(54) Title: METHOD AND APPARATUS FOR SIMULTANEOUSLY CONVOLVING MULTIPLE DIGITAL BINARY IMAGES USING A SINGLE CONVOLVER WITH A BINARY MASK TO DETERMINE PIXEL DENSITIES

(57) Abstract

A system for simultaneously convolving first and second digital binary images in parallel with a single convolver having a binary mask. A first window is selected from the first digital binary image and a second window is selected from the second digital binary image. A first binary pixel is selected from the first window and a second binary pixel is selected from the second window. The first binary pixel is bit-shifted by concatenating a plurality of trailing zero bits to the first binary pixel. A multi-bit input pixel is formed by combining the bit-shifted first binary pixel and the second binary pixel. A single multi-bit output value is generated by simultaneously applying a plurality of multi-bit input pixels to a single convolver. A first convolution result is formed from only the least significant bits of the output value and a second convolution result is formed from only the most significant bits of the output value, wherein the first and second convolution results respectfully represent the results of sequentially applying a single convolver to the first and second windows.

METHOD AND APPARATUS FOR SIMULTANEOUSLY CONVOLVING MULTIPLE
DIGITAL BINARY IMAGES USING A SINGLE CONVOLVER WITH A BINARY
MASK TO DETERMINE PIXEL DENSITIES

Cross-Reference To Related Application

The present application is a continuation-in-part of pending U.S. Patent Application Serial No. 07/883,853, filed May 14, 1992, the contents of which are hereby incorporated herein in their entirety by reference.

Field Of The Invention

This invention relates to the reading and processing of package labels generally and particularly to systems for locating and extracting and decoding bar codes and other symbols from low resolution, noisy or cluttered CCD images.

Background Of The Invention

Package handling and sorting operations often require recognition systems for reading bar codes and other symbols which have been affixed to packages. Some types of sorting equipment, for example, use bar code recognition systems to sort packages in accordance with information which has been included in the bar code symbol.

Overhead CCD scanner systems have employed stationary reading devices to scan labels affixed to moving packages. Such devices typically include a linear array of photosensitive cells aligned orthogonally to the motion of the package and a lens system for projecting the image at a scanning window onto the linear array. The cells of the array are scanned at a rate which is relatively high compared to the

motion of the package through the read station. The images produced by such scanning equipment are often noisy and of low resolution.

Overhead CCD scanning systems which employ linear arrays and bar code laser scanners typically do not accurately determine the location and/or orientation of a bar code symbol affixed to a moving package. In high speed package sorting operations, this problem is exacerbated by the fact that individual bar code symbols, which are affixed to packages on a moving belt, will typically not have a common alignment or orientation.

A further complication to reading a bar code symbol is introduced when the symbol is embedded against a cluttered background on the moving package. The cluttered background can result from other information, besides the bar code symbol being scanned, which has been placed on the package in close proximity to the bar code symbol. A cluttered or noisy image can also result from stray marks on the package near the bar code symbol, or from a torn, smudged, or mutilated bar code symbol.

A still further complication to extracting and reading bar code symbols embedded in CCD images relates to limitations in image processing hardware that may be employed to process such images. In particular, currently available image processing boards typically include only a limited number of convolvers, thereby limiting the number of images that can be simultaneously convolved with a given mask to the number of convolvers on the image processing board. If an image processing application requires the convolution of

multiple images in parallel and a separate convolver is not available on the image processing board for each image being convolved, multiple image processing boards will have to be employed thereby substantially increasing the hardware costs associated with implementing an image processing system.

It is an object of the present invention to provide a system for reading bar code symbols of varying orientation which are affixed to packages on a moving belt.

It is a further object of the present invention to provide a system for reading bar code symbols embedded against a noisy or cluttered background using low resolution scanning equipment.

It is a still further object of the present invention to provide a system for locating within an intensity image varying types of objects or symbols including bar codes, stacked bar codes, square arrays and hexagonal arrays.

It is a still further object of the present invention to provide a system for determining the fine angular orientation within an intensity image of varying types of objects or symbols including bar codes and stacked bar codes.

It is a still further object of the present invention to provide a system for determining bar widths from a two dimensional image representative of a degraded or corrupted bar code symbol.

It is a still further object of the present invention to provide an image processing system which allows a standard convolver to simultaneously convolve multiple digital binary images in parallel using the same binary convolution

mask in order to determine pixel densities with each of the binary images.

Further objects and advantages of the invention will become apparent from the description of the invention which follows.

Summary Of The Invention

A system for simultaneously convolving first and second digital binary images in parallel with a single convolver having a binary mask is disclosed. A first window is selected from the first digital binary image and a second window is selected from the second digital binary image. A first binary pixel is selected from the first window and a second binary pixel is selected from the second window. The first binary pixel is bit-shifted by concatenating a plurality of trailing zero bits to the first binary pixel. A multi-bit input pixel is formed by combining the bit-shifted first binary pixel and the second binary pixel. A single multi-bit output value is generated by simultaneously applying a plurality of multi-bit input pixels to a single convolver. A first convolution result is formed from only the least significant bits of the output value and a second convolution result is formed from only the most significant bits of the output value, wherein the first and second convolution results respectfully represent the results of sequentially applying the single convolver to the first and second windows.

Figure 13D shows an exemplary projection signal derived from the application of the second global scaling method of the present invention to the projection signal of Figure 13C.

Figure 13E is an expanded representation of the projection signal of Figure 13D.

Figure 14 shows an exemplary low resolution image having a plurality of scan lines superimposed thereon in accordance with a preferred embodiment of the present invention.

Detailed Description Of The Preferred Embodiment

The present invention is directed to a system for locating an object within an intensity image, a system for determining the fine angular orientation and/or position of an object within an intensity image and a system for image processing. The object locating system is discussed in connection with Figures 1-8; the object orientation system is discussed in connection with Figures 9 and 10; and the image processing system is discussed in connection with Figures 11-14. As used herein, the term "object" refers to symbols, figures, patterns, shapes or areas having dense edges. Without limitation, the term "object" includes bar code symbols, stacked bar code symbols, and arrays of squares, hexagons and other polygons.

Object Locating System

Referring now to Figure 1, there is shown a flow diagram illustrating the operation of a preferred embodiment of a system for locating an object in an intensity image according to the present invention. The system accepts as its input intensity image 100 which is preferably a digitized gray scale representation of an imaged region being scanned. In

the preferred embodiment, intensity image 100 is a low resolution pixel image derived from a linear array of CCDs. The system shown includes means 200 for analyzing an intensity image with at least two different edge detectors to detect a multiplicity of edges oriented in at least two directional ranges. Means 300 is provided for comparing information representative of detected edges angularly oriented in a first of said at least two directional ranges to information representative of detected edges angularly oriented in a second of said at least two directional ranges. Based on the results of comparisons made by means 300, means 400 selects at least one foreground region from intensity image 100 wherein detected edges are angularly oriented substantially in accordance with a target orientation. Means 500 is provided for extracting from intensity image 100 information that is representative of the foreground region selected by means 400. In the preferred embodiment, means 500 determines the position (i.e., the spatial coordinates) within intensity image 100 of the centroid (or center of mass) of an object region that corresponds to the foreground region selected by means 400.

Referring now to Figure 2A, there are shown two edge detectors 210, 220 which are employed by means 200 in connection with a preferred embodiment of the present invention. In a preferred embodiment, means 200 applies edge detector 210 to intensity image 100 on a pixel-by-pixel basis to determine the X component (ΔX) of each edge gradient. Similarly, edge detector 220 is applied to intensity image 100 on a pixel-by-pixel basis to determine the Y component (ΔY) of each edge gradient. Based on this X and Y component

information, means 200 determines edge magnitude information (M_n) and direction information (D_n) at each pixel in intensity image 100 according to equations (1) and (2) below:

$$M_n = (\Delta X_n^2 + \Delta Y_n^2)^{1/2} \quad (1)$$

$$D_n = \arctan (\Delta Y_n / \Delta X_n) \quad (2)$$

In a preferred embodiment, intensity image 100 is formed of 782 x 1288 8-bit pixels and M_n is normalized to range from 0-127. This normalization is achieved by dividing the result of equation (1) by 8.

In an alternative preferred embodiment, edge detectors 230, 240, 250, 260 of Figure 2B are applied by means 200 to determine edge magnitude information and edge direction information at each pixel in intensity image 100. More particularly, edge detector 230 is applied to intensity image 100 on a pixel-by-pixel basis to determine magnitude information corresponding to edges angularly oriented in a directional range within 22.5 degrees on either side of the 0 degree axis; edge detector 240 is applied to intensity image 100 on a pixel-by-pixel basis to determine magnitude information corresponding to edges angularly oriented in a directional range within 22.5 degrees on either side of the 45 degree axis; edge detector 250 is applied to intensity image 100 on a pixel-by-pixel basis to determine magnitude information corresponding to edges angularly oriented in a directional range within 22.5 degrees on either side of the 90 degree axis; and edge detector 260 is applied to intensity image 100 on a pixel-by-pixel basis to determine magnitude information corresponding to edges angularly oriented in a

directional range within 22.5 degrees on either side of the 135 degree axis.

Edge information from means 200 is next applied to edge information comparator 300. In a preferred embodiment, edge information comparator 300 is comprised of means 310 for generating at least two feature images, means 330 for forming a composite feature image and means 350 for forming a pixel cluster region in a composite feature image.

In a preferred embodiment, means 310 generates at least two feature images by associating the edge magnitude information determined for each pixel in intensity image 100 with one of at least two corresponding directional ranges. In a first preferred embodiment, edge detectors 210, 220 are used to determine the angular orientation of each edge detected from intensity image 100, and each detected edge is then classified as being angularly oriented in one of at least three directional ranges. For example, each detected edge may be classified as being oriented in either (i) a first directional range within 30 degrees on either side of the 0 degree axis, (ii) a second directional within 30 degrees on either side of the 60 degree axis or (iii) a third directional within 30 degrees on either side of the 120 degree axis. For each directional range, means 310 associates the detected edges angularly oriented in that directional range with a corresponding feature image. In a preferred embodiment, each feature image is formed of binary pixels which are used to represent the detected edges which have been associated with that respective feature image. The position of each binary pixel set high (or set white) on a given feature image

preferably corresponds to the position in intensity image 100 of the detected edges associated with that feature image.

In an alternate preferred embodiment, each edge detected by detectors 210, 220 is classified as being angularly oriented in one or two of at least three partially overlapping directional ranges. In this embodiment, the preferred degree of overlap is approximately 5 degrees on either side of each directional range, although other amounts of overlap may be used. Thus, each detected edge may be classified as being oriented in (i) a first directional range within 35 degrees on either side of the 0 degree axis, (ii) a second directional range within 35 degrees on either side of the 60 degree axis and/or (iii) a third directional range within 35 degrees on either side of the 120 degree axis. A detected edge will be classified in only one directional range if it is not oriented in one of the overlapping range portions. Similarly, a detected edge will be classified in two directional ranges if it is oriented in an overlapping range portion. As in the paragraph immediately above, for each directional range, means 310 associates the detected edges oriented in that directional range with a corresponding feature image.

In still further alternate embodiments, means 310 may classify detected edges into other directional ranges of differing size or direction. In addition, at least two and more than three directional ranges may be used to classify the detected edges. For example, edge detectors 230, 240, 250, 260 may be used by means 310 to classify each edge from an

imaged region into one of the four directional ranges associated with those edge detectors.

Means 310 is preferably formed from means 310a for forming at least two binary images and means 310b for generating at least two feature images from the output of means 310a. Referring now to Figure 3A, there is shown a flow diagram illustrating the operation of means 310a for forming at least two binary images, wherein each of the at least two binary images formed corresponds to one of at least two directional ranges of detected edges. Means 310a accepts as its input magnitude information and directional information for each edge detected by means 200. Means 311 is provided for selecting a detected edge for processing. Means 312 compares the magnitude information corresponding to the selected edge to a first predetermined threshold (T_1). If it is determined that the magnitude information corresponding to the selected edge exceeds T_1 , means 313 selects from at least two directional ranges the one directional range corresponding to the direction of the selected edge. If the magnitude information exceeds T_1 , means 313 also selects from at least two binary images the one binary image corresponding to the selected directional range. Means 314 then sets high the pixel in the selected binary image which corresponds in position to the position of the selected edge in intensity image 100. Means 315 is provided for repeating this process from means 311 for each detected edge.

In an alternate preferred embodiment used for processing detected edges which are to be classified in one or two of at least three partially overlapping directional

ranges, means 313 selects from at least three directional ranges the one or two directional ranges corresponding to the direction of the selected edge. In this embodiment, means 313 also selects from at least three binary images the one or two binary images corresponding to the selected directional range(s). Means 314 then sets high the pixel(s) in the selected binary image(s) which correspond in position to the position of the selected edge in intensity image 100.

In a still further preferred embodiment, means 310 accepts as input magnitude information determined by each of edge detectors 230, 240, 250, 260. The magnitude information corresponding to each detected edge is then compared against T_1 . For each edge detected by detector 230 with a magnitude exceeding T_1 , a binary pixel is set high in a first binary image. The position of the binary pixel set high corresponds to the position in intensity image 100 of the edge represented by that binary pixel. Similarly, for each edge detected by detector 240 with a magnitude exceeding T_1 , a corresponding binary pixel in a second binary image is set high; for each edge detected by detector 250 with a magnitude exceeding T_1 , a corresponding binary pixel in a third binary image is set high; and for each edge detected by detector 260 with a magnitude exceeding T_1 , a corresponding binary pixel in a fourth binary image is set high.

Figure 6A shows an exemplary low resolution intensity image (610), for processing by the object locator system, of the present invention. Figure 6B shows four binary images which resulted from application of edge detectors 230, 240, 250, 260 to the intensity image of Figure 6A. Thus, the

white pixels in first binary image 620 represent edges detected by detector 30 with magnitudes exceeding T_1 and angular orientations in the directional range within 22.5 degrees on either side of the 0 degree axis; the white pixels in second binary image 622 represent edges detected by detector 240 with magnitudes exceeding T_1 , and angular orientations in the directional range within 22.5 degrees on either side of the 45 degree axis; the white pixels in third binary image 624 represent edges detected by detector 250 with magnitudes exceeding T_1 and angular orientations in the directional range within 22.5 degrees on either side of the 90 degree axis; and the white pixels in fourth binary image 626 represent edges detected by detector 260 with magnitudes exceeding T_1 and angular orientations in the directional range within 22.5 degrees on either side of the 135 degree axis.

In a preferred embodiment, means 310b subjects each of the at least two binary images output by means 310a to a filtering process referred to as weighed morphology or "majority dilation/minority erosion". This process is used to "dilate" areas in each binary image where the concentration of pixels set high exceeds a second predetermined threshold (T_2), and to "erode" areas in each binary image where the concentration of binary pixels set high does not exceed T_2 . In a preferred embodiment of means 310b, this majority dilation/minority erosion process is also used to simultaneously perform "subsampling" on each binary image. According to this embodiment, each of the at least two binary images is divided into a plurality of regions or blocks. For example, a binary image 782 x 1288 pixels in dimension would

preferably be divided into pixel blocks 8 x 8 pixels in size. Next, the concentration of binary pixels set high in each block of the plurality of blocks is determined and compared against T_2 . An output binary image (or feature image) is then formed by representing each block from the binary image with a single binary pixel in the feature image. The single binary pixel in the feature image is set high when the corresponding block in the binary image has a determined concentration which exceeds T_2 . The single binary pixel in the feature image is set low when the corresponding block in the binary image has a determined concentration which does not exceed T_2 . Since a single binary pixel is used in a feature image to represent each 8 x 8 block of pixels in a binary image, a feature image which is 97 x 161 pixels in dimension will be formed from a binary image which is 782 x 1288 pixels in dimension.

Referring now to Figure 3B, there is shown a flow diagram of means 310b for generating at least two feature images from at least two binary images according to the majority dilation/minority erosion process described above. In the embodiment shown, means 316 is provided for tiling each of the binary images into a plurality of blocks. One block from the plurality of tiled blocks is then selected by means 317 and the number of binary pixels set high in the selected block is determined by pixel counter 318. Comparing means 319 is provided for comparing the number of pixels determined by counter 318 to T_2 . If the number of binary pixels set high in the selected block exceeds T_2 , then means 320 sets a corresponding binary pixel in a corresponding feature image high (or white). If the number of binary pixels set high in

the selected block does not exceeds T_2 , then means 321 sets a corresponding binary pixel in a corresponding feature image low (or black). Means 322 is provided for repeating this process from means 317 for each tiled block. Figure 6C shows four exemplary feature images 630, 632, 634, 636 which respectively resulted from the application of the majority dilation/minority erosion process of Figure 3B to binary images 620, 622, 624, 626 of Figure 6B.

In an alternate preferred embodiment of means 310b, a "sliding" window is applied to each of the at least two binary images. The sliding window is, for example, an 8 x 8 block of pixels. This window is first applied to the 8 x 8 block of pixels in the upper left hand corner of a selected binary image. The number of pixels set high in the window is compared against T_2 . If the number of pixels in the window set high exceeds T_2 , then a corresponding binary pixel in a corresponding feature image is set high; otherwise, the corresponding binary pixel in the corresponding feature image is set low. The window is then moved one pixel to the right and the process is repeated. This process continues until the right side of the sliding window reaches the right side of the selected binary image. At this point, the window is moved downward by one pixel and over to the left most column of pixels. This process is repeated until the sliding window reaches the bottom right hand corner of the selected binary image.

In a still further preferred embodiment of means 310b, the majority dilation/minority erosion process is achieved by first dividing each of the at least three binary

images into a plurality of regions. Next, the concentration of binary pixels set high in each region of the plurality of regions is determined and compared against T_2 . In each region where the determined concentration exceeds T_2 , a pixel cluster region is formed by setting all binary pixels in that region high (or white). In each region where the determined concentration does not exceed T_2 , a blank region is formed by setting all binary pixels in that region low (or black).

The output of feature image generator 310 is provided to composite feature image generator 330. Figure 3C is a flow diagram illustrating the operation of a preferred composite feature image generator according to the present invention. In a preferred embodiment, first, second, third and fourth feature images are provided to means 330. The first feature image having been determined from a first binary image representing edges orientated in the directional range within 22.5 degrees on either side of the 0 degree axis; the second feature image having been determined from a second binary image representing edges orientated in the directional range within 22.5 degrees on either side of the 45 degree axis; the third feature image having been determined from a third binary image representing edges orientated in the directional range within 22.5 degrees on either side of the 90 degree axis; and the fourth feature image having been determined from a fourth binary image representing edges orientated in the directional range within 22.5 degrees on either side of the 135 degree axis.

Referring still to Figure 3C, pixel selector means 331a, 331b, 331c, 331d are provided for selecting

corresponding binary pixels from the first, second, third and fourth feature images. First Oring means 332a is provided for performing an exclusive logical OR operation on a binary pixel in the first feature image and a corresponding binary pixel in the third feature image, and second Oring means 332b is provided for performing an exclusive logical OR operation on a binary pixel in the second feature image and a corresponding binary pixel in the fourth feature image. The outputs of first Oring means 332a and second Oring means 332b are provided to third Oring means 333 where they are compared on a pixel-by-pixel basis. More particularly, means 333 performs a logical OR operation on its inputs and sets either high or low a corresponding binary pixel in a composite feature image depending on the result of the OR operation. The binary pixel set in the composite feature image corresponds in position to the position within each of the four feature images of the binary pixels selected by means 331a, 331b, 331c, 331d. Figure 6D shows an exemplary composite feature image 640 which resulted from the application of the process of Figure 3C to feature images 630, 632, 634, 636 of Figure 6C.

Referring now to Figure 3D, there is shown an alternative composite feature image generator wherein only two feature images are provided to means 330. Pixel selector means 335a, 335b, are provided for selecting corresponding binary pixels from each of first and second feature images. Pixel comparator means 336 is provided for setting high a binary pixel in a composite feature image if only one of the two selected corresponding binary pixels is set high. In a further alternative embodiment (not shown) wherein three

feature images are provided to means 330 and three corresponding binary pixels are selected from each of first, second and third feature images, pixel comparator means 336 sets high a binary pixel in a composite feature image if only one or only two of the three selected corresponding binary pixels are set high. The pixel set high in the composite feature image corresponds in position to the position within each of the feature images of the selected corresponding binary pixels. This process is repeated on a pixel-by-pixel basis for each group of corresponding pixels in the feature images.

A still further alternative embodiment of a composite feature image generator according to the present invention is shown in Figure 3E. In the embodiment shown, N feature images are provided to the composite feature image generator, wherein N is greater than or equal to two. Means 340 are provided for selecting a corresponding pixel from each of M feature images, wherein M is greater than or equal to two and less than or equal to N (for bar code symbols, M is preferably two). At least two of the M selected corresponding binary pixels are preferably selected from feature images representing edges oriented in subsequent directional ranges. For example, where M is two and there are first, second, third and fourth (N=4) feature images respectively representing detected edges in a first directional range of 22.5 degrees on either side of the 0 degree axis, a second directional range of 22.5 degrees on either side of the 95 degree axis, a third directional range of 22.5 degrees on either side of the 90 degree axis and a fourth directional range on either side of

the 135 degree axis, the two selected corresponding binary pixels are preferably from either the first and second, or the second and third, or the third and fourth, or the fourth and first feature images. Means (not shown) are also provided for selecting a pixel from a composite feature image; the selected pixel in the composite feature image corresponds in position to the position within each of the M feature images of the selected corresponding binary pixels. The selected pixel from the composite feature image is then set high by pixel comparator 342 if at least one of the M selected corresponding binary pixels is set high and less than all of the M selected corresponding binary pixels are set high. This process is repeated on a pixel-by-pixel basis for each pixel in the composite feature image.

The output of composite feature image generator 330 is provided to pixel cluster region generator 350. Pixel cluster region generator 350 filters the composite feature image using a modified version of the majority dilation/minority erosion described above. In particular, pixel cluster region generator 350 is used to "dilate" areas in the composite feature image where the concentration of pixels set high exceeds a third predetermined threshold (T_3), and to "erode" areas in the composite feature image where the concentration of binary pixels set high does not exceed T_3 . In a preferred embodiment of pixel cluster region generator 350, this majority dilation/minority erosion process is achieved by applying a "sliding" window to the input composite feature image. More particularly, in the sliding window operation of pixel cluster region generator 350, a window

(preferably 3 x 3 pixels in dimension) is first applied to the pixels in the upper left hand corner of the input composite feature image. Thus, if a window 3 x 3 pixels in dimension were employed, it would first be applied to the 3 x 3 block of pixels in the upper left hand corner of the input composite feature image. The number of pixels set high in the window is compared against T_3 . If the number of pixels in the window set high exceeds T_3 , then a corresponding pixel positioned in the center of the 3 x 3 window will be set high in the output composite feature image; otherwise, the corresponding pixel in the output composite feature image will be set low. The window is then moved one pixel to the right and the process is repeated. This process continues until the right side of the window reaches the right side of the input composite feature image. At this point, the window is moved downward one pixel and over to the left most column of pixels in the input composite feature image. This process is repeated until the sliding window reaches the bottom right hand corner of the input composite feature image. Figure 6E shows an exemplary output composite feature image (650) which resulted from the application of the majority dilation/minority erosion process described above to composite feature image 640 of Figure 6D.

In an alternative preferred embodiment of pixel cluster region generator 350, the majority dilation/minority erosion process is achieved by first dividing the composite feature image into a plurality of regions. Next, the concentration of binary pixels set high in each region of the plurality of regions is determined and compared against T_3 . In each region where the determined concentration exceeds T_3 ,

a pixel cluster region is formed by setting all binary pixels in that region high (or white). In each region where the determined concentration does not exceed T_3 , a blank region is formed by setting all binary pixels in that region low (or black).

Referring now to Figure 3F, there is shown a flow diagram of a pixel cluster region generator for processing a composite feature image according to the majority dilation/minority erosion process described in the paragraph immediately above. Means 352 is provided for tiling each of the composite feature image into a plurality of blocks. One block from the plurality of tiled blocks is then selected by means 354 and the number of binary pixels set high in the selected block is determined by pixel counter means 356. Comparing means 358 is provided for comparing the number of pixels determined by means 356 to T_3 . If the number of binary pixels set high in the selected block exceeds T_3 , then means 360 sets all binary pixels in the selected block high. If the number of binary pixels set high in the selected block does not exceed T_3 , then means 362 sets all binary pixels in the selected block low. Means 364 is provided for repeating this process from means 354 for each tiled block.

Referring now to Figure 3G, there is shown a diagram illustrating a system 370 for efficiently forming a plurality of binary images from an input intensity image according to a preferred embodiment of the present invention. The operation implemented by system 370 corresponds in function to that performed by means 310a of Figure 3A. In the embodiment shown in Figure 3G, system 370 is configured to form four binary

images, wherein each binary image corresponds to one of four directional ranges (i.e., directional range 0, directional range 1, directional range 2 and directional range 3) of detected edges. The binary image corresponding to directional range 0 preferably represents detected edges oriented within 27.5 degrees on either side of the 0 degree axis; the binary image corresponding to directional range 1 preferably represents detected edges oriented within 27.5 degrees on either side of the 45 degree axis; the binary image corresponding to directional range 2 preferably represents detected edges oriented within 27.5 degrees on either side of the 90 degree axis; and the binary image corresponding to directional range 3 preferably represents detected edges oriented within 27.5 degrees on either side of the 135 degree axis.

System 370 accepts as its input 8-bit pixel values from intensity image 100. These 8-bit input pixels are sequentially selected and applied (in 3x3 windows) to edge detectors 210, 220, thereby yielding an 8-bit ΔX value and an 8-bit ΔY value corresponding to each pixel in intensity image 100. Next, for each input pixel selected from intensity image 100, a corresponding pair of ΔX , ΔY values are applied to look-up table (LUT) 372.

For each possible pair of ΔX , ΔY values that may be applied to LUT 372, four corresponding 1-bit values (DIR0, DIR1, DIR2, DIR3) are stored in LUT 372. The values of these 1-bit entries stored in LUT 372 are preferably determined prior to the acceptance of intensity image 100 by the present invention. For each entry (or pair of ΔX , ΔY values)

referenced in LUT 372, the corresponding values of DIR0, DIR1, DIR2 and DIR3 are determined by first applying the ΔX , ΔY values corresponding to the table entry to equations (1) and (2) above, thereby calculating a magnitude value (M_n) and a direction value (D_n) corresponding to the table entry. If the magnitude value (M_n) is less than or equal to the threshold (T_1), then the values in the table entry corresponding to DIR0, DIR1, DIR2 and DIR3 are all set to zero. If the magnitude value (M_n) is greater than the threshold (T_1), then the direction value (D_n) is compared against direction ranges 0, 1, 2 and 3 to determine which of these four directional ranges includes direction value (D_n). If D_n falls within directional range 0 and not in any of the other directional ranges, then the value in the table entry corresponding to DIR0 will be set high and the values corresponding to DIR1, DIR2 and DIR3 will all be set low; if D_n falls within directional range 1 and not within any of the other directional ranges, then the value in the table entry corresponding to DIR1 will be set high and the values corresponding to DIR0, DIR2 and DIR3 will all be set low; if D_n falls within directional range 2 and not within any of the other directional ranges, then the value in the table entry corresponding to DIR2 will be set high and the values corresponding to DIR0, DIR1 and DIR3 will all be set low; and if D_n falls within directional range 3 and not within any of the other directional ranges, then the value in the table entry corresponding to DIR3 will be set high and the values corresponding to DIR0, DIR1 and DIR2 will all be set low. Since directional ranges 0-3 overlap each other by 5 degrees,

two of the DIR0, DIR1, DIR2, DIR3 bits will be set high if D_n falls within a region where the directional ranges overlap. The purpose of using overlapping directional ranges is to ensure detection of bar code symbols that might otherwise fall at the edge of a non-overlapping angular range and thus go undetected.

Thus, for each selected input pixel from intensity image 100, a pair of ΔX , ΔY values are applied to LUT 372 which then outputs the four 1-bit values DIR0, DIR1, DIR2 and DIR3. Each of these values represents a pixel in a binary image which corresponds in location to the position of the selected input pixel in intensity image 100. More particularly, the 1-bit value DIR0 represents the value of a corresponding binary pixel in the binary image representing directional range 0; the 1-bit value DIR1 represents the value of a corresponding binary pixel in the binary image representing directional range 1; the 1-bit value DIR2 represents the value of a corresponding binary pixel in the binary image representing directional range 2; and the 1-bit value DIR3 represents the value of a corresponding binary pixel in the binary image representing directional range 3. For each input pixel from intensity image 100, the corresponding 1-bit values DIR0, DIR1, DIR2, DIR3 are grouped to form 4-bit words which are provided to system 380.

When each of the input pixels from intensity image 100 have been processed by system 370, the 4-bit words output by LUT 372 collectively represent four binary images, wherein each binary image corresponds to one of four directional ranges of edges (i.e., directional range 0, directional range

1, directional range 2 and directional range 3). Since these four directional ranges are overlapping, one or two bits within each 4-bit word output by LUT 372 will be set high. In alternate embodiments that employ binary images corresponding to non-overlapping directional ranges, only one bit within each 4-bit word output by LUT 372 may be set high.

The use of LUT 372 to form separate binary images directly from the outputs of edge detectors 210, 220 substantially simplifies the computations required to implement means 310a in real time. In particular, the use of LUT 372 to form binary images directly from the outputs of edge detectors 210, 220 eliminates the need to repeatedly calculate the magnitude (M_n) and direction (D_n) of each edge in intensity image 100 in accordance with equations (1) and (2) above. Since equations (1) and (2) are computationally intensive, the use of a look-up table that eliminates the need to repeatedly solve these equations has the advantage of substantially enhancing the operational speed of the present invention. Although in the embodiment shown in Figure 3G system 370 is configured to form four binary images, wherein each binary image corresponds to one of four directional ranges of detected edges, it will be understood by those skilled in the art that system 370 may be configured to form more or fewer than four binary images corresponding to different directional ranges by varying the number of columns and the content of the entries in LUT 372.

Referring now to Figure 3H, there is shown a diagram illustrating a system 380 for efficiently forming a composite feature image from data representative of a plurality of

binary images according to a preferred embodiment of the present invention. The operation implemented by system 380 corresponds in function to the operations shown by Figures 3B and 3C described above.

System 380 preferably accepts as its inputs the 4-bit words generated by LUT 372. Each 4-bit word is applied to bit shifter 382 which forms two 8-bit words (INPUT WORD 1 and INPUT WORD 2) from each 4-bit word that is applied thereto. More particularly, shifter 382 places the 1-bit value DIR0 in bit position 0 of INPUT WORD 1; shifter 382 places the 1-bit value DIR1 in bit position 6 of INPUT WORD 1; shifter 382 places the 1-bit value DIR2 in bit position 0 of INPUT WORD 2; and shifter 382 places the 1-bit value DIR3 in bit position 0 of INPUT WORD 2. Shifter 382 sets bit positions 1-5 and 7 to zero in both INPUT WORD 1 and INPUT WORD 2. Next, the 8-bit value INPUT WORD 1 output by shifter 382 is applied to convolver 384, and the 8-bit value INPUT WORD 2 output by shifter 382 is applied to convolver 386.

Convolver 384, 386 represent standard image processing convolvers such as those found on a Datacube™ Maxvideo™ image processing system. Convolver 384, 386 are each configured to accept 8-bit words at their inputs, each of the 8-bit words corresponding to an 8-bit pixel. The 8-bit pixels which are input to each convolver collectively correspond to an image which can be thought of as being comprised of a two-dimensional array of 8x8 pixel blocks. Each convolver 384, 386 convolves an 8x8 block of input pixels with binary mask 388 by first superimposing binary mask 388 (which is 8x8 pixels in dimension) on a respective 8x8 block

of input pixels and then multiplying on a pixel-by-pixel basis each pixel from the 8x8 block of input pixels with the value from binary mask 388 that has been superimposed thereon. For each 8x8 block of input pixels input to convolver 384, a 12-bit value (OUTPUT WORD 1) is generated which represents the sum of the resultant products of its pixel-by-pixel multiplications. Similarly, for each 8x8 block of input pixels input to convolver 386, a 12-bit value (OUTPUT WORD 2) is generated which represents the sum of the resultant products of its pixel-by-pixel multiplications. As shown in Figure 3H, binary mask 388 is preferably 8x8 binary pixels in dimension, wherein all the binary pixels in the mask are set to "1" except the pixels at the corners of the mask which are set to "0". In alternate embodiments, the number of binary pixels set to "1" in mask 388 can range from 0 to 63.

Next, OUTPUT WORD 1 and OUTPUT WORD 2 are respectively applied to shifter/comparator 390 and shifter/comparator 392. Shifter/comparator 390 forms a 6-bit value DIR0 RESULT from bit positions 0-5 of OUTPUT WORD 1, and a 6-bit value DIR1 RESULT from bit positions 6-11 of OUTPUT WORD 1. More particularly, DIR0 RESULT is a value ranging from 0-63 representing the 6 least-significant-bits of OUTPUT WORD 1, and DIR1 RESULT is a value ranging from 0-63 representing the 6 most-significant-bits of OUTPUT WORD 1. Similarly, shifter/comparator 392 forms a 6-bit value DIR2 RESULT from bit positions 0-5 of OUTPUT WORD 2, and a 6-bit value DIR3 RESULT from bit positions 6-11 of OUTPUT WORD 2. DIR2 RESULT is a value ranging from 0-63 representing the 6 least-significant-bits of OUTPUT WORD 2, and DIR3 RESULT is a

value ranging from 0-63 representing the 6 most-significant-- bits of OUTPUT WORD 2. For purposes of comparison to the flow diagrams shown earlier, it should be noted that each DIR0 RESULT value determined by shifter/comparator 390 is substantially equivalent to the output that binary pixel counter 318 would have yielded had counter 318 been applied to a selected 8x8 binary pixel block in the binary image corresponding to directional range 0 (as described above in conjunction with Figure 3G); each DIR1 RESULT value determined by shifter/comparator 390 is substantially equivalent to the output that binary pixel counter 318 would have yielded had counter 318 been applied to a selected 8x8 binary pixel block in the binary image corresponding to directional range 1; each DIR2 RESULT value determined by shifter/comparator 392 is substantially equivalent to the output that binary pixel counter 318 would have yielded had counter 318 been applied to a selected 8x8 binary pixel block in the binary image corresponding to directional range 2; and each DIR3 RESULT value determined by shifter/comparator 392 is substantially equivalent to the output that binary pixel counter 318 would have yielded had counter 318 been applied to a selected 8x8 binary pixel block in the binary image corresponding to directional range 3.

Shifter/comparator 390 next compares each DIR0 RESULT with the predetermined threshold T_2 . If the value of DIR0 RESULT is greater than T_2 , then a value F_DIR0 which is output by shifter/comparator 390 is set high; otherwise the value of F_DIR0 is set low. Shifter/comparator 390 also compares each DIR1 RESULT with T_2 and, if DIR1 RESULT is

greater than T_2 , then a value F_DIR1 output by shifter/comparator 390 is set high; otherwise the value of F_DIR1 is set low. Similarly, shifter/comparator 392 compares each DIR2 RESULT with T_2 . If the value of DIR2 RESULT is greater than T_2 , then a value F_DIR2 output by shifter/comparator 392 is set high; otherwise the value of F_DIR2 is set low. Shifter/comparator 392 also compares each DIR3 RESULT with T_2 and, if DIR3 RESULT is greater than T_2 , then a value F_DIR3 output by shifter/comparator 390 is set high; otherwise the value of F_DIR3 is set low.

For purposes of comparison to the flow diagrams and description set forth above, it should be noted that each F_DIR0 value output by shifter/comparator 390 represents a pixel in a feature image corresponding to directional range 0; each F_DIR1 value output by shifter/comparator 390 represents a pixel in a feature image corresponding to directional range 1; each F_DIR2 value output by shifter/comparator 392 represents a pixel in a feature image corresponding to directional range 2; and each F_DIR3 value output by shifter/comparator 392 represents a pixel in a feature image corresponding to directional range 3.

The four 1-bit values F_DIR0, F_DIR1, F_DIR2, F_DIR3 are next applied to LUT 394. The operation implemented by LUT 394 preferably corresponds in function to one of the voting operations shown in Figures 3C-3E described above. For each possible group of F_DIR0, F_DIR1, F_DIR2, F_DIR3 values that may be applied to LUT 394, a single corresponding 1-bit value (output) is stored in LUT 394. The values of the 1-bit Output entries stored in LUT 394 are preferably determined prior to

the acceptance of intensity image 100 by the present invention. For each entry (or group of F_DIR0, F_DIR1, F_DIR2, F_DIR3 values) referenced in LUT 394, a corresponding 1-bit Output value is determined by performing a first exclusive logical OR operation on F_DIR0 and F_DIR2, and a second exclusive logical OR operation on F_DIR1 and F_DIR3. A logical OR operation is then performed on the results of the first and second exclusive OR operations, thereby yielding the 1-bit Output value corresponding to the table entry. For purposes of comparison, each 1-bit Output value that is output by LUT 394 corresponds to a pixel in a composite feature image.

Although in the embodiment shown in Figure 3H, LUT 394 is configured to form a composite feature image from four feature images, wherein each feature image corresponds to one of four directional ranges of detected edges, it will be understood by those skilled in the art that LUT 394 may be configured to form a composite feature image from more or fewer than four feature images corresponding to different directional ranges by varying the number of columns and the content of the entries in LUT 394. In this way, LUT 394 can be used to implement any logical voting operation.

The output of edge information comparator 300 (i.e., a composite feature image) is provided to means 400 for selecting at least one foreground region from intensity image 100. Means 400 selects at least one foreground region wherein detected edges are angularly oriented substantially in accordance with a target orientation. In a first preferred embodiment, a foreground region selected by means 400 will

typically correspond in location to the position of a bar code symbol or a stacked bar code symbol in intensity image 100. In this first embodiment, foreground region selector 400 preferably selects a foreground region with detected edges having a target orientation wherein (i) substantially all the detected edges are angularly oriented in only one or only two of four directional ranges, (ii) substantially all the detected edges are angularly oriented in only one of at least two directional ranges, or (iii) detected edges angularly oriented within at least one and less than all of at least two directional ranges are substantially present. The composite feature image generators shown in Figures 3C, 3D, 3E are respectively directed to the formation of composite feature images which facilitate the selection by means 400 of foreground regions in accordance with the above three target orientations.

In a second preferred embodiment, a foreground region selected by means 400 will typically correspond in location to the position of a symbol comprised of a matrix of squares. In this second embodiment, foreground region selector 400 selects at least one foreground region from an intensity image wherein a substantial percentage of detected edges in the foreground region are orthogonal with respect to each other. By selecting foreground regions in accordance with a target orientation of orthogonal edges, foreground region selector 400 may locate within an intensity image symbols coded in accordance with the Vericode™ or Datacode™ symbologies. Details of the Vericode™ and Datacode™ symbologies are disclosed in U.S. Patent Nos. 4,924,078 and

4,939,154 which are hereby incorporated herein in their entirety by reference. A composite feature image useful for selecting foreground regions having orthogonal edges may be formed by comparing feature images corresponding to directional ranges oriented 90 degrees apart.

In a third preferred embodiment, a foreground region selected by means 400 will typically correspond in location to the position of a symbol comprised of a matrix of hexagons. In this third embodiment, foreground region selector 400 selects at least one foreground region from an intensity image wherein a substantial percentage of detected edges in the foreground region are oriented at 60 degrees with respect to each other. By selecting foreground regions in accordance with a target orientation of edges oriented at 60 degrees with respect to each other, foreground region selector 400 may locate within an intensity image symbols coded in accordance with the UPSCode™ symbology. Details of the UPSCode™ symbology are disclosed in U.S. Patent Nos. 4,998,010, 4,896,029 and 4,874,936 which are hereby incorporated herein in their entirety by reference. A composite feature image useful for selecting foreground regions having edges oriented at 60 degrees with respect to each other may be formed by comparing feature images corresponding to directional ranges oriented 60 degrees apart.

In an alternate preferred embodiment of the object locator system of the present invention, means 400 for selecting at least one foreground region is comprised of (i) first means for selecting at least one foreground region in the intensity image wherein detected edges are angularly

oriented substantially in accordance with a first target orientation, and (ii) second means for selecting at least one foreground region in the intensity image wherein detected edges are angularly oriented substantially in accordance with a second target orientation. This embodiment may be employed to process a packaging label encoded with two different types of symbologies. An exemplary packaging label encoded with both one-dimensional bar code symbols (710) and (720) and a two-dimensional code symbol (730) formed from an array of hexagons is shown in Figure 7. Other one-dimensional symbols including stacked bar code symbols, and other two-dimensional symbols including square arrays and arrays of other polygonal shapes, may be positioned on the same label and then located in accordance with the present invention.

Referring now to Figures 4 and 4A, in the preferred embodiment of the present invention, foreground region selector 400 is provided with means for processing the composite feature image prior to selecting at least one foreground region. This preferred processing step is shown in Figure 4 and employs means 410 for connecting at least two neighboring pixels in the composite feature image to form at least one connected region. Means 410 connects neighboring pixels by applying either an eight neighbor connectivity operator (410a) or a four neighbor connectivity operator (410b) throughout the composite feature image. Means 420 for calculating the area of each connected region and means 430 for comparing each calculated area to a fourth predetermined threshold (T_4) and a fifth predetermined threshold (T_5) are also provided. Means

430 filters out of the composite feature image each connected region with an area below T_4 or above T_5 . At least one foreground region is then selected by means 400 from the remaining unfiltered connected regions. In the first preferred embodiment discussed above for selecting bar code or stacked bar code symbols, the comparison against T_4 and T_5 is used to eliminate from the selection process those potential foreground regions which are either too small or too large to comprise a bar code or stacked bar code symbol.

Referring now to Figure 5, in the preferred embodiment of the present invention, output from foreground selection means 400 is provided to means 500 for extracting image information representative of at least one object from intensity image 100. Means 500 includes means 510 for mapping at least one selected foreground region onto intensity image 100 to form at least one selected object region in intensity image 100, and means 520 for calculating the coordinates (row, column) within intensity image 100 of the centroid (or center of mass) of the selected object region.

The object locator system of the present invention may be employed to locate bar code symbols and other types of symbols affixed to packages positioned on a moving belt. In Figure 8, there is shown means 800 for associating each foreground region selected by means 400 with a particular package. Means 800 performs a preferred pre-processing step which allows the present invention to tie together (or associate) a plurality of symbols (for example symbols 710, 720, 730) which are affixed to the same package. Means 800 includes means 810 for determining the contour or outline of

each package on a belt. As shown in Figure 8A, belt 830 (which is preferably colored dark) appears as a large contiguous dark region when scanned; a package 840, however, appears as a contiguous bright region when scanned. Means 810 preferably determines contour 850 of package 840 by application of either a contour tracing algorithm or a connectivity operator to intensity image 100. Means 820 is provided for comparing a contour with a foreground region selected by means 400. Means 830 then associates a foreground region selected by means 400 with a package if that foreground region is positioned within the contour corresponding to that package.

The present invention may be implemented on a Datacube™ Maxvideo™ system. When edge magnitude information normalized to range from 0-127 has been determined for each pixel in an intensity image formed of 782 x 1288 8-bit pixels, suitable values of T_1 , T_4 , and T_5 , are 24, 128 and 2048 respectively. When these parameters are used and the blocks tiled by means 316 are 8 x 8 pixels in dimension and the sliding window used by pixel cluster region generator 350 is 3 x 3 pixels in dimension, suitable values of T_2 and T_3 are 24 and 6 respectively.

Object Positioning And Fine Angular Orientation System

Referring now to Figures 9A, 9B, there is shown a flow diagram illustrating the operation of a preferred system 900 for determining the fine angular orientation of a selected object in an intensity image according to the preferred embodiment of the present invention. System 900 accepts as

its input the coordinates within intensity image 100 of the centroid (or center of mass) of a selected object region as calculated by means 520. For purposes of illustration, a portion 960 of an exemplary intensity image is shown in Figure 9C. Portion 960 includes selected object region 962. The position of the centroid or center of mass of object 962 is identified by centroid point 964.

Window selector 902 is provided for initially selecting a pixel window from intensity image 100 which is centered about the centroid of the selected object region. In the preferred embodiment, the selected pixel window is 32x32 pixels in dimension, although windows of other dimensions may be used. For purposes of illustration, the pixel window initially selected by selector 902 corresponds to window 966 in the example of Figure 9C. Means 904 is provided for applying edge detectors 210, 220 to each pixel in the selected window. Based on the outputs of edge detectors 210, 220, means 904 determines a magnitude value (M_n) and a direction value (D_n) for each pixel in the selected window in accordance with equations (1) and (2) above.

Classifier 906 is provided for associating each pixel in the selected window that has a magnitude value that exceeds a threshold (T_6) with one or more of a plurality of possible directional ranges. In the preferred embodiment, classifier 906 associates each such pixel with one or more of the eight directional ranges shown in Figure 9D. Each of these eight preferred directional ranges spans 120 degrees. However, each of the eight preferred ranges as centered about a different angle. More particularly, as shown in Figure 9D,

Range 1 is centered about a 0 degree angle; Range 2 is centered about 22.5 degree angle; Range 3 is centered about a 45 degree angle; Range 4 is centered about a 67.5 degree angle; Range 5 is centered about a 90 degree angle; Range 6 is centered about a 112.5 degree angle; Range 7 is centered about a 135 degree angle; and Range 8 is centered about a 157.5 degree angle. For each pixel in the selected window having a magnitude value that exceeds T_6 , classifier 906 compares the directional value corresponding to that pixel with the eight directional ranges described immediately above to select the one or ones of these eight directional ranges that include the directional value associated with the pixel. Classifier 906 then associates the pixel with each of the selected directional ranges.

After all the pixels in the selected window have been processed by classifier 906, range selector 908 selects one of the eight directional ranges shown in Figure 9D for further processing. Although in the preferred embodiment, range selector 908 selects from eight possible directional ranges, in alternate embodiments more or fewer than eight directional ranges may be used. Density calculator 910 determines a density value corresponding to the selected range by counting the number of pixels that were associated with the selected range by classifier 906. Angular mean calculator 912 determines an angular mean value corresponding to the selected range by averaging the directional values corresponding to the pixels that were associated with the selected range by classifier 906. Noise calculator 914 determines a noise value

corresponding to the selected range by calculating the standard deviation of the directional values corresponding to the pixels that were associated with the selected range by classifier 906.

Comparator 916 is provided for comparing the density value for the selected range with a threshold T_7 . Comparator 918 is provided for taking the absolute value of the difference between the angular mean value for the selected range and the angular center of the selected directional range, and then comparing this absolute difference to a threshold T_8 . For purposes of comparator 918, the angular center of Range 0 is 0 degrees; the angular center of Range 1 is 22.5 degrees; the angular center of Range 3 is 45 degrees; the angular center of Range 4 is 67.5 degrees; the angular center of Range 5 is 90 degrees; the angular center of Range 6 is 112.5 degrees; the angular center of Range 7 is 135 degrees; and the angular center of Range 8 is 157.5 degrees. Comparator 920 is provided for comparing the noise value for the selected range with a further threshold T_9 .

The outputs of comparators 916, 918 and 920 are coupled to AND gate 922 for performing a logical AND operation on the outputs of the three comparators. If the outputs of these three comparators are all high (corresponding to the condition where the density value for the selected range exceeds T_7 , the absolute difference between the angular mean value for the selected range and the angular center of the selected directional range is less than T_8 and the noise value for the selected range is less than T_9), then means 924 designates the selected directional range as a candidate

directional range. In alternate embodiments, gate 922 may be replaced with other logic circuitry such that the output of gate 922 will be high (and the selected directional range will be designated as a candidate directional range) if at least one of the outputs from comparators 916, 918, 920 is high.

Repeater 926 is provided for repeating the above process starting from range selector 908 until each of the 8 directional ranges shown in Figure 9D have been processed. When repeater 926 indicates that all 8 directional ranges have been processed, comparator 928 determines whether at least one of the 8 directional ranges was designated as a candidate directional range. If comparator 928 determines that at least one of the 8 directional ranges was designated as a candidate directional range, then comparator 930 determines whether only one of the 8 directional ranges was designated as a candidate directional range. Where only one of the 6 directional ranges was designated as a candidate directional range, means 932 determines the fine angular orientation of the selected object region to be the angular mean value associated with the one designated candidate directional range.

In the preferred embodiment, if comparator 930 determines that more than one directional range was designated as a candidate directional range, then selector 934 selects the candidate directional range having the lowest noise value for further analysis. Comparator 936 compares this lowest noise value to a threshold T_{10} . If this lowest noise value does not exceed T_{10} , then means 938 determines the fine angular orientation of the selected object region to be the angular mean value associated with the candidate directional range

selected by selector 934. If the lowest noise value exceeds T_{10} , then means 940 compares the angular mean value associated with each candidate directional range to the angular center associated with that candidate directional range. As was the case with comparator 918, for purposes of means 940 the angular center of Range 0 is 0 degrees; the angular center of Range 1 is 22.5 degrees; the angular center of Range 3 is 45 degrees; the angular center of Range 4 is 67.5 degrees; the angular center of Range 5 is 90 degrees; the angular center of Range 6 is 112.5 degrees; the angular center of Range 7 is 135 degrees; and the angular center of Range 8 is 157.5 degrees. Means 940 then selects the candidate directional range having an angular mean value which differs the least from its associated angular center, and then determines the fine angular orientation of the selected object region to be the angular mean value associated with this selected candidate directional range.

If comparator 928 determined that no candidate directional ranges had been designated for the selected pixel window, then processing returns to window selector 902 which then selects a further pixel window for processing. In the preferred embodiment, window selector 902 next selects the 32x32 pixel window positioned immediately adjacent to the left hand edge of the pixel window that was initially selected for processing. For purposes of illustration, the second pixel window selected by selector 902 corresponds to window 968 in the example of Figure 9C. Thereafter, the process is repeated from selector 902, wherein a further attempt is made to determine the fine angular orientation of the selected object

region. If comparator 928 determines that no candidate directional ranges have been designated for the second selected pixel window, then processing returns to window selector 902 which then selects a third pixel window for processing. For purposes of illustration, the third pixel window selected by selector 902 corresponds to window 970 in the example of Figure 9C. Thereafter, if comparator 928 determines that no candidate directional ranges have been designated for the second selected pixel window, then processing returns to window selector 902 which then selects a further pixel window for processing. Window selector 902 continues to select pixel windows adjacent to window 966 in a clockwise direction until either a candidate directional range is designated or all eight windows surrounding window 966 have been processed. If after selection and processing of all pixel windows no candidate directional range has been designated, the selected object region is rejected based on the system's inability to determine its orientation.

When edge magnitude information normalized to range from 0-127 has been determined for each pixel in intensity image 100 and the pixel window selected by selector 902 is 32x32 pixels in dimension, suitable values of T_7 , T_8 , T_9 , and T_{10} are 512, 30 degrees, 20 degrees and 15 degrees, respectively.

Referring now to Figure 10, there is shown a flow diagram illustrating the operation of a system 1000 for determining the coarse orientation of an object within an intensity image according to an alternate preferred embodiment of the present invention. The system accepts as its input intensity image 1010 which is preferably a digitized gray

scale representation of an imaged region being scanned. In the preferred embodiment, intensity image 1010 is a low resolution image derived from a linear array of CCDs. The system shown includes means 1020 for analyzing intensity image 1010 with at least two different edge detectors to detect a multiplicity of edges oriented in at least two directional ranges. Means 1020 functions substantially the same as means 200 described above. Means 1030 is provided for comparing information representative of detected edges angularly oriented in a first of said at least two directional ranges and information representative of detected edges angularly oriented in a second of said at least two directional ranges. Means 1030 functions substantially the same as means 300 described above. Based on the results of comparisons made by means 1030, means 1040 selects an acquisition region from intensity image 1010 wherein detected edges are angularly oriented substantially in accordance with a target orientation. Means 1050 then determines the position and orientation of at least one object in intensity image 1010 in accordance with the selected acquisition region.

The output of means 1030 is provided to means 1040 for selecting an acquisition region from intensity image 1010. Means 1040 selects an acquisition region wherein detected edges are angularly oriented substantially in accordance with a target orientation. Means 1040 functions substantially the same as means 400 described above, except means 1040 selects an acquisition region as opposed to a foreground region. Thus, the acquisition region selected by means 1040 may correspond in location to (i) the position of a bar code

symbol or a stacked bar code symbol in intensity image 1010, (ii) the position of a symbol comprised of a matrix of squares in intensity image 1010, or (iii) the position of a symbol comprised of a matrix of hexagons or other polygons in intensity image 1010.

Means 1050 determines the orientation of at least one object in intensity image 1010 in accordance with the acquisition region selected by means 1040. In system 1000, the acquisition region selected by means 1040 has a known spatial relationship to at least one object in intensity image 1010. For example, in the label of Figure 7, symbols 710, 720, 730 will preferably have a predetermined spatial relationship which is known to means 1050. Thus, if an acquisition region representative of symbol 730 is selected, means 1050 can determine the position of symbols 710, 720 by application of a known spatial relationship to the selected acquisition region. Alternatively, a bar code symbol (such as 710) may be used by means 1050 to find (or acquire) either another bar code symbol (such as 720) or a two-dimensional symbol (such as 730) or a text block (such as 740) within intensity image 1010.

Image Processing System

Referring now to Figure 11, there is shown a flow diagram illustrating the operation of a preferred system for determining bar widths associated with a selected object region from a two-dimensional image 1100 representative of a bar code symbol. In a preferred embodiment, image 1100 is a low resolution image formed of gray scale pixels from

intensity image 100. The system shown includes means 1110 for forming a one-dimensional intensity projection signal from two-dimensional image 1100, means 1120 for globally scaling the projection signal, means 1130 for locally scaling the projection signal, means 1140 for resolving undefined points in the projection signal, means 1150 for calculating the areas of a plurality of regions described by the projection signal and means 1160 for determining a plurality of bar widths from the areas calculated by means 1150.

In accordance with the preferred embodiment of the present invention, means 1110 selects as an initial scan line a line which (i) passes through the center of mass of the selected object region (as determined by means 520) and (ii) has a slope that is equal to fine angular orientation value determined by system 900. For purposes of illustration, an exemplary initial scan line 1400 is shown in Figure 14.

Figure 12 shows a portion 1200 of an exemplary low resolution image to be processed according to the image processing system of the present invention. Low resolution image portion 1200 is representative of a bar code symbol having bars oriented parallel to the bar direction shown by arrow 1202. Bar direction 1202 is preferably determined as being perpendicular to the fine angular orientation value determined by system 900. In alternate embodiments, bar direction 1202 may be determined either from (i) finder points (not shown) in the quiet zone of the bar code symbol, (ii) through the application of equation (2) above to the edges of image 1200 or (iii) by computing the major axis of image 1200.

Referring now to Figure 12, a two-dimensional portion of image 1200 lying along the selected scan line is next divided into a plurality of two-dimensional sections (or bins) 1204, 1206. Bins 1204, 1206 are oriented parallel to bin axis 1208 and perpendicular to bar direction 1202. Thus, bin 1204 is bounded on its top and bottom by reference lines 1210, 1212 and on its left and right by reference lines 1214, 1216. Similarly, bin 1206 is bounded on its top and bottom by reference lines 1210, 1212 and on its left and right by reference lines 1216, 1218. Reference lines 1210, 1212 are each parallel to the selected scan line and, in the preferred embodiment, reference lines 1210, 1212 are each separated from the selected scan by a distance equivalent to 6 pixels.

Next, the present invention determines information representative of the intensity of the pixels in each bin 1204, 1206. This intensity information determination is preferably made for a given bin by calculating the average intensity of all pixels in that bin. Means 1110 then forms a one-dimensional projection signal by plotting this intensity information for each bin 1204, 1206 along the bin axis. Figure 13A shows an exemplary one-dimensional projection signal derived from a low resolution image representative of a bar code symbol in accordance with the method described above. By originally calculating each point in the projection signal from a two-dimension section (or bin), it was found that the present image processing system could be used to recover bar widths even from a corrupted bar code symbol which included a defect such as spot 1220.

The output of means 1110 is provided to means 1120 for performing a first global scaling operation on a projection signal in accordance with a minimum global scaling parameter and a maximum global scaling parameter. Means 1120 includes means for determining a plurality of local maximum values (1302, 1304) from the projection signal, and means for determining a plurality of local minimum values (1306, 1308) from the projection signal. In the preferred embodiment, a local maximum value is determined at each peak in the projection signal, and a local minimum value is determined at the bottom of each valley in the projection signal. Means 1120 determines a maximum global scaling parameter (P_{max}) by averaging the local maximum values determined above, and a minimum global scaling parameter (P_{min}) by averaging the local minimum values determined above.

Means 1120 globally scales the projection signal by "stretching" the projection signal so that it extends along its entire dynamic range. In a preferred embodiment of the first global scaling method, all values of the projection signal exceeding P_{max} are first rectified to P_{max} , and all values of the projection signal below P_{min} are rectified to P_{min} . Means then 1120 globally scales each pixel (P) in the rectified projection signal according to equation (3) below:

$$P_{GS} = P * (\text{dynamic range}) / (P_{max} - P_{min})$$

(3)

The exemplary projection signal of Figure 13A was determined from an image formed of 8-bit pixels having a dynamic range from 0 to 255. Figure 13B shows an exemplary projection signal derived from the application of the first global

scaling method described above to the projection signal of Figure 13A.

The output of means 1120 is provided to means 1130 for locally scaling a projection signal in accordance with the local maximum and minimum values determined above. Means 1130 includes means for positioning a sliding window (1310) on pixels from the globally scaled projection signal, means for calculating a contrast value for pixels in the window, means for locally scaling pixels in the window and means for marking pixels in the window as undefined. As shown in equation (4) below, means 1130 calculates a contrast value (C_{win}) for pixels in the sliding window by subtracting the maximum value (Max_{win}) in the window from the minimum value in the window (Min_{win}) and dividing this amount by the maximum of the dynamic range:

$$C_{win} = (Max_{win} - Min_{win}) / (dynamic\ range)$$

(4)

Means 1130 then compares C_{win} against a predetermined threshold (T_{11}). If C_{win} is greater than (T_{11}), then means 1130 locally scales the pixels in the window; otherwise, means 1130 marks the pixels in the window as undefined. In a preferred embodiment, after the pixels in window 1310 are processed as above, the window is moved to the right by one bin and the process is repeated. The process continues for the full length of the projection signal.

Means 1130 locally scales the pixels in a window by "stretching" the pixels in the window so that they extend along the entire dynamic range. In a preferred embodiment, means 1130 locally scales each pixel (P) in a window according to equation (5) below:

$$P_{LS} = P * (\text{dynamic range}) / (\text{Max}_{win} - \text{Min}_{win})$$

(5)

In an alternative preferred embodiment, means 1130 searches the globally scaled projection signal for pairs of subsequent local peaks/valleys, and forms a locally scaled projection signal by linearly interpolating between each such subsequent pair.

The output of means 1130 is provided to means 1140 for resolving any pixels marked undefined by means 1130. In a preferred embodiment, means 1140 resolves a pixel marked undefined by linearly interpolating between the closest defined pixels on either side of the undefined pixel. Figure 13C shows an exemplary projection signal derived from the application of the local scaling and interpolation methods described above to the projection signal of figure 13B. In determining the projection signal of Figure 13C, a window (or bin) width of approximately 5 pixels was employed and T_{11} was set to approximately 15% of the full dynamic range. In the preferred embodiment, means 1140 also performs a second global scaling operation following the linear interpolation step described above. In this second global scaling operation, any peaks (1312) or valleys (1314) not spanning the full dynamic range are stretched to the limits of the dynamic range. Figure 13D shows an exemplary projection signal derived from the application of this second global scaling method to the projection signal of Figure 13C.

The output of means 1140 is provided to means 1150 for calculating the areas of a plurality of regions described by the projection signal. Referring now to Figure 13E, there

is shown an expanded view of the projection signal of Figure 13D. Means 1150 calculates a value representative of each area 1351, 1352, 1353, 1354, 1355, 1356 bounded by the projection signal. In the projection signal shown in Figure 13E, every area is alternatively representative of either a black or a white bar. Thus, areas 1351, 1353, 1355 are representative of black bars, and areas 1352, 1354, 1356 are representative of white bars. The widths of the bars in the bar code symbol being processed are determined from the calculated areas, and an attempt is made to decode the bar code symbol. If the bar code symbol cannot be successfully decoded because, for example, there was a checksum error, then means 1110 selects a further scan line (1410, 1420, 1430, 1440) and the process is repeated until either a bar code symbol is successfully decoded or five scan lines have been processed. If, after processing five scan lines, a bar code symbol has not been successfully decoded, then a determination is made that the selected object region provided by means 500 cannot be successfully decoded.

The present invention may be embodied in other specific forms without departing from the spirit or essential attributes of the invention. Accordingly, reference should be made to the appended claims, rather than the foregoing specification, as indicating the scope of the invention.

What is claimed is:

1. A method for simultaneously convolving first and second digital binary images in parallel with a single convolver having a binary mask comprising the steps of:

- (A) selecting a first window from said first digital image and a second window from said second digital image for processing;
- (B) selecting a first pixel from said first window and a second pixel from said second window;
- (C) bit shifting said first pixel by concatenating a plurality of trailing zero bits to said first pixel;
- (D) forming a multi-bit input pixel by combining said bit shifted first pixel and said second pixel;
- (E) forming a plurality of multi-bit input pixels by repeating steps (B) - (D);
- (F) generating a single multi-bit output value by simultaneously applying said plurality of multi-bit input pixels to said single convolver;
- (G) forming a first convolution result from only the least significant bits of said output value and a second convolution result from only the most significant bits of said output value; and
wherein said first and second convolution results respectively represent the results of

sequentially applying said single convolver to said first and second windows.

2. The method of claim 1, wherein said first and second windows are respectively positioned at corresponding coordinates within said first and second digital images, and wherein said first and second pixels are respectively positioned at corresponding coordinates within said first and second windows.

3. The method of claim 2, further comprising the steps of:

(H) forming a plurality of first convolution results and a plurality of second convolution results by successively translating said first and second windows and repeating steps (B)-(G); and

(I) forming a first convolved image from said first plurality of convolution results and a second convolved image from said second plurality of convolution results.

4. The method of claim 1, wherein said binary mask is square and is comprised of zeros at its corners and ones at all other positions.

5. An apparatus for simultaneously convolving first and second digital binary images in parallel with a single convolver having a binary mask comprising:

(A) a window selector for selecting a first window from said first digital image and a second window from said second digital image for processing;

- (B) a pixel selector for selecting a first pixel from said first window and a second pixel from said second window;
- (C) a shifter for bit shifting said first pixel by concatenating a plurality of trailing zero bits to said first pixel;
- (D) bit merging means for forming a multi-bit input pixel by combining said bit shifted first pixel and said second pixel;
- (E) a convolver for generating a single multi-bit output value by simultaneously applying a plurality of multi-bit input pixels to said convolver;
- (F) a word separator for forming a first convolution result from only the least significant bits of said output value and a second convolution result from only the most significant bits of said output value; and

wherein said first and second convolution results respectively represent the results of sequentially applying said convolver to said first and second windows.

6. The apparatus of claim 5, wherein said first and second windows are respectively positioned at corresponding coordinates within said first and second digital images, and wherein said first and second pixels are respectively positioned at corresponding coordinates within said first and second windows.

7. The apparatus of claim 6, further comprising:
- (G) translating means for forming a plurality of first convolution results and a plurality of second convolution results by successively translating said first and second windows; and
 - (H) means for forming a first convolved image from said first plurality of convolution results and a second convolved image from said second plurality of convolution results.

8. The apparatus of claim 4, wherein said binary mask is square and is comprised of zeros at its corners and ones at all other positions.
