MANAGING CONTENTION-FREE TIME ALLOCATIONS IN A NETWORK

TECHNICAL FIELD

The invention relates to network protocols, and more particularly to managing contention-free time allocations in a network.

BACKGROUND

Communication stations can share a communication medium using any of a variety of access techniques. Some access techniques (e.g., carrier sense multiple access (CSMA) techniques) include a contention period in which stations determine contend for use of the medium for transmitting a signal by sensing when the medium is idle. In CSMA techniques, “collisions” sometimes occur when signals from two or more stations overlap. Some CSMA techniques attempt to detect collisions and abort transmission to reduce the negative impact of collisions (e.g., CSMA/CD techniques). Other CSMA techniques include mechanisms to avoid or reduce the probability of collisions (e.g., CSMA/CA techniques). For example, different transmissions may be assigned one of multiple priorities. Access is granted using a Priority Resolution Period in which stations signal the priority at which they intend to transmit, and only the highest priority transmissions are allowed to continue in the contention process. A random backoff mechanism spreads the time over which stations attempt to transmit, thereby reducing the probability of collision.

Other access techniques (e.g., time division multiplexing (TDM) techniques) allocate predetermined time intervals in which certain stations are granted use of the medium. A particular station will transmit within a time slot assigned to that station. In these techniques, a synchronization mechanism is used to ensure that the stations agree about when their slot occurs with respect to a common time reference.

54830-3

SUMMARY

According to an aspect of the present invention, there is provided a method for communicating between stations in a network, the method comprising: receiving, at a first station, a beacon transmission from a coordinator station, wherein the beacon transmission
5 indicates a time slot assigned to the first station; transmitting from the first station to a second station during the time slot assigned to the first station; and transmitting, from the first station, information that grants permission to the second station to transmit during at least a portion of the time slot assigned to the first station.

According to another aspect of the present invention, there is provided a
10 system for communicating between stations, the system comprising: a coordinator station configured to provide a beacon transmission to a first station, wherein the beacon transmission indicates a time slot assigned to the first station; and a first station configured to: receive the beacon transmission from the coordinator station; transmit to a second station during the time slot assigned to the first station; and transmit information that grants permission to the second
15 station to transmit during at least a portion of the time slot assigned to the first station.

According to another aspect of the present invention, there is provided a system for communicating between stations in a network, the system comprising: means for receiving, at a first station, a beacon transmission from a coordinator station, wherein the beacon transmission indicates a time slot assigned to the first station; means for transmitting
20 from the first station to a second station during the time slot assigned to the first station; and means for transmitting, from the first station, information that grants permission to the second station to transmit during at least a portion of the time slot assigned to the first station.

In one aspect, the invention features a method and corresponding system for communicating between stations in a network. In some embodiments, the method includes
25 providing repeated beacon transmissions from a coordinator station for coordinating transmissions among a plurality of the stations; transmitting from a first station to a second station during a time slot assigned to the first station by at least one of the beacon transmissions; and transmitting from the first station information that grants permission to the

54830-3

second station to transmit during at least a portion of a time slot assigned to the first station.

Non-limiting examples of implementations of this aspect of the invention may incorporate one or more of the following.

5 The time slot assigned to the first station includes time during which the second station is able to transmit acknowledgement information to the first station confirming successful transmission of information from the first station to the second station.

 The portion of the time slot during which the second station has received permission to transmit is larger than the time during which the second station transmits the acknowledgement information.

10 The first station provides permission for the second station to transmit during at least a portion of a time slot assigned to the first station after receiving a request from the second station included in the acknowledgement information.

 The acknowledgement information includes information designating which of multiple segments of information were successfully received by the second station and which
15 of the multiple segments of information should be retransmitted by the first station.

 Information transmitted from the second station in the portion of the time slot is information other than acknowledgement information confirming successful transmission of information from the first station to the second station.

 The time slot assigned to the first station is determined from a time reference
20 contained in a beacon transmission.

 The time reference includes a time at which a predetermined portion of the beacon transmission is received.

Determining the time slot from the time reference includes determining starting and ending times for the time slot measured from the time reference, based on information in the beacon transmission.

The first station transmits grant information to the second station specifying a
5 portion of the time slot during which the second station is allowed to transmit.

The portion of the time slot includes a portion of the same time slot during which the grant information was received by the second station.

The portion of the time slot includes a portion of a time slot subsequent to the time slot during which the grant information was received by the second station.

10 The first station is assigned a plurality of non-contiguous time slots between successive beacon transmissions for transmitting to the second station.

The portion of the time slot includes a portion of a time slot subsequent to the time slot during which the grant information was received by the second station.

The grant information is included in header information of a transmission from
15 the first station to the second station.

The first station provides permission for the second station to transmit during at least a portion of a time slot assigned to the first station after receiving a transmission from the second station that includes an amount of time that is requested.

The first station provides permission for the second station to transmit during at
20 least a portion of a time slot assigned to the first station after determining that the requested amount of time will be available in the time slot.

The first station provides permission for the second station to transmit during at least a portion of a time slot assigned to the first station without first receiving a request from the second station.

25 The first station indicates an amount of time granted to the second station.

The second station relinquishes an unused portion of the time granted back to the first station.

Information transmitted from the second station to the first station during the portion of the time slot assigned to the first station includes information used to
30 maintain data flow from the first station to the second station.

Information transmitted from the second station to the first station during the portion of the time slot assigned to the first station includes adaptation information used by the first station to prepare a signal to be transmitted to the second station.

54830-3

The adaptation information includes a map that designates a type of modulation that is to be used, respectively, on each of multiple carriers in the signal.

Information transmitted from the second station to the first station during the portion of the time slot assigned to the first station includes acknowledgement information
5 used to confirm successful transmission of information from the first station to the second station.

The method further includes, in response to not receiving permission from the first station for the second station to transmit during a time slot assigned to the first station, transmitting from the second station to the first station during a time slot allocated based on
10 contention with other stations according to at least one of the beacon transmissions received by the second station from the coordinator station.

Transmitting from a first station to a second station during a time slot determined based on at least one of the beacon transmissions received by the first station from the coordinator station includes, after failing to successfully receive a recent beacon
15 transmission at either or both the first and second station, transmitting from the first station to a second station during a time slot determined based on information contained in a beacon transmission prior to the recent beacon transmission.

One or more embodiments may provide one or more of the following benefits.

Some embodiments may enable stations to operate reliably and at higher data
20 rates under various power line environments. Some embodiments may provide a channel adaptation mechanism that can be used in power line communication systems as well as other media that are affected by periodically varying channel impairments. Some embodiments may provide a higher level of guaranteed quality of service (QoS). Some embodiments may enable more efficient utilization of contention-free time allocations by enabling a transmitting station
25 to grant some of its allocated time to a receiving station.

In some embodiments, the time granted from the allocated time slot enables a receiving station to send information other than acknowledgement information. For example,

54830-3

a time slot assigned to a first station may include time during which a second receiving station is able to transmit acknowledgement information to the first station confirming successful transmission of information from the first station to the second station. The reverse grant procedure preserves the ability of the receiving station to transmit such

54830-3

acknowledgement information without obtaining specific permission, and provides a way for the receiving station to obtain permission to transmit further information.

Other features and advantages of some embodiments of the invention will be found in the detailed description and drawings.

DESCRIPTION OF DRAWINGS

FIG. 1 is a schematic diagram of a network configuration.

FIG. 2 is a block diagram of a communication system.

FIG. 3 is a timing diagram of a beacon period.

FIG. 4 is a diagram of schedules.

FIG. 5 shows an example of the variation in noise with AC line cycle waveform period.

FIG. 6 is a timing diagram for a reverse-grant procedure.

DETAILED DESCRIPTION

There are a great many possible implementations of the invention, too many to describe herein. Some possible implementations that are presently preferred are described below. It cannot be emphasized too strongly, however, that these are descriptions of implementations of the invention, and not descriptions of the invention, which is not limited to the detailed implementations described in this section but is described in broader terms in the claims.

System Overview

As shown in FIG. 1, a network configuration 100 provides a shared communication medium 110 for a number of communication stations (e.g., computing devices, or audiovisual devices) to communicate with each other. The communication medium 110 can include one or more types of physical communication media such as coaxial cable, unshielded twisted pair, or power lines, for example. The network configuration 100 can also include devices such as bridges or repeaters. The communication stations communicate with each other using predetermined physical (PHY) layer and medium access control (MAC) layer communication protocols. The MAC layer is a sub-layer of the data link layer and provides an interface to the PHY layer, according to the Open Systems Interconnection (OSI) network architecture

standard. The network configuration 100 can have any of a variety of network topologies (e.g., bus, tree, star, mesh). The communication stations communicate with one another based on requests from software applications running on the hardware of the respective station.

5 The stations can have differences in the specific communication protocols used, and are still able to communicate with each other if the protocols are compatible. For example, network configuration 100 includes a first type of communication station including stations 102A, 102B, 102C that use a first MAC layer protocol “MAC-A” with a second type of communication station including stations 104A and 104B that use
10 a second type of MAC layer protocol “MAC-B.” The MAC-A and MAC-B protocols are compatible with each other and also use the same or at least compatible PHY layer protocols (e.g., one station uses a MAC-A protocol and a PHY-A protocol, and another station uses a MAC-B protocol and a PHY-B protocol, where PHY-A and PHY-B implement compatible signal modulation formats).

15 The co-existence of multiple MAC layer protocols can be used, for example, to allow improvements in capabilities and/or performance of the MAC layer while also allowing devices using a new MAC layer protocol to be compatible with legacy devices using an older MAC layer protocol that may exist in the network configuration 100. In some implementations, a dual-mode (DM) device can communicate with a legacy
20 single-mode (SM) device using a first protocol, and can communicate with other DM devices using either the first protocol or a second protocol. The protocol to be used can be set by a communication mode that is determined at network setup time or when a device joins the network. For example, stations 104A and 104B include a network interface module 108 that uses MAC-A. Stations 102A, 102B, and 102C include a
25 network interface module 106 that can use either MAC-A or MAC-B depending on the determined communication mode.

 An example of a difference between the protocol layers (or “protocol stack”) used by different types of devices (e.g., the DM and SM devices) is the use of a “central coordinator” (CCo) station. The CCo is a communication station that is selected to
30 provide certain coordination functions for at least some of the other stations in the network configuration 100. A set of stations operating under the coordination of a single CCo is called a Basic Service Set (BSS). Functions performed by the CCo include: authentication of stations upon joining the BSS, provisioning of identifiers for

stations, and scheduling and timing of medium access. For example, the CCo broadcasts a repeated beacon transmission from which the stations in the BSS can determine scheduling and timing information. This beacon transmission includes fields that carry information used by the stations to coordinate communication. Though the
5 format of each of the repeated beacon transmission is similar, the content typically changes in each transmission. The beacon transmission is repeated approximately periodically, and, in some implementations, is synchronized to a characteristic of the communication medium 110. In some cases, a Proxy Coordinator (PCo) can be used to manage stations that are "hidden" from the CCo (e.g., stations that do not reliably
10 receive signals from the CCo).

There may also be differences in the access techniques implemented by the MAC-A and MAC-B protocols. For example, in one scenario, the MAC-A protocol uses a first access technique the MAC-B protocol is compatible with the first access technique and provides a second access technique. The MAC-A protocol uses a carrier
15 sense multiple access with collision avoidance (CSMA/CA) technique to access the network configuration 100. The MAC-B protocol uses a hybrid approach that includes a contention-free period (CFP) in which a time division multiple access (TDMA) technique is used, and optionally includes a contention period (CP) in which a CSMA/CA technique is used. The contention-free period is scheduled and managed by
20 the CCo to provide improved quality of service (QoS) for certain applications run on a device (e.g., audio and/or video applications). Other MAC protocols can use any one or combination of these or other access techniques.

In some implementations, the network interface modules use protocols that include features to improve performance when the network configuration 100 includes
25 a communication medium 110 that exhibits varying transmission characteristics. For example, when the communication medium 110 includes AC power lines in a house, optionally coupled to other media (e.g., coaxial cable lines), the communication channel between any two stations provided by the communication medium 110 may exhibit periodic variation in noise characteristics and frequency response.

30 To improve performance and QoS stability in the presence of varying channel characteristics, such as power line noise, the CCo synchronizes the beacon transmissions with the frequency of the AC line (e.g., 50 or 60 Hz). There are typically variations in the phase and frequency of the AC line cycle from the power generating

plant and local noise and load changes. This synchronization enables the time slots assigned to the various stations relative to a time reference in the beacon transmission to use consistent channel adaptation optimized for a particular phase region of the AC line cycle. The CCo also provides information in the beacon transmissions including a
5 time stamp that can be used by the stations to synchronize local clocks with respect to a master network clock located at the CCo.

Another aspect of mitigating potential impairments caused by the varying channel characteristics involves using a robust signal modulation format such as orthogonal frequency division multiplexing (OFDM), also known as Discrete Multi
10 Tone (DMT). OFDM is a spread spectrum signal modulation technique in which the available bandwidth is subdivided into a number of narrowband, low data rate channels or “carriers.” To obtain high spectral efficiency, the spectra of the carriers are overlapping and orthogonal to each other. Data are transmitted in the form of symbols that have a predetermined duration and encompass some number of carriers. The data
15 transmitted on these carriers can be modulated in amplitude and/or phase, using modulation schemes such as Binary Phase Shift Key (BPSK), Quadrature Phase Shift Key (QPSK), or m-bit Quadrature Amplitude Modulation (m-QAM).

PHY layer communication system architecture

Any of a variety of communication system architectures can be used to
20 implement the portion of the network interface module that converts data to and from a signal waveform that is transmitted over the communication medium. An application running on a station provides and receives data to and from the network interface module in segments. A “MAC Protocol Data Unit” (MPDU) is a segment of information including overhead and payload fields that the MAC layer has asked the
25 PHY layer to transport. An MPDU can have any of a variety of formats based on the type of data being transmitted. A “PHY Protocol Data Unit (PPDU)” refers to the modulated signal waveform representing an MPDU that is transmitted over the power line.

In OFDM modulation, data are transmitted in the form of OFDM “symbols.”
30 Each symbol has a predetermined time duration or symbol time T_s . Each symbol is generated from a superposition of N sinusoidal carrier waveforms that are orthogonal to each other and form the OFDM carriers. Each carrier has a peak frequency f_i and a

phase Φ_i measured from the beginning of the symbol. For each of these mutually orthogonal carriers, a whole number of periods of the sinusoidal waveform is contained within the symbol time T_s . Equivalently, each carrier frequency is an integral multiple of a frequency interval $\Delta f = 1/T_s$. The phases Φ_i and amplitudes A_i of the carrier waveforms can be independently selected (according to an appropriate modulation scheme) without affecting the orthogonality of the resulting modulated waveforms. The carriers occupy a frequency range between frequencies f_1 and f_N referred to as the OFDM bandwidth.

There can be two types of PPDU structures, depending on whether the PHY-A or PHY-B protocol is being used. For example, the PHY-B signals can use denser OFDM carrier frequency spacing and correspondingly longer symbols.

Referring to FIG. 2, a communication system 300 includes a transmitter 302 for transmitting a signal (e.g., a sequence of OFDM symbols) over a communication medium 304 to a receiver 306. The transmitter 302 and receiver 306 can both be incorporated into a network interface module at each station. The communication medium 304 can represent a path from one device to another over the power line network.

At the transmitter 302, modules implementing the PHY layer receive an MPDU from the MAC layer. The MPDU is sent to an encoder module 320 to perform processing such as scrambling, error correction coding and interleaving.

The encoded data is fed into a mapping module 322 that takes groups of data bits (e.g., 1, 2, 3, 4, 6, 8, or 10 bits), depending on the constellation used for the current symbol (e.g., a BPSK, QPSK, 8-QAM, 16-QAM constellation), and maps the data value represented by those bits onto the corresponding amplitudes of in-phase (I) and quadrature-phase (Q) components of a carrier waveform of the current symbol. This results in each data value being associated with a corresponding complex number $C_i = A_i \exp(j\Phi_i)$ whose real part corresponds to the I component and whose imaginary part corresponds to the Q component of a carrier with peak frequency f_i . Alternatively, any appropriate modulation scheme that associates data values to modulated carrier waveforms can be used.

The mapping module 322 also determines which of the carrier frequencies $f_1, \dots, f_N$ within the OFDM bandwidth are used by the system 300 to transmit information. For example, some carriers that are experiencing fades can be avoided, and no

information is transmitted on those carriers. Instead, the mapping module 322 uses coherent BPSK modulated with a binary value from the Pseudo Noise (PN) sequence for that carrier. For some carriers (e.g., a carrier $i = 10$) that correspond to restricted bands (e.g., an amateur radio band) on a medium 304 that may radiate power no energy is transmitted on those carriers (e.g., $A_{10} = 0$). The mapping module 322 also determines the type of modulation to be used on each of the carriers (or “tones”) according to a “tone map.” The tone map can be a default tone map, or a customized tone map determined by the receiving station, as described in more detail below.

An inverse discrete Fourier transform (IDFT) module 324 performs the modulation of the resulting set of N complex numbers (some of which may be zero for unused carriers) determined by the mapping module 322 onto N orthogonal carrier waveforms having peak frequencies $f_1, \dots, f_N$. The modulated carriers are combined by IDFT module 324 to form a discrete time symbol waveform $S(n)$ (for a sampling rate f_R), which can be written as

$$S(n) = \sum_{i=1}^N A_i \exp[j(2\pi i n/N + \Phi_i)]$$

Eq.(1)

where the time index n goes from 1 to N , A_i is the amplitude and Φ_i is the phase of the carrier with peak frequency $f_i = (i/N) f_R$, and $j = \sqrt{-1}$. In some implementations, the discrete Fourier transform corresponds to a fast Fourier transform (FFT) in which N is a power of 2.

A post-processing module 326 combines a sequence of consecutive (potentially overlapping) symbols into a “symbol set” that can be transmitted as a continuous block over the communication medium 304. The post-processing module 326 prepends a preamble to the symbol set that can be used for automatic gain control (AGC) and symbol timing synchronization. To mitigate intersymbol and intercarrier interference (e.g., due to imperfections in the system 300 and/or the communication medium 304) the post-processing module 326 can extend each symbol with a cyclic prefix that is a copy of the last part of the symbol. The post-processing module 326 can also perform other functions such as applying a pulse shaping window to subsets of symbols within the symbol set (e.g., using a raised cosine window or other type of pulse shaping window) and overlapping the symbol subsets.

An Analog Front End (AFE) module 328 couples an analog signal containing a continuous-time (e.g., low-pass filtered) version of the symbol set to the communication medium 304. The effect of the transmission of the continuous-time version of the waveform $S(t)$ over the communication medium 304 can be represented
5 by convolution with a function $g(\tau;t)$ representing an impulse response of transmission over the communication medium. The communication medium 304 may add noise $n(t)$, which may be random noise and/or narrowband noise emitted by a jammer.

At the receiver 306, modules implementing the PHY layer receive a signal from the communication medium 304 and generate an MPDU for the MAC layer. An AFE
10 module 330 operates in conjunction with an Automatic Gain Control (AGC) module 332 and a time synchronization module 334 to provide sampled signal data and timing information to a discrete Fourier transform (DFT) module 336.

After removing the cyclic prefix, the receiver 306 feeds the sampled discrete-time symbols into DFT module 336 to extract the sequence of N complex numbers
15 representing the encoded data values (by performing an N -point DFT). Demodulator/Decoder module 338 maps the complex numbers onto the corresponding bit sequences and performs the appropriate decoding of the bits (including deinterleaving and descrambling).

Any of the modules of the communication system 300 including modules in the
20 transmitter 302 or receiver 306 can be implemented in hardware, software, or a combination of hardware and software.

Beacon Transmissions

Various stations in a network may generate regular beacon transmissions for various purposes. A repeated beacon transmission from a CCo to each of the stations in
25 a BSS is called a Central Beacon (CB) transmission. The stations may communicate with each other in time periods between CB transmissions, provided the power line channel characteristics between any two communicating stations permits it.

One of the main functions of CB transmission is to carry medium allocation (or scheduling) information. The scheduling information allocates some of the time
30 between CB transmissions as a contention period during which stations may contend for access to the power line medium. The scheduling information also allocates a

contention-free period during which time slots are assigned to particular stations for access to the power line medium.

As described in more detail below, the CB transmission is synchronized with respect to the AC line cycle such that the time between CB transmissions (or “beacon period”) is based on the underlying AC line cycle frequency. The CB transmission can be synchronized to the AC line cycle by transmitting the CB at a fixed time interval from a detectable feature of the power line waveform such as a zero crossing. The beacon period can be set to any multiple of a half of the AC line cycle period, for example, by waiting for a given number of zero crossings.

In some cases it is desirable to increase the beacon period to make more efficient use of the medium by reducing the percentage of time devoted to sending the “overhead” information in the CB transmission. There is also overhead information associated with transmissions from the stations. It may also be desirable to keep the beacon period small enough to provide a desired number transmission opportunities in a given length of time. Thus, the beacon period can be selected according to a trade-off between keeping overhead low and latency between transmission opportunities low. For example, in some implementations the beacon period is selected to be twice the AC line cycle period. In this case, when operating in power line environments with an AC line cycle frequency of 60 Hz, the beacon period would be approximately 33.33 msec. When operating in power line environments with an AC line cycle frequency of 50 Hz, the beacon period would be approximately 40 msec. Variations in the beacon period may occur due to drift in the AC line cycle frequency.

FIG. 3 shows the structure of an exemplary beacon period 400 which consists of a Beacon Region 402 followed by a Contention Region 404 and a Reserved Region 406. Optionally, the Beacon Region 402 can be followed by any number of Contention Regions and Reserved Regions in any order. The Contention Region 404 is a time in which stations can contend for permission to transmit using a shared medium access protocol such as CSMA/CA.

The Reserved Region 406 includes a contention-free period (CFP) 408 which includes time slots assigned for use by predetermined stations (e.g., using a TDMA protocol). The CFP 408 can be divided into contiguous time slots for each of the participating stations. Alternatively, the CFP 408 can be divided into sessions, each of

which is divided into time slots for each of the participating stations. Therefore, a station may be allocated multiple times slots during the CFP 408.

The Contention Region 404 and the CFP 408 within the Reserved Region 406 are “persistent” in that they typically remain valid over multiple beacon periods. This persistent scheduled time allows stations that miss a beacon period for some reason to use previously stored schedule information, as described in more detail below. The Reserved Region 406 also includes a “non-persistent” period 410 that is not guaranteed to be valid for more than one beacon period. This non-persistent scheduled time allows rapid response to urgent time slot allocation requests, and time for network maintenance activities. For example, the non-persistent period 410 can include a time slot for a station to take a turn in transmitting a Discover Beacon used for setting up and maintaining the network. The non-persistent period 410 can use either or both of contention or contention-free access as needed. In this example, the non-persistent period 410 includes a non-persistent contention region 410A and a non-persistent contention-free “Extra Allocation” session 410B.

The Beacon Region 402 is the time allocated for the CCo to broadcast the CB transmission to the stations in the BSS. The CB transmission is sent using an OFDM waveform including preamble, frame control fields, and a beacon payload. In this example, the start 420 of the CB transmission (and thus the start of the Beacon Region 402) is synchronized to the AC line cycle at predetermined offset of Δ from the zero crossing. The beacon payload carries information used by the stations to determine the timing of the Reserved Regions and Contention Regions. In this example, one Contention Region 404 immediately follows the Beacon Region 402. If one or more Reserved Regions are present, additional Contention Regions may also be present in the beacon period 400.

Information describing the allocation of time slots within the beacon period is broadcast in the beacon payload within one or more beacon entries (BENTRYs). This information is used by stations within the network to coordinate sharing of bandwidth. The beacon payload carries three types of scheduling information:

- Beacon Region information
- persistent scheduling information
- non-persistent scheduling information

Beacon Region information is carried in a Regions BENTRY. This BENTRY contains the duration of Reserved Region 406 and the Contention Region 404.

Allocations of time slots to transmitting stations for contention-free access can occur during the persistent CFP 408 in the Reserved Region 404 or during the non-persistent
5 period 410.

Persistent CFP schedule information is carried in the Persistent Schedule BENTRY. The persistent CFP schedule is provided for use by transmitting stations requiring guaranteed QoS. It is critical that these transmitting stations obtain a sufficient amount of time during each beacon period to deliver their data and meet their
10 loss rate and latency requirements. For example, a station is assigned a sufficient amount of time to include opportunities to retransmit lost data and still meet or exceed a minimum latency between successful transmissions. Since it is possible for a station to miss a CB transmission, this schedule is persistent.

The Persistent Schedule BENTRY has two fields that are used to interpret the
15 persistence of schedule information:

- Current Schedule Count Down (CSCD)
- Preview Schedule Count Down (PSCD)

If the schedule is not changing, the schedule information reflects the current schedule and the Preview Schedule Count Down is zero. In this case, the Current
20 Schedule Count Down indicates the minimum number of beacon periods for which the current schedule may be assumed valid. The Current Schedule Count Down value should not be smaller than the previous Current Schedule Count Down value minus one. In this way, stations that miss Beacons will know how long they may use the current schedule information they have.

When the schedule changes, the Preview Schedule Count Down is set to a non-zero value. This value indicates that the schedule information is a new schedule (not the current schedule) and when the new schedule will take effect. In this case, the Current Schedule Count Down previews the value that the new schedule will have for its Current Schedule Count Down during the first beacon period when it takes effect.
30 The Current Schedule Count Down value in this case is a preview value and should not change from its initial value. In this way, stations that miss CB transmissions will know when they can use the new schedule information they have and for how long it will be valid. This approach allows a number of repetitions of the new schedule to

ensure that all stations have the relevant information, even if some stations miss the CB transmission during the beacon period when the new schedule takes effect.

FIG. 4 shows examples of schedule changes. A Schedule Information chart 500 shows values for PSCD and CSCD in the BENTRY of the CB transmission sent by the CCo. A Current Schedule chart 502 shows which of two schedules, Schedule A or Schedule B, is in effect during a given beacon period. Initially, Schedule A is in effect. In Beacon Period 2, the CCo determines that the schedule should change to Schedule B. So, beginning in Beacon Period 3, the CCo includes a BENTRY containing Schedule B with the values of PSCD and CSCD shown for the schedule. (The previewed schedules are shaded in FIG. 4.) Although the CCo has the option of transmitting both Schedule A and Schedule B in separate BENTRYs, transmitting Schedule A is no longer necessary.

Once the CCo has announced Schedule B in Beacon Period 3, the earliest that Schedule B can be replaced by a new Schedule C is Beacon Period 11. That is because while the PSCD for Schedule B is non-zero, the CSCD is a preview of what the CSCD will be in the first Beacon Period that B is current (Beacon Period 6). Since the CCo chose a preview value of 4, Schedule B must be the current schedule for 5 Beacon Periods.

The CCo can update the schedule, including the size of time slots allocated to stations, in response to requests from stations or without an explicit request from a station. For example, the CCo can update the schedule based on information obtained from monitoring transmissions between stations over the shared communication medium. The CCo can adjust time slots to account for changes to channel capacity due to changes to the communication medium, or to account for changes in channel utilization.

One way the CCo is able to determine changes in various transmission characteristics is by reading information in the header fields of transmissions. For example, header fields can indicate the amount of pending data awaiting transmission, or "bit loading estimates" representing number of user data bits (e.g., excluding certain overhead data) that are being transmitted in a given amount of time (e.g., 1 microsecond). The CCo uses these fields to determine whether to increase or decrease persistent and/or non-persistent schedules.

The CCo is also able to respond to detected changes such as an increased error rate on a link between stations. For example, a station may be increasing a data rate by using a modulation with higher error rate that is more than compensated for by the increased data rate. The CCo can change the schedules to give more time to those
5 stations that appear to need a higher data rate, or to optimize global characteristics such as total network throughput.

Persistence of schedule information improves reliability, but decreases responsiveness to urgent needs. A station that requests additional time for transmission during the CFP 408 might communicate its request to the CCo in the same Beacon
10 Period (3) in which a new schedule (B) is announced. This calls for the transmitting station to wait for the announced schedule (B) to take effect before a revised schedule (C) can be broadcast. The revised schedule (C) must then count down before it becomes effective, so the transmitting station may be forced to wait several Beacon Periods before it can obtain the additional CFP time slot allocation it needs.

15 The Non-Persistent Schedule information indicates which stations are allocated a time slot during the Extra Allocation session 410B to satisfy urgent requests for more transmission time. A transmitting station must receive the CB transmission to utilize any Extra Allocation time slot it is given in a beacon period, which makes Extra Allocation time slots less reliable than the persistent CFP 408 time slots.

20 A transmitting station with a regular CFP 408 time slot allocation is allowed to start its transmission at its start time, as defined by the schedule, and should end its transmission by its end time, as defined by the schedule. If a transmitting station does not receive the CB transmission, but the transmitting station has the current effective schedule information (due to schedule persistence), it may start its transmission during
25 its allocated time slot.

The CFP 408 time slot assigned to a transmitting station includes time after transmission of an MPDU during which the receiving station (or stations) can send a selective acknowledgement (SACK) according to a Selective Repeat Automatic Retransmission Request (SR-ARQ) approach. Each PPDU waveform representing an
30 MPDU includes a preamble, a frame control field, and a payload made up of multiple segments or PHY blocks (PBs) that are encrypted independently. The preamble and frame control field together are called the start-of-frame (SOF) delimiter. Each PB is contained in its own FEC Block. An MPDU may contain variable number of FEC

54830-3

blocks, depending on the data rate and payload duration. A SACK can be transmitted in response to a single MPDU, or a burst of multiple MPDUs (e.g., four) can be sent with a single SACK in response.

For example, within a time slot allocated to a transmitting station, the station may send multiple PPDU's each spanning an interval designated by the receiving station for a given channel adaptation. Each PPDU includes a SOF delimiter that can be used by the receiver to estimate phase and amplitude distortion within that adaptation interval for coherent demodulation. While a single long PPDU within a time slot may have lower overhead, transmitting multiple PPDU's enables each PPDU to use a different adaptation and provides a more accurate estimate of phase and amplitude distortion, which is likely to change in each adaptation interval. However, a single SACK can be used to acknowledge all of the MPDUs within the time slot.

The SACK format provides support for four SACK Type (SACKT) fields (one per MPDU in a burst of four MPDUs). The SACKT indicates whether:

- All the PBs in the corresponding MPDU were received correctly (SACKT = 0b00),
- All the PBs in the corresponding MPDU were received with errors or the corresponding MPDU is not detected (SACKT = 0b01), or
- A mixture of good and bad PBs were found in the corresponding MPDU (SACKT = 0b11). In this case SACK information field (SACKI) is present. This field contains a bit map indicating the reception status of each PB within the MPDU.

Line-Cycle Synchronization

As described above, various techniques can be used to take into account varying channel characteristics of a shared communications medium. For stations communicating using a communication protocol without a CCo, such as the MAC-A protocol, different channel adaptation can be assigned to each of multiple phase regions of a periodically varying channel by a channel adaptation facility in a station that interacts with the channel adaptation facility at other stations, as described in U.S. Patent No. 7,715,425 entitled "Channel Adaptation Synchronized to Periodically Varying Channel," filed February 26, 2004. For stations communicating using a communication protocol with a CCo,

such as the MAC-B protocol, channel adaptation can be based on synchronizing the beacon transmission to the periodically varying channel. The stations can then perform channel adaptation according to the received beacon transmission without the need for each station to directly detect the phase of the periodically varying channel.

5 Line-cycle synchronization can be achieved by having the CCo track a particular point in the AC line cycle using a Digital Phase Locked Loop (DPLL) or equivalent. Using a filter or digital lock loop at the CCo is helpful to eliminate noise events or jitter in the measurement of the AC line cycle phase. The CCo uses its local tracking history to also predict future locations of the beacon transmissions and
10 announce this to all stations in the beacon schedule. To ensure that stations with persistent allocations can transmit even when a CB transmission is not detected, the CCo provides information about the location of future CB transmissions within the beacon payload.

Clock Synchronization

15 The CCo includes a Network Clock that is used to provide a distributed time reference for the stations in the BSS. The CCo transmits a time stamp generated from the Network Clock in the CB transmission. For example, the time stamp can be a 32-bit value from a counter that increments with an edge (e.g., a rising edge) of the CCo's 25 MHz Network Clock. All timing of the network, including the beacon period and
20 schedule, can be derived from the Network Clock. Each station synchronizes a local time reference (e.g., a digital phase locked loop) to the Network Clock. The start of transmission (e.g., start of the preamble) of the CB transmission occurs close (e.g., within less than a microsecond) to the time stamp value.

 The Network Clock is used to synchronize the PHY layer signaling between
25 stations to eliminate inter-carrier interference without the need for high accuracy clocks. For example, while a local clock at a station may be accurate enough to provide accurate sample times for sampling a PHY-A signal with 200 kHz carrier spacing, the local clock may cause inter-carrier interference when used for sampling a PHY-B signal having only a 25 kHz carrier spacing. The denser carrier spacing corresponds to
30 longer symbols and more time for a frequency error between transmitting and receiving station clocks to lead to sampling errors. Other signal characteristics can also contribute to a signal's sensitivity to sampling errors. For example, higher order

modulation (e.g., 16-QAM vs. 4-QAM) typically has tighter timing tolerances. The consequence of the sampling errors may be that the carriers are no longer strictly orthogonal. This sampling error may affect high-frequency carriers more than low-frequency carriers.

- 5 The PHY layer clock used to determine sampling times may be faster than the local clock that is synchronized to the Network Clock based on the time stamps. In some implementations the PHY layer clock is 75 MHz, and is adjusted based on the local 25 MHz clock. For example, if the local clock tracking the Network Clock is adjusted by 10 parts per million (ppm) (relative to 25 MHz), then the PHY layer clock
- 10 is also adjusted by 10 ppm (relative to 75 MHz).

Channel Estimation

Channel estimation is the process of measuring the characteristics of the power line channel to adapt the operation of the PHY layer to provide optimal performance.

Channel estimation can include:

- 15 • Selection of the Tone Map designating modulation method(s) to be used on each carrier. Any given carrier may use different modulations at different times within the beacon period.
- Selection of the FEC rate.
- Selection of the guard interval length.
- 20 • Selection of the intervals within the beacon period where a particular Tone Map, FEC rate, and guard interval setting applies.

The FEC rate and guard interval length can vary over the AC line cycle period, but they are the same for all carriers at any given time.

- The results of channel estimation are reported to the CCo for use in allocating
- 25 time slots in the CFP. The CCo can allocate time for communication between a transmitting and receiving station to perform channel estimation. The CCo can then use this channel estimation information in determining or updating the schedule of time slots allocated to stations in the CFP.

- The channel-estimation procedures may differ slightly between the CP and the
- 30 CFP. In the CP, the receiving station can designate a default Tone Map that may be used by the transmitting station anywhere in the CP. The receiving station may optionally define additional Tone Maps that may be used in the CP during particular

intervals of the beacon period. This approach allows the transmitting station to begin communicating using Tone Map modulated data quickly, and avoids complicated interactions between the CSMA access procedure and the channel-estimation procedures for the CP. This approach is well suited to the transport of best effort data.

- 5 Alternatively, the receiving station can designate intervals within a beacon period over which particular channel adaptation applies without taking into account whether a transmission is within the CP or the CFP.

Before data communication occurs in the CFP, the receiving station defines a Tone Map that is valid in the interval of the beacon period where the transmission is
10 scheduled. If no valid Tone Map is defined in an interval, the transmitting station sends a "SOUND MPDU" in the interval until the receiving station defines a Tone Map that for the interval. The SOUND MPDU includes a signal known to the receiving station from which the receiving station can estimate characteristics of the channel. The receiving station defines a tone map in which the modulation for a carrier is tailored to
15 the characteristics of the channel at that carrier frequency. In addition to channel characteristics, the receiving station can also define a tone map based on a type of data to be transmitted (e.g., more robust modulation for applications more sensitive to data loss). The Tone Map is sent to the transmitting station in a channel estimation response (CER) message.

20 Alternatively, if no valid Tone Map is defined in an interval, the transmitting station can use a default Tone Map that has enough redundancy to be successfully transmitted assuming worst case channel characteristics. This default Tone Map may be more appropriate if the transmitting station only has a relatively small amount of data to send.

25 The channel-estimation procedures also include mechanisms for maintaining the lists of the intervals within the beacon period where each Tone Map may be used. Tone Map intervals are defined as time periods within the beacon period where a particular Tone Map may be used. Since the CCo locks the beacon period to the AC line cycle, intervals are synchronized to the AC line cycle.

30 Channel and noise characteristics over the power line tend to be periodic with the underlying AC line cycle. In some cases, these impairments occur at twice the frequency of the AC line cycle (i.e., 100 or 120 Hz) as shown in FIG. 5, while in other cases they may occur at the same frequency as the AC line cycle (e.g., a noise source

that responds to the polarity of the AC line waveform). Because of the different access mechanisms and QoS requirements, intervals occurring in the CP and CFP may be treated differently.

The receiving station specifies the intervals within which various Tone Maps
5 may be used, subject to certain guidelines which may include any of the following:

- The CP default Tone Map may be used anywhere in the contention period.
- With the exception of default Tone Map, intervals are disjoint (non-overlapping).
- 10 • The transmitter may not transmit PPDU's with the PPDU Payload crossing the boundary between intervals using different Tone Maps.
- The receiver specifies intervals that are large enough to carry a complete PPDU, based on the indicated Tone Map.
- The current intervals definition is carried in the CER message.
- 15 • The current intervals definition becomes stale if a period of 30 seconds has elapsed since the last CER message was received from the receiving station.

Contention-Free Reverse-Grant

In some implementations, the stations support a "reverse-grant" procedure.
20 This procedure allows a transmitting station to allocate part of its contention-free allocation of time to the receiving station, so the receiving station can send data to the transmitting station (i.e., over the reverse channel). This procedure may be used, for example, to send an updated Tone Map to a transmitting station in response to a change in the channel characteristics as determined by the receiving station.

25 The receiving station initiates the reverse-grant procedure using the Request Reverse Grant (RRG) field in a message transmitted during the receiving station's allocated time interval for sending a SACK message. The RRG field indicates the presence of the request and the number of blocks that the receiving station wants to send. The receiving station also indicates the type of data to be sent over the reverse
30 grant in a Request Reverse Grant Data Type Field.

Upon receiving the request, the transmitting station decides whether the request will be honored and its duration. The transmitting station signals that the reverse grant

is allowed by sending grant information. For example, the transmitting station sets a RGLen field in the SOF delimiter of the next PPDU transmission. The RGLen field specifies the maximum frame length (FL_AV) of the PPDU that may be transmitted in the reverse-grant time allocation. The reverse-grant time allocation can occur in the same beacon period in which the grant information was sent, or in a subsequent beacon period. If the reverse grant occurs in a subsequent beacon period, the persistent schedule information enables the reverse-grant allocation to be used even if either the transmitting or receiving station misses the corresponding CB transmission.

FIG. 6 shows an example of a reverse-grant procedure. In this example, Station A is transmitting data to Station B in the CFP. Station B initiates the reverse grant by setting the RRG field to a value indicating the requested amount of data (e.g., RRG = 10 indicating one PB) in a SACK message 600. The response time of station A is such that it cannot necessarily grant the request in a SOF delimiter frame control field immediately following the SACK containing the request. In this case, station B repeats the request in the next SACK message 602 and station A grants the request in the subsequent SOF delimiter 604. Station A signals the grant by placing the maximum allowable frame length "len" in the RGLen field of the SOF delimiter 604.

Upon receiving the data indicating that the reverse grant is allowed, station B transmits a SACK 606 to acknowledge the data received. Station B then transmits a SOF with RGLen = 00 followed by the desired data to be sent up to length "len" in the reverse grant period 610. Station A transmits a SACK 612 in response to this SOF, ending the reverse grant period 610. Station A resumes normal transmission of SOF delimiters followed by payload data and station B transmits a SACK PPDU in response. Alternatively, the information transmitted in the SACK responses 610 or 612 can be included in the subsequent SOF, obviating the need for a separate SACK response.

Variations on these reverse grant procedures are possible. A transmitting station may make unsolicited reverse grants; for example, the transmitting station can set RGLen to a non-zero value without first receiving a non-zero value of RRG from a receiving station requesting a reverse grant. If the receiving station does not need to use the entire period of time granted in the unsolicited reverse grant, the receiving station can relinquish the time back to the transmitting station. For example, the receiving station can send a message to the transmitting station indicating that the

remainder of the granted time can be used by the transmitting station. Many other implementations of the invention other than those described above are within the invention, which is defined by the following claims.

54830-3

CLAIMS:

1. A method for communicating between stations in a network, the method comprising:

receiving, at a first station, a beacon transmission from a coordinator station,

5 wherein the beacon transmission indicates a time slot assigned to the first station;

transmitting from the first station to a second station during the time slot assigned to the first station; and

transmitting, from the first station, information that grants permission to the second station to transmit during at least a portion of the time slot assigned to the first station.

10 2. The method of claim 1, wherein the time slot assigned to the first station includes time during which the second station is able to transmit acknowledgement information to the first station, the acknowledgement information confirming successful transmission of information from the first station to the second station.

3. The method of claim 2, wherein the portion of the time slot during which the
15 second station has received permission to transmit is larger than the time during which the second station is able to transmit the acknowledgement information.

4. The method of claim 2, wherein the first station provides permission for the second station to transmit during at least the portion of the time slot assigned to the first station in response to receiving a request from the second station included in the
20 acknowledgement information.

5. The method of claim 2, wherein the acknowledgement information includes information designating which of multiple segments of information were successfully received by the second station and which of the multiple segments of information should be retransmitted by the first station.

54830-3

6. The method of claim 1, wherein information transmitted from the second station in the portion of the time slot is information other than acknowledgement information confirming successful transmission of information from the first station to the second station.

7. The method of claim 1, wherein the time slot assigned to the first station is
5 determined from a time reference contained in the beacon transmission.

8. The method of claim 7, wherein the time reference comprises a time at which a predetermined portion of the beacon transmission is received.

9. The method of claim 7, wherein determining the time slot from the time reference comprises determining starting and ending times for the time slot measured from the
10 time reference, based on information in the beacon transmission.

10. The method of claim 1, wherein the first station transmits grant information to the second station specifying the portion of the time slot during which the second station is allowed to transmit.

11. The method of claim 10, wherein the portion of the time slot comprises a
15 portion of the same time slot during which the grant information was received by the second station.

12. The method of claim 10, wherein the portion of the time slot comprises a portion of a subsequent time slot following the time slot during which the grant information was received by the second station.

20 13. The method of claim 10, wherein the first station is assigned a plurality of noncontiguous time slots between successive beacon transmissions.

14. The method of claim 13, wherein the portion of the time slot comprises a portion of a subsequent time slot following the time slot during which the grant information was received by the second station.

54830-3

15. The method of claim 10, wherein the grant information is included in header information of a transmission from the first station to the second station.

16. The method of claim 1, wherein the first station provides permission for the second station to transmit during at least the portion of the time slot assigned to the first station in response to receiving a transmission from the second station that includes an amount of time that is requested.

17. The method of claim 16, wherein the first station provides permission for the second station to transmit during at least the portion of the time slot assigned to the first station in response to determining that the requested amount of time will be available in the time slot.

18. The method of claim 1, wherein the first station provides permission for the second station to transmit during at least the portion of the time slot assigned to the first station without first receiving a request from the second station.

19. The method of claim 18, wherein the first station indicates a time period granted to the second station.

20. The method of claim 19, wherein the second station relinquishes an unused portion of the time period back to the first station.

21. The method of claim 1, wherein the information transmitted from the second station to the first station during the portion of the time slot assigned to the first station comprises information used to maintain data flow from the first station to the second station.

22. The method of claim 21, wherein the information transmitted from the second station to the first station during the portion of the time slot assigned to the first station comprises adaptation information used by the first station to prepare a signal to be transmitted to the second station.

23. The method of claim 22, wherein the adaptation information comprises a map that designates a type of modulation that is to be used on multiple carriers in the signal.

54830-3

24. The method of claim 21, wherein the information transmitted from the second station to the first station during the portion of the time slot assigned to the first station comprises acknowledgement information used to confirm successful transmission of information from the first station to the second station.

5 25. The method of claim 1, further comprising, in response to not receiving the permission from the first station for the second station to transmit during the time slot assigned to the first station, transmitting from the second station to the first station during another time slot allocated based on contention with other stations in the network.

26. The method of claim 1, wherein transmitting from the first station to the second
10 station during the time slot comprises, after failing to successfully receive a recent beacon transmission at either or both the first and second station, transmitting from the first station to the second station during the time slot determined based on information contained in a prior beacon transmission preceding the recent beacon transmission.

27. The method of claim 1, wherein the coordinator station coordinates the
15 transmissions among the stations to occur in an interval between successive beacon transmissions.

28. The method of claim 1, wherein the beacon transmission allocates a plurality of time slots to the stations.

29. The method of claim 1, wherein the information that grants permission to the
20 second station to transmit is included in a transmission from the first station to the second station that includes a payload for the second station.

30. A system for communicating between stations, the system comprising:
a coordinator station configured to provide a beacon transmission to a first station,

25 wherein the beacon transmission indicates a time slot assigned to the first station; and

54830-3

a first station configured to:

receiving the beacon transmission from the coordinator station;

transmit to a second station during the time slot assigned to the first station; and

transmit information that grants permission to the second station to transmit

5 during at least a portion of the time slot assigned to the first station.

31. A system for communicating between stations in a network, the system comprising:

means for receiving, at a first station, a beacon transmission from a coordinator station, wherein the beacon transmission indicates a time slot assigned to the first station;

10 means for transmitting from the first station to a second station during the time slot assigned to the first station; and

means for transmitting, from the first station, information that grants permission to the second station to transmit during at least a portion of the time slot assigned to the first station.
