a line 37a from the anodic chamber, delivered O₂-enriched liquid to the middle inlet 13 of the reactor. Because of the fluid continuity between the two reactor stages, CH₄ produced in the lower stage rises and feeds the methanotrophic upper compartment, together with compounds partially dechlorinated.

Results and Discussion.

(059) The system was operated at a PCE inlet concentration which varied from 13 to 60 μM, a PCE load, from 37 to 1.5 μmol/L_{rx}·d, and an HRT, from 1 to 47 days, for 17 months. PCE dechlorination to DCE in the first stage was always between 95 and 100% while in the second stage, DCE mineralization improved from 49 to near 100% with the HRT increase (Table 2). During the last steady state, no chlorinated ethenes were detected in the reactor gas

phase, while in the liquid phase, average concentrations (ppb, standard deviation in brackets) for PCE, TCE, 1,2-*cis*-DCE and vinyl chloride (VC) were as following: 31 (38), 0, 168 (124) and 3 (8), respectively. The aerobic biomass colonization of perlite slightly increased, at least till the 12th month of operation (end of the period at an HRT of 24 d), while its methanotrophic DCE-oxidizing potential achieved a three-fold increase.

(060) Eight months after the startup of the dual-stage system, kinetics parameters (K_S and k_{max}) of the upper methanotrophic biomass were estimated for DCE mineralization under strict methanotrophic conditions. Mineralization of DCE was assayed for a range of initial DCE concentrations, in 120 ml serum bottles equipped with a KOH trap and spiked with ^{14}C -uniformly-labeled DCE (80,000 dpm), as described elsewhere (Lyew *et al.* 2002). Abiotic controls were obtained by autoclaving the biomass (30 min at 121°C, 3 times). The radiolabeled CO_2 trapped in the KOH solution was quantified periodically using a scintillation counter (model 2100 TR, Packard Instrument Company, Meriden, CT). For each DCE concentration tested, the initial mineralization slope was reported to the biomass-VSS content in the assay to obtain the specific mineralization rate, k_0 . Experimental values of k_0 and initial DCE aqueous concentrations (C_0) were fit into the Michaelis model ($k_0 = k_{max} \cdot C_0 / [K_S + C_0]$), using non-linear regression techniques. Values of 5 μM DCE and 1.15 μmol DCE/gVSS·d were obtained for K_S and k_{max} , respectively. A substrate balance around the reactor at steady state ($C_e = C_0 - k \cdot X_{rx}^{aer} \cdot HRT$) gives the residual substrate concentration in the effluent, C_e , as a function of the substrate inlet concentration, C_0 , the biomass content, X_{rx}^{aer} , the in-reactor specific degradation rate, k , and the HRT. The latter equation and the Michaelis one can be simultaneously solved for expressing C_e as a function of HRT and C_0 , knowing k_{max} , K_S and X_{rx}^{aer} , as following:

$$E(\%) = 100 \left(1 - \frac{C_0 - K_S - k_{max} \cdot X_{rx} \cdot HRT + \sqrt{(C_0 - K_S - k_{max} \cdot X_{rx} \cdot HRT)^2 + 4 \cdot K_S \cdot C_0}}{2 \cdot C_0} \right)$$

(061) This equation, plugged with the above kinetics parameters (i.e. 5 μM DCE and 1.15 μmol DCE/gVSS·d for K_S and k_{max} , respectively), predicted that for an inlet PCE concentration of 50 μM and assuming all PCE was stoichiometrically reduced into DCE, an HRT of 14, 20 and 41 days would be

necessary for the mineralization efficiency to exceed 70%, with an aerobic biomass content of 3, 2 and 1 g VSS/L_{rx}, respectively. Similarly, for the residual DCE concentration to be below 50 ppb, an HRT of 26 days would be required with an inlet PCE concentration of 1 mg/L and an aerobic biomass content of 2 g VSS/L_{rx}. This seems to indicate that the kinetics properties of the methanotrophic stage are instrumental in fixing the performance limit of the overall mineralization process. This likely explains in part the change in the mineralization efficiency from 49 up to over 83, then over 95%, when HRT was increased from 1 to 24, then 47 days (Table 2), although those results are significantly higher than those predicted as above for such actual conditions. Such discrepancy is likely explained by the presence of monooxygenase-possessing aerobes other than methanotrophs and their contribution to the DCE degradation. This anticipates DCE degradation standards are within reach providing both the aerobic biomass density (X_{rx}^{aer}) and its methanotrophic DCE-oxidizing potential (k_{max}^{DCE}) are optimized and HRT, accordingly adjusted.

(062) In another experiment, in a set of two soil columns, designed to mimic both a bioreactive system and the adjacent aquifer, preliminary results with PCE are shown in the following Table 3. The bioreactive soil column had a volume of 6 L, packed with peat moss, inoculated with anaerobic sludge and methanotrophic enrichment, and operated with a HRT of 1 day. The electrical power applied to the electrolysis cell was 1.2-1.5 watts, resulting in a transfer of 50 to 120 mg O₂ per liter of column and per day.

TABLE 3

Dissolved O ₂ (DO) mg/L	PCE in mg/L	PCE removed %	1,2-DCE out mg/L (%)	Dechlorination %	Mineralization %
2-3	1.49	97	0.34 (39)	71	61
2-3	0.98	100	0.04 (7)	97	93

(063) The results indicate that a single-stage bioelectrolytic coupled system can achieve a PCE mineralization almost complete, providing a certain PCE load is not exceeded, in this case 1 mg PCE/L_{brx}.day.

APPLICATIONS

(064) The above concept is easily implemented in a bioreactor system (figure 1a) (e.g. for wastewater anaerobic/aerobic biotreatment or, for *ex situ* bioremediation of a contaminated aquifer (*ie.* above-ground treatment of contaminated groundwater, using the so-called pump and treat approach).

(065) When *in situ* (underground) remediation is preferred, the above concept is also easily implementable in a permeable reactive barrier (abbreviated as PRB) application (figure 6) taken in a broad sense. Indeed, *in situ* remediation of groundwater is most often preferred over *ex situ* groundwater treatment. And groundwater remediation by PRB is now established as one of the most cost-effective techniques. In the present applications, the reactive element is biological in essence, and abbreviated as PbRB, or *biobarrier*, taken as well in a broad sense, as detailed in the following paragraphs.

(066) As seen in figure 6 the *biobarrier* comprises a permeable bioreactive zone, system or wall B placed *in situ* across the path of a contaminated plume. As the contaminated groundwater moves under natural (*semi-active* mode) or forced (*active* mode) hydraulic gradient through the permeable bioreactive component, the contaminants are removed or biodegraded. Decontaminated groundwater emerges from the downgradient side, thus preventing off-site migration of the dissolved-phase contamination, while not confining the groundwater. This mode of operation, which is the most commonly used, is typically called semi-active, as the groundwater flows through the bioreactive element as a function of the natural hydraulic gradient, as opposed to the active mode, where the groundwater passage through the bioreactive component is accelerated by the means of an extraction-injection setup. This may be used to clean contamination at the source, or to process decontamination at a depth that cannot be reached by a trench (in the case of a permeable wall), or by sheet pilings (in the case of a funnel and gate or a panel and drain). This active mode of treatment is typically used for sandy aquifers (*i.e.* coarse sand) with a sufficiently high hydraulic conductivity. The two modes are compared in Figures 6a and 6b, for the same bioreactive element. In the active mode, continuous pumping of water internally to the biological element, may also be required to supply at an independent rate sufficient amounts of O₂

and H_2 (electron acceptors and donors) through the electrolysis cell as well as nutrients and organic matter (source of carbon).

(067) In one application, within the so-called semi-active category, the bioreactive component – apparatus – at the core of the remediation approach can be made of a trench filled with a permeable material packing, which is eventually colonized by the appropriate microorganisms. The bioreactive barrier B is intersecting the contamination plume (Figure 6a). In order to supply the microbial populations with H_2 and O_2 , as well as C-, N- and P- sources, and mineral salts, the liquid is internally recirculated, passed through the electrolytic cell, and supplemented with the necessary nutrients before being returned to the bioreactive component. The nutrients addition and water electrolysis are regrouped within a fueling electrolytic facility (E in the schematics, in Figure 6 and following), above ground for practicality of maintenance. The internal liquid recirculation is managed by pumping out the groundwater from a location at the top and on the downstream side of the permeable wall B, and reinjecting it towards several locations at the bottom of the wall on the upstream side, as illustrated in Figure 7a. Conversely, the extraction well may be placed upfront the biobarrier B (Figure 7b), such as to maximize the hydraulic gradient between the upstream soil and the biobarrier, and so, the ground water capture efficacy of the funnel or panel; the extracted liquid is reinjected at the bottom of the biocassette (e.g. through a set of horizontal perforated pipes), generating essentially a liquid upflow circulation in the biocassette. Any other configurations are acceptable providing a high turnover of the H_2 and O_2 enriched liquid is generated upward, to facilitate a fast distribution of the gas species within the overall biological component.

(068) In another application, as seen in figure 8A, a removeable and replaceable biocassette B can be placed, as a readily controllable biological unit, at the convergence and treatment point (“gate” or “drain”) of an impermeable wall system 70 (funnel, panel) that captures the contaminated plume. The bioreactive component B placed at the “gate” (one or several) of an impermeable wall, may have various configurations, such as a circular cartridge (or several ones within a rectangular crib) or a rectangular cartridge, with upward flow of the groundwater together with upflow liquid circulation, or a rectangular cassette with horizontal

feeding and tangential passage of the groundwater while the internal circulation is upflow. If retention time has to be magnified, several cassettes and cartridges can be placed in series (sequentially). In order to supply the microbial populations with H_2 and O_2 , as well as C-, N- and P- sources, and mineral salts, the liquid is internally recirculated, passed through the electrolytic cell, and supplemented with the necessary nutrients before being returned to the bioreactive component. The nutrients addition and water electrolysis are regrouped within a fueling electrolytic facility (E in the schematics, in Figure 8A and following), above ground for practicality of maintenance. The internal liquid recirculation is managed by pumping out the groundwater from a location at the bottom of the biocassette B, and reinjecting it at the top of the biocassette, as illustrated in Figure 8A. Conversely, the extraction well may be placed upfront the biobarrier B (Figure 8B-B), such as to maximize the hydraulic gradient between the upstream soil and the biobarrier, and so, the ground water capture efficacy of the funnel or panel; the extracted liquid is reinjected at the bottom of the biocassette (e.g. through a set of horizontal perforated pipes), generating essentially a liquid upflow circulation in the biocassette. Any other configurations are acceptable providing a high turnover of the H_2 and O_2 enriched liquid is generated upward, to facilitate a fast distribution of the gas species within the overall biological component.

(069) An experiment was carried out in a large stainless steel box (2.4 m x 2.4 m x 1.5 m) (Figure 8B-A, C) which was filled with coarse sand (sand thickness: approximately 1.2 m). Contaminated groundwater (15-20°C) was simulated by feeding the box with tap water together with a concentrated PCE aqueous solution (50-70 mg/L) kept in a stainless steel tank, through nine ports evenly distributed on the box wall, using peristaltic pumps. Water was flowing through the box at a linear velocity of ~15 cm/d, with a level of 0.9 m from the floor. The PCE-contaminated plume was captured using a funnel and gate system. The gate frame (caisson) hosted three cassettes (Figure 8B-B). The first and last cassettes were filled with pea gravel. The middle cassette, removable, was packed with a mixture of peat (bacterial support), volcanic rock (structural support), anaerobic sludge granules and methanotrophic enrichment. The bioactive volume of the cassette was 0.6 m³ (0.9 m width x 0.75 m length x 0.9 m liquid height). A submersible pump located at bottom of the extraction well, in front of the bioactive cassette was used to recirculate water back to the bioactive cassette via

horizontal perforated pipes located at the bottom of the cassette (Figure 8B-B), so as to maximize the hydraulic gradient between the upstream soil and the barrier, and the groundwater capture efficacy of the funnel. H_2 and O_2 were generated and transferred to the cassette liquid using an electrolysis cartridge (EC in Figure 8B-B) placed in the recirculation line. Stock solutions of ethanol (10 g/L) and nutrients (20 g/L fertilizer 20:20:20) were each added to the recirculation line at a rate of 1 L/d (i.e. a solution-to-water ratio in the feed of 1:200, vol./vol.). Carbonated water was introduced into the pre-electrolytic stream of the recirculation loop.

(070) The barrier was operated with an HRT of 4-5 days. The electrical power applied to the electrolytical cartridge (15-20 W) generated oxygen at a flow rate of between 30 and 100 g O_2/m^3 reactive barrier-d. Dissolved O_2 was measured in the circulating liquid as between 1.8 and 3.5 mg/L, and dissolved CH_4 , between 5 and 12 mg/L. For an influent PCE concentration of 1 to 22 μM (0.2 to 3.7 mg/L), the PCE removal was complete and mineralization fluctuated between 38 and 68% after 40 days of operation, then exceeded 98% after 80 days of operation. The concentrations of PCE, TCE, DCE, and VC in the groundwater downstream from the barrier were inferior to 50 ppb (detection limit). Afterwards incidental increase of the PCE inlet concentration to 85 μM still showed an efficiency removal of over 97%, with effluent concentrations inferior to 50 ppb, for PCE, TCE and DCE, and of 157 ± 33 ppb, for VC. Measurements of inorganic chloride in the inlet and effluent at an influent PCE concentration of 14 mg/L showed a balance of 9 ± 4 mg/L: this means an inorganic chloride-to-PCE chlorine ratio of $75 \pm 33\%$ indicating a stoichiometric recovery.

(071) In another application, as seen in figure 9 the electrolytic cell 20a is designed and placed in the biocassette B in such a way that the system would be entirely passive (no pump, no liquid cycle; biosystem is fed only by the natural groundwater flow). The electrodes 26, 28 are placed at the bottom of the biocassette B within a well 80, the bottom of which is screened 86, such as they can be retrieved readily for maintenance (cleanup or repair). For that purpose, the electrodes are fixed at one end of a rigid rod (or tube) 82. The tube's extremity at which are fixed the electrodes, is of an external diameter slightly smaller than that of the well and is tapped down such as to have a slope for deflecting the gas

laterally. Above the tapped extremity a rubber O-ring 84 (or any other suitable seal) is set around the tube to watertighten the well portion containing the electrode from the rest of the well (figure 9c). This is to force the gas produced to go laterally out of the well through the screen and spray into the liquid phase of the biosystem. An example of this device implementation is demonstrated within a barrier configuration made of a circular cartridge with upward flow of the groundwater (Figures 9a,b).

(072) In the case of the dual zone system a single bioreactive cassette B of cylindrical shape is provided within a rectangular crib, the electrolytic cell 20b is designed such as to separate the flux of hydrogen from the flux of oxygen. The anode 28, with a tubular and hollow shape, is surrounded by an interstitial membrane 30 and the cathode 26, also tubular (Figure 10). The electrolytic cell 20b is placed at the bottom of the biosystem, i.e. at the bottom of the anaerobic compartment 22, within a well 60 screened at the bottom. Openings are realized so that all the stream crosses the cell; 95 % of the water passes outside the membrane 30 and through the cathode 26 and gets enriched in hydrogen, and gets directed towards the anaerobic compartment 22; while 5% of the liquid stream is carried out inside the anode tube 28, from where, enriched in oxygen, it is directed towards the upper aerobic compartment 24 through a tube prolonging the inner membrane surface. The well 60 is screened at mid-height 62, and above-sealed at 64 to holding pole 65, such as to allow the O₂-enriched liquid to leave the well and diffuse within the aerobic compartment from its bottom.

(073) An experiment is being carried out in a pilot-scale stainless steel caisson (0.9 m width x 1.4 m length x 1.8 m height) containing a two-stage upflow cylindrical biocassette, removable, according to the same schematics as that of figure 10 A and B. The bioactive volume of each part (or stage) i.e. the lower part and the upper part, each removable, is 0.29 m³ (0.77 m diameter x 0.63 m height). Contaminated groundwater (20-21°C) was simulated by feeding the caisson with carbonated tap water (130-150 mg CO₂/L) together with an ethanol and nutrients solution, and a concentrated PCE aqueous solution (50-70 mg/L), through nine ports evenly distributed on the caisson wall, using peristaltic pumps. The solutions flows-to-water flow ratio were adjusted so to have an inlet concentration (i.e. in front of the anaerobic cassette) of 5 mg PCE/L, 50 mg/L of

ethanol-COD, 8 mg/L NH_4^+ , 3 mg/L phosphate. The lower part of the cassette, removable, was filled with anaerobic sludge granules (280 L at a VSS content of 27 g/L), and the upper part of the cassette, was packed with granulated activated carbon (100 Kg, 56% porosity), and inoculated with methanotrophs-containing activated sludge (140 L at a VSS content of 21 g/L). H_2 and O_2 were generated and transferred, separately, to the cassette liquid using three two-chamber electrolysis cylindrical probes (as detailed in Figure 10 C) placed at the bottom of three wells. The biocassette was operated with an HRT of 5 days. The electrical power applied to each electrolytical probe (6 W: 10 V and 0.6 A) generates hydrogen and oxygen, which are diffusing passively in the liquid of the lower and upper compartments, respectively. The results presented below are preliminary, as covering two months of operation. Dissolved O_2 was measured at the bottom of the upper cassette as between 1.2 and 3.8 mg/L. Hydrogen is recovered in the off-gas at a flow rate of only 0.15 L/day, as compared to 3 L/d for CH_4 and 10 L/d for O_2 . This indicates that the lower cassette is anaerobically active, as well as the upper aerobic one, methanotrophically active. For an influent PCE concentration of 5 mg/L, the removal of PCE and chlorinated intermediates was complete, after 60 days of operation. The concentrations of PCE, TCE, DCE, and VC in the groundwater downstream from the biocassette are inferior to 50 ppb. The inorganic chlorine balance between the inlet and the effluent is in the order of 6 mg/L; this indicates a stoichiometric recovery of chlorine and that PCE mineralization too should be complete.

(074) In another application, as a particular alternative to the wall approach (either permeable, or impermeable with gates or drains), an array of wells that include a bioreactive component are placed perpendicularly in the path of the contaminated plume. Such a so-called reactive circulation well consists of a double screened well to simultaneously mobilize and treat contaminants from the capillary fringe and the saturated zone. Treatment in the saturated zone is achieved by a combination of soil flushing, and biodegradation in the bioreactor segment (B, in Figure 10) of the well, filled with MAMO coupled bioparticles (single-stage), or with anaerobic and aerobic bioparticles separately (dual-stage). Figure 10 illustrates the standard mode of operation, where groundwater enters the well through the lower screen and leaves through the upper screen.

Circulating water is forced through the electrolytic cell, to enrich it in H₂ and O₂, and appropriate nutrients (E, electrolytic fueling unit, in Figure 8A). In the reverse circulation mode, groundwater enters the well through the upper screen and leaves through the lower screen.

(075) In another application, a setup of extraction and injection wells can be used to transform a part of aquifer between the injection and extraction wells in a bioreactive zone by promoting microbial growth (either of indigenous or added populations) of methanogenic and methanotrophic populations due to the presence of hydrogen and oxygen, produced by the electrolysis cell placed on the path of the water circulation between the extraction and injection wells 90 and 92 (Figure 11). In an alternative application, extraction and injection wells can be placed such as have a downflow biofiltration bed in the vadose zone, (Figure 12), above the contamination source or any area required to be cleaned. The circulation of the extracted water is downflow through the biobed. The circulating water also is supplied in H₂ and O₂ produced by the electrolysis cell (not shown) placed also on the path of the water circulation between the extraction and injection wells.

(076) Overall, the proposed method of hydrogen and oxygen supply to aquifer can be used in a variety of configurations aimed at combined anaerobic-aerobic biodegradation.

CLAIMS:

1. A method for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) providing a bioreactor containing a coupled single phase anaerobic(methanogenic)/aerobic(methanotrophic) biofilm, said biofilm comprising an anaerobic (methanogenic) zone located at a central core area of the biofilm, and a juxtaposed aerobic (methanotrophic) zone at a surrounding peripheral area of the biofilm, in fluid communication with the anaerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic (methanotrophic) zone to the anaerobic (methanogenic) zone toward the core area, and an electrolytic cell for hydrolyzing water, in fluid communication with the bioreactor,

(b) circulating the contaminated liquid through the electrolytic cell to together introduce a controlled amount of dissolved oxygen and hydrogen into the contaminated liquid, and

(c) continuously cycling the oxygenated and hydrogenated contaminated liquid through the bioreactor, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria including methanogens; and dissolved oxygen is used as an electron acceptor by aerobic, including methanotrophic bacteria, and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

2. A method according to claim 1, wherein the amount of oxygen dissolved in said contaminated liquid is adjusted to the rate of oxygen consumption by the biofilm .

3. A method according to claim 1, wherein the contaminated liquid is ground water.

4. A method according to claim 1, wherein the contaminated liquid comprises contaminants which include those which are reductively degradable by anaerobic bacteria to forms which are further oxidatively degradable by aerobic bacteria to non-toxic forms.

5. A method according to claim 4, wherein the contaminants include highly chlorinated organic compounds.

6. A method for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) providing a bioreactor containing a coupled dual phase anaerobic(methanogenic)/aerobic(methanotrophic) biofilm, said biofilm comprising an aerobic (methanotrophic) zone in fluid communication with and superimposing an anaerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic (methanotrophic) zone to the anaerobic (methanogenic) zone, and an electrolytic cell for hydrolyzing water, in fluid communication with the bioreactor,

(b) circulating the contaminated liquid through the electrolytic cell to separately introduce a controlled amount of dissolved oxygen and hydrogen into the contaminated liquid, and providing dissolved oxygen to the aerobic (methanotrophic) zone and dissolved hydrogen to the anaerobic (methanogenic) zone, and

(c) continuously cycling the oxygenated and hydrogenated contaminated liquid through the bioreactor, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria including methanogens; and dissolved oxygen is used as an electron acceptor by aerobic, including methanotrophic bacteria and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

7. A method according to claim 6, wherein the amount of oxygen dissolved in said contaminated liquid is adjusted to the rate of oxygen consumption by the biofilm .

8. A method according to claim 6, wherein the contaminated liquid is ground water.

9. A method according to claim 6, wherein the contaminated liquid comprises contaminants which include those which are reductively degradable by anaerobic bacteria to forms which are further oxidatively degradable by aerobic bacteria to non-toxic forms.

10. A method according to claim 9, wherein the contaminants include highly chlorinated organic compounds.

11. An apparatus for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) a bioreactor containing a coupled single phase anaerobic(methanogenic)/aerobic(methanotrophic) biofilm, said biofilm comprising an anaerobic(methanogenic) zone located at a central core area of the biofilm, and a juxtaposed aerobic(methanotrophic) zone at a surrounding peripheral area of the biofilm, in fluid communication with the anerobic (methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic(methanotrophic) zone to the anerobic (methanogenic) zone toward the core area,

(b) inlet means in said bioreactor for influent contaminated liquid,

(c) first outlet means in said bioreactor for effluent treated liquid,

(d) second outlet means in said bioreactor for effluent gas,

(e) conduit means outside of said bioreactor for connecting said inlet and said first outlet means to define a closed loop including said bioreactor,

(f) an electrolytic cell for hydrolyzing water associated with said conduit means for together introducing oxygen and hydrogen into said conduit means, whereby a controlled amount of oxygen and hydrogen is dissolved in said liquid outside of said bioreactor, and

(g) pump means for continuously cycling contaminated liquid through the apparatus, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria, including methanogens, and dissolved oxygen is used as an electron acceptor by aerobic, including methanotrophic bacteria and methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

12. An apparatus according to claim 11, wherein the amount of oxygen dissolved in said contaminated liquid is an amount up to the rate of consumption of oxygen by the biofilm.

13. An apparatus according to claim 11, wherein the contaminated liquid is ground water.

14. An apparatus according to claim 11, wherein the contaminated liquid comprises contaminants which include those which are reductively degradable by anaerobic bacteria to forms which are further oxidatively degradable by aerobic bacteria to non-toxic forms.

15. An apparatus according to claim 11, wherein the biofilm is in the form of a suspended granular anaerobic sludge bed colonized with aerobic bacteria.

16. An apparatus according to claim 15, wherein the particle size of the granules is between 300 and 600 μm .

17. An apparatus for the continuous synchronous bioremediation of an aqueous contaminated liquid including a contaminant requiring reductive and oxidative steps for its biodegradation, comprising

(a) a bioreactor containing a coupled dual phase anaerobic (methanogenic)/aerobic(methanotrophic) biofilm, said biofilm comprising an aerobic(methanotrophic) zone in fluid communication with and superimposing an anaerobic(methanogenic) zone, and including a decreasing gradient of oxygen concentration from the aerobic(methanotrophic) zone to the anaerobic (methanogenic) zone,

(b) inlet means in said bioreactor for influent contaminated liquid,

(c) first outlet means in said bioreactor for effluent treated liquid,

(d) second outlet means in said bioreactor for effluent gas,

(e) conduit means outside of said bioreactor for connecting said inlet and said first outlet means to define a closed loop including said bioreactor,

(f) an electrolytic cell for hydrolyzing water associated with said conduit means for separately introducing oxygen and hydrogen into said conduit means, whereby a controlled amount of oxygen and hydrogen is dissolved in said liquid outside of said bioreactor, and

(g) pump means for continuously cycling contaminated liquid through the bioreactor, wherein dissolved hydrogen is used as an electron donor by methanogenic bacteria and to in situ generate methane, and by anaerobic bacteria including methanogens; and dissolved oxygen is used as an electron acceptor by aerobic, including methanotrophic bacteria and

methane is used by methanotrophic bacteria, to remediate the contaminated liquid, respectively by reductive and oxidative steps.

18. An apparatus according to claim 17, wherein the amount of oxygen dissolved in said contaminated liquid is an amount up to the rate of consumption of oxygen by the biofilm.

19. An apparatus according to claim 17, wherein the contaminated liquids is ground water.

20. An apparatus according to claim 17, wherein the contaminated liquid comprises contaminants which include those which are reductively degradable by anaerobic bacteria to forms which are further oxidatively degradable by aerobic bacteria to non-toxic forms.
