Embody elements disclose a process for converting gaseous hydrocarbons to higher molecular weight hydrocarbons. The process includes the following steps:

1. **Alkane Bromination**: The feed gas, containing higher molecular weight hydrocarbons, is treated with bromine vapor to form alkyl bromides.

2. **Alkyl Bromide Conversion**: The alkyl bromides are subjected to a dehydration reaction, which may be catalyzed by various metals or metal oxides, to produce higher molecular weight hydrocarbons and bromine vapor.

3. **Dehydration & Product Recovery**: The dehydration reaction is coupled with a bromine recovery system to recycle the bromine vapor. The hydrocarbon liquid product is recovered at the end of the process.

4. **Recycle + Feed Gas**: The bromine vapor generated during the dehydration step is recirculated back to the reaction zone to promote further conversion.

The process is versatile and can be adapted to different feedstocks and reaction conditions to optimize the conversion of hydrocarbons to higher molecular weight products.

PROCESS FOR CONVERTING GASEOUS ALKANES TO LIQUID HYDROCARBONS

REFERENCE TO RELATED PATENT APPLICATION:

BACKGROUND OF THE INVENTION

[0003] 1. Field of the Invention
[0004] The present invention relates to a process for converting lower molecular weight, gaseous alkanes to olefins, higher molecular weight hydrocarbons, or mixtures thereof that may be useful as fuels or monomers and intermediaries in the production of fuels or chemicals, such as lubricant and fuel additives, and more particularly, in one or more embodiments, to a process wherein a gas containing lower molecular weight alkanes is reacted with a dry bromine vapor to form alkyl bromides and hydrobromic acid which in turn are reacted over a crystalline alumino-silicate catalyst to form olefins, higher molecular weight hydrocarbons or mixtures thereof.

[0005] 2. Description of Related Art
[0006] Natural gas, which is primarily composed of methane and other light alkanes, has been discovered in large quantities throughout the world. Many of the locales in which natural gas has been discovered are far from populated regions which have significant gas pipeline infrastructure or market demand for natural gas. Due to the low density of natural gas, transportation thereof in gaseous form by pipeline or as compressed gas in vessels is expensive. Accordingly, practical and economic limits exist to the distance over which natural gas may be transported in gaseous form. Cryogenic liquefaction of natural gas (LNG) is often used to more economically transport natural gas over large distances. However, the LNG process is expensive and there are limited regasification facilities in only a few countries that are equipped to import LNG

[0007] Another use of methane is as feed to processes for the production of methanol. Methanol is made commercially via conversion of methane to synthesis gas (CO and H₂) at high temperatures (approximately 1000° C.) followed by synthesis at high pressures (approximately 100 atmospheres). There are several types of technologies for the production of synthesis gas from methane. Among these are steam-methane reforming (SMR), partial oxidation (POX), autothermal reforming (ATR), gas-heated reforming (GHR), and various combinations thereof. SMR and GHR operate at high pressures and temperatures, generally in excess of 600° C., and require expensive furnaces or reactors containing special heat and corrosion-resistant alloy tubes filled with expensive reforming catalyst. POX and ATR processes operate at high pressures and even higher temperatures, generally in excess of 1000° C. As there are no known practical metals or alloys that can operate at these temperatures, complex and costly refractory-lined reactors and high-pressure waste-heat boilers to quench and cool the synthesis gas effluent are required. Also, significant capital cost and large amounts of power are required for compression of oxygen or air to these high-pressure processes. Thus, due to the high temperatures and pressures involved, synthesis gas technology is expensive, resulting in a high cost methanol product which limits higher-value uses thereof, such as for chemical feedstocks and solvents. Furthermore production of synthesis gas is thermodynamically and chemically inefficient, producing large excesses of waste heat and unwanted carbon dioxide, which tends to lower the conversion efficiency of the overall process. Fischer-Tropsch Gas-to-Liquids (GTL) technology can also be used to convert synthesis gas to heavier liquid hydrocarbons, however investment cost for this process is even higher.

In each case, the production of synthesis gas represents a large fraction of the capital costs for these methane conversion processes.

[0008] Numerous alternatives to the conventional production of synthesis gas as a route to methanol or synthetic liquid hydrocarbons have been proposed. However, to date, none of these alternatives has attained commercial status for various reasons. Some of the previous alternative prior-art methods, such as disclosed in U.S. Pat. Nos. 5,243,098 or 5,334,777 to Miller, teach reacting a lower alkane, such as methane, with a metallic halide to form a metal halide and hydrohalic acid which are in turn reduced with magnesium oxide to form the corresponding alkalin. However, halogenation of methane using chlorine as the preferred halogen results in poor selectivity to the monomethyl halide (CH₃Cl), resulting in unwanted by-products such as CH₂Cl₂ and CHCl₃ which are difficult to convert or require severe limitation of conversion per pass and hence very high recycle rates.

[0009] Other prior art processes propose the catalytic chlorination or bromination of methane as an alternative to generation of synthesis gas (CO and H₂). To improve the selectivity of a methane halogenation step in an overall process for the production of methanol, U.S. Pat. No. 5,998,679 to Miller teaches the use of bromine, generated by thermal decomposition of a metal bromide, to brominate alkanes in the presence of excess alkanes, which results in improved selectivity to mono-halogenated intermediates such as methyl bromide. To avoid the drawbacks of utilizing fluidized beds of moving solids, the process utilizes a circulating liquid mixture of metal chloride hydrates and metal bromides. Processes described in U.S. Pat. No. 6,462,243 B1, U.S. Pat. No. 6,472,572 B1, and U.S. Pat. No. 6,525,230 to Grosso are also capable of attaining higher selectivity to mono-halogenated intermediates by the use of bromination. The resulting alkyl bromide intermediates such as methyl bromide, are further converted to the corresponding alcohols and ethers, by reaction with metal oxides in circulating beds of moving solids.

Another embodiment of U.S. Pat. No. 6,525,230 avoids the drawbacks of moving beds by utilizing a zoned reactor vessel containing a fixed bed of metal bromide/oxide solids that is...
operated cyclically in four steps. While certain ethers, such as dimethyl ether ("DME") are a promising potential diesel engine fuel substitute, as of yet, there currently exists no substantial market for DME, and hence an expensive additional catalytic process conversion step would be required to convert DME into a currently marketable product. Other processes have been proposed which circumvent the need for production of synthesis gas, such as U.S. Pat. No. 4,467,130 to Olah in which methane is catalytically condensed into gasoline-range hydrocarbons via catalytic condensation using superacid catalysts. However, none of these earlier alternative approaches have resulted in commercial processes.

[0010] It is known that substituted alcanes, in particular methanol, can be converted to olefins and gasoline boiling-range hydrocarbons over various forms of crystalline aluminosilicates also known as zeolites. In the Methanol to Gasoline (MTG) process, a shape selective zeolite catalyst, ZSM-5, is used to convert methanol to gasoline. Coal or methane gas can thus be converted to methanol using conventional technology and subsequently converted to gasoline. However due to the high cost of methanol production, and at current or projects prices for gasoline, the MTG process is not considered economically viable. Thus, a need exists for an economic process for the conversion of methane and other alkanes found in natural gas to olefins, higher molecular weight hydrocarbons or mixtures thereof which, due to their higher density and value, are more economically transported thereby significantly aiding development of remote natural gas reserves. Further, a need exists for such a process that is relatively inexpensive, safe and simple.

SUMMARY OF THE INVENTION

[0011] To achieve the foregoing and other objects, and in accordance with the purposes of the present invention, as embodied and broadly described herein, one characterization of the present invention is a process comprising: separating hydrobromic acid from a gaseous stream comprising hydrobromic acid and hydrocarbons; converting said hydrobromic acid to at least bromine; and contacting said bromine with gaseous alkanes to form bromination products comprising alkyl bromides.

[0012] In another characterization of the present invention, a process is provided that comprises: contacting a gaseous stream comprising hydrobromic acid and hydrocarbons with an aqueous solution comprising a base selected from the group consisting of a metal hydroxide, a metal oxo-bromide species, and combinations thereof such that the hydrobromic acid is neutralized to form a metal bromide salt in the aqueous solution; oxidizing said aqueous solution containing said metal bromide salt to form oxidation products comprising bromine and said base; separating said bromine from said aqueous solution comprising said base; and contacting said bromine with gaseous alkanes to form alkyl bromides.

[0013] In another characterization of the present invention, a process is provided that comprises: contacting a gaseous stream comprising hydrobromic acid and hydrocarbons with water, wherein said hydrobromic acid dissolves in said water to form an aqueous solution comprising said water and said hydrobromic acid; neutralizing said hydrobromic acid to form a metal bromide salt; oxidizing said metal bromide salt to form an oxidation product comprising bromine; and contacting said bromine with gaseous alkanes to form bromination products comprising alkyl bromides.

[0014] In another characterization of the present invention, a process is provided that comprises: reacting hydrobromic acid with a metal oxide to form reaction products comprising a metal bromide and steam, wherein said hydrobromic acid is contained in a gaseous stream comprising said hydrobromic acid and hydrocarbons; reacting said metal bromide with a gas comprising oxygen to form reaction products comprising bromine and said metal oxide; and contacting said bromine with gaseous alkanes to form bromination products comprising alkyl bromides.

BRIEF DESCRIPTION OF THE DRAWINGS

[0015] The accompanying drawings, which are incorporated in and form a part of the specification, illustrate the embodiments of the present invention and, together with the description, serve to explain the principles of the invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

As utilized throughout this description, the term “lower molecular weight alkanes” refers to methane, ethane, propane, butane, pentane or mixtures thereof. As also utilized throughout this description, “alkyl bromides” refers to mono, di, and tri brominated alkanes. Also, the feed gas in lines 11 and 111 in the embodiments of the process of the present invention as illustrated in FIGS. 2 and 3, respectively, is preferably natural gas which may be treated to remove sulfur compounds and carbon dioxide. In any event, it is important to note that small amounts of carbon dioxide, e.g., less than about 2 mol %, can be tolerated in the feed gas to the process of the present invention.

A block flow diagram generally depicting an embodiment of a process of the present invention is illustrated in FIG. 1, while specific embodiments of the process illustrated in FIG. 1 are illustrated in FIGS. 2 and 3. Referring to FIG. 1, a gas stream comprising recycle gas and a natural feed gas is combined with dry bromine vapor and fed to an alkane bромination reactor. The recycle gas and the natural gas feed may comprise lower molecular weight hydrocarbons. In the alkane bромination reactor, the gas stream and the dry bromine vapor are reacted to produce gaseous alkyl bromides and hydrobromatic acid vapors. As illustrated, gaseous alkyl bromides and hydrobromatic acid vapors are fed to the alkyl bromide conversion reactor. In the alkyl bromide conversion reactor, the gaseous alkyl bromides are reacted to form higher molecular weight hydrocarbons and additional hydrobromatic acid vapors. In the illustrated embodiment, the hydrobromatic acid vapors are then removed from the higher molecular weight hydrocarbons in the hydrobromatic acid removal unit by a recirculated aqueous solution. As illustrated in FIG. 1, the recirculated aqueous solution carries the hydrobromatic acid (or metal bromide salt if the acid is neutralized by the aqueous solution) to the bromide oxidation unit. As will be discussed in more detail below, the hydrobromatic acid may be neutralized in the bromide oxidation unit to form a metal bromide salt. Oxygen or air is supplied to the bromide oxidation unit to oxidize the metal bromide salt to form the bromine, which is then recycled to the alkane bромination reactor.

In the illustrated embodiment, a natural gas feed is also introduced into the hydrobromatic acid removal unit. From the hydrobromatic acid removal unit, the natural gas feed and the higher molecular weight hydrocarbons are fed to the dehydration and product recovery unit. In the dehydration and product recovery unit, water is removed from the higher molecular weight hydrocarbons and a hydrocarbon liquid product is produced. In addition, a gas stream of recycle gas and the natural gas feed are conveyed to the alkane bромination reactor. Accordingly, the process illustrated in FIG. 1 may be used to produce a liquid hydrocarbon product from lower molecular weight hydrocarbons.

Referring to FIG. 2, a gas stream containing lower molecular weight alkanes, comprised of a mixture of a feed gas plus a recycled gas stream at a pressure in the range of about 1 bar to about 30 bar, is transported or conveyed via line, pipe or conduit 62. The feed gas is mixed with dry bromine liquid transported via line 25 and pump 24, and passed to waste heat exchanger 26 wherein the liquid bromine is vaporized. The mixture of lower molecular weight alkanes and dry bromine vapor is fed to reactor 30. Preferably, the molar ratio of lower molecular weight alkanes to dry bromine vapor in the mixture introduced into reactor 30 is in excess of 2:5:1. Reactor 30 has an inlet preheater zone 28 which heats the mixture to a reaction initiation temperature in the range of about 250°C to about 400°C.

In first reactor 30, the lower molecular weight alkanes are reacted exothermically with dry bromine vapor at a relatively low temperature in the range of about 250°C to about 600°C, and at a pressure in the range of about 1 bar to about 30 bar to produce gaseous alkyl bromides and hydrobromatic acid vapors. The upper limit of the operating temperature range is greater than the upper limit of the reaction initiation temperature range to which the feed mixture is heated due to the exothermic nature of the bромination reaction. In the case of methane, the formation of methyl bromide occurs in accordance with the following general reaction:

\[ \text{CH}_4(g) + \text{Br}_2(g) \rightarrow \text{CH}_3\text{Br}(g) + \text{HBr}(g) \]

This reaction occurs with a significantly high degree of selectivity to methyl bromide. For example, in the case of bромination of methane, a methane to bromine ratio of about 4:5:1 increases the selectivity to the mono-brominated methyl bromide to that obtained using smaller methane to bromine ratios. Small amounts of dibromomethane and tribromomethane are also formed in the bромination reaction. Higher alkanes, such as ethane, propane and butane, are also readily brominated resulting in mono and multiple brominated species such as ethyl bromides, propyl bromides and butyl bromides. If an alkane to bromine ratio of significantly less than about 2.5 to 1 is utilized, a lower selectivity to methyl bromide occurs and significant formation of undesirable carbon soot is observed. Further, the dry bromine vapor that is fed into first reactor 30 is substantially water-free. Applicant has discovered that elimination of substantially all water vapor from the bромination step in first reactor 30 substantially eliminates the formation of unwanted carbon dioxide thereby increasing the selectivity of alkane bромination to alkyl bromides and eliminating the large amount of waste heat generated in the formation of carbon dioxide from alkanes.

The effluent that contains alkyl bromides and hydrobromatic acid is withdrawn from the first reactor via line 31 and is partially cooled in heat exchanger 32 before flowing to a second reactor 34. The temperature to which the effluent is cooled is partially cooled in heat exchanger 34 is in the range of about 150°C to about 550°C, when it is desired to convert the alkyl bromides to higher molecular weight hydrocarbons in second reactor 34, or to a range of about 150°C to about 450°C, when it is desired to convert the alkyl bromides to olefins in second reactor 34.

In second reactor 34, the alkyl bromides are reacted exothermically over a fixed bed 33 of crystalline alumino-silicate catalyst, preferably a zeolite catalyst. The temperature and pressure employed in second reactor, as well as the zeolite catalyst, will determine the product(s) that is formed from the reaction of alkyl bromides occurring in second reactor 34.

The crystalline alumino-silicate catalyst employed in second reactor 34 is preferably a zeolite catalyst and most preferably a ZSM-5 zeolite catalyst when it is desired to form higher molecular weight hydrocarbons. Although the zeolite catalyst is preferably used in the hydrogen, sodium or magnesium form, the zeolite may also be modified by ion exchange with other alkali metal cations, such as Li, Na, K or...
Cs, with alkali-earth metal cations, such as Mg, Ca, Sr or Ba, or with transition metal cations, such as Ni, Mn, V, W, or to the hydrogen form. Other zeolite catalysts having varying pore sizes and acidities, which are synthesized by varying the alumina-to-silica ratio may be used in the second reactor 34 as will be evident to a skilled artisan.

When it is desired to form olefins from the reaction of alkyl bromides in reactor 34, the crystalline aluminosilicate catalyst employed in second reactor 34 is preferably a zeolite catalyst, and most preferably an X type or Y type zeolite catalyst. A preferred zeolite is 10 X or Y type zeolite, although other zeolites with differing pore sizes and acidities, which are synthesized by varying the alumina-to-silica ratio may be used in the process of the present invention as will be evident to a skilled artisan. Although the zeolite catalyst is preferably used in a protonic form, a sodium form or a mixed protonic/sodium form, the zeolite may also be modified by ion exchange with other alkali metal cations, such as Li, K or Cs, with alkali-earth metal cations, such as Mg, Ca, Sr or Ba, or with transition metal cations, such as Ni, Mn, V, W, or to the hydrogen form. These various alternative cations have an effect of shifting reaction selectivity. Other zeolite catalysts having varying pore sizes and acidities, which are synthesized by varying the alumina-to-silica ratio may be used in the second reactor 34 as will be evident to a skilled artisan.

The temperature at which the second reactor 34 is operated is an important parameter in determining the selectivity of the reaction to higher molecular hydrocarbons or to olefins.

Where a catalyst is selected to form higher molecular weight hydrocarbons in reactor 34, it is preferred to operate second reactor 34 at a temperature within the range of about 150° C. to about 450° C. Temperatures above about 300° C. in the second reactor result in increased yields of light hydrocarbons such as undesirable methane, whereas lower temperatures increase yields of heavier molecular weight hydrocarbon products. At the low end of the temperature range, with methyl bromide reacting over ZSM-5 zeolite at temperatures as low as 150° C. significant methyl bromide conversion on the order of 20% is noted, with a high selectivity towards C₂⁺ products. Notably, in the case of the alkyl bromide reaction over the preferred zeolite ZSM-5 catalyst, cyclization reactions also occur such that the C₇⁺ fractions are composed primarily of substituted aromatics. At increasing temperatures approaching 400° C., methyl bromide conversion increases towards 90% or greater, however selectivity towards C₂⁺ products decreases and selectivity towards lighter products, particularly undesirable methane, increases. Surprisingly, very little ethene or C₂⁻, olefin components are formed. At temperatures approaching 450° C., almost complete conversion of methyl bromide to methane occurs. In the optimum operating temperature range of between about 300° C. and 400° C., as byproduct of the reaction, a small amount of carbon will build up on the catalyst over time during operation, causing a decline in catalyst activity over a range of hours, up to hundreds of hours, depending on the reaction conditions and the composition of the feed gas. It is believed that higher reaction temperatures above about 400° C., associated with the formation of methane favors the thermal cracking of alkyl bromides and formation of carbon or coke and hence an increase in the rate of deactivation of the catalyst. Conversely, temperatures at the lower end of the range, particularly below about 300° C. may also contribute to coking due to a reduced rate of desorption of heavier products from the catalyst. Hence, operating temperatures within the range of about 150° C. to about 450° C., but preferably in the range of about 300° C. to about 400° C. in the second reactor 34 balance increased selectivity of the desired C₂⁺ products and lower rates of deactivation due to carbon formation, against higher conversion per pass, which minimizes the quantity of catalyst, recycle rates and equipment size required.

Where a catalyst is selected to form olefins in reactor 34, it is preferred to operate second reactor 34 at a temperature within the range of about 250° C. to about 500° C. Temperatures above about 450° C. in the second reactor can result in increased yields of light hydrocarbons such as undesirable methane and also deposition of coke, whereas lower temperatures increase yields of ethylene, propylene, butylene and heavier molecular weight hydrocarbon products. Notably, in the case of the alkyl bromide reaction over the preferred 10 X zeolite catalyst, it is believed that cyclization reactions also occur such that the C₇⁺ fractions contain substantial substituted aromatics. At increasing temperatures approaching 400° C., it is believed that methyl bromide conversion increases towards 90% or greater, however selectivity towards C₂⁺ products decreases and selectivity towards lighter products, particularly olefins increases. At temperatures exceeding 550° C., it is believed that a high conversion of methyl bromide to methane and carbonaceous, coke occurs. In the preferred operating temperature range of between about 300° C. and 450° C., as byproduct of the reaction, a lesser amount of coke probably will build up on the catalyst over time during operation, causing a decline in catalyst activity over a range of hours, up to hundreds of hours, depending on the reaction conditions and the composition of the feed gas. It is believed that higher reaction temperatures above about 400° C., associated with the formation of methane favors the thermal cracking of alkyl bromides and formation of carbon or coke and hence an increase in the rate of deactivation of the catalyst. Conversely, temperatures at the lower end of the range, particularly below about 300° C. may also contribute to coking due to a reduced rate of desorption of heavier products from the catalyst. Hence, operating temperatures within the range of about 150° C. to about 450° C., but preferably in the range of about 300° C. to about 400° C. in the second reactor 34 balance increased selectivity of the desired C₂⁺ products and lower rates of deactivation due to carbon formation, against higher conversion per pass, which minimizes the quantity of catalyst, recycle rates and equipment size required.

The catalyst may be periodically regenerated in situ, by isolating reactor 34 from the normal process flow, purging with an inert gas via line 70 at a pressure in a range from about 1 to about 5 bar at an elevated temperature in the range of about 400° C. to about 650° C. to remove unreacted material adsorbed on the catalyst insofar as is practical, and then successively oxidizing the deposited carbon to CO₂ by addition of air or inert gas-diluted oxygen to reactor 34 via line 70 at a pressure in the range of about 1 bar to about 5 bar at an elevated temperature in the range of about 400° C. to about 650° C. Carbon dioxide and residual air or inert gas is vented from reactor 34 via line 75 during the regeneration period.

The effluent which comprises hydrobromic acid and higher molecular weight hydrocarbons, olefins or mixtures thereof is withdrawn from the second reactor 34 via line 35 and is cooled to a temperature in the range of 0° C. to about 100° C. in exchanger 36 and combined with vapor effluent in
line 12 from hydrocarbon stripper 47, which contains feed gas and residual higher molecular weight hydrocarbons stripped-out by contact with the feed gas in hydrocarbon stripper 47. The combined vapor mixture is passed to a scrubber 38 and contacted with a concentrated aqueous partially-oxidized metal bromide salt solution containing metal hydroxide, metal oxide, metal oxy-bromide or mixtures of these species, which is transported to scrubber 38 via line 41. The preferred metal of the bromide salt is Fe(III), Cu(II) or Zn(II), or mixtures thereof, as these are less expensive and readily oxidized at lower temperatures in the range of about 120°C to about 180°C, allowing the use of glass-lined or fluoropolymer-lined equipment; although Co(II), Ni(II), Mn(II), V(II), Cr(II) or other transition-metals which form oxidizable bromide salts may be used in the process of the present invention. Alternatively, alkaline-earth metals which also form oxidizable bromide salts, such as Ca(II) or Mg(II) may be used. Any liquid hydrocarbons condensed in scrubber 38 may be skimmed and withdrawn in line 37 and added to liquid hydrocarbons exiting the product recovery unit 52 in line 54. Hydrobromic acid is dissolved in the aqueous solution and neutralized by the metal hydroxide, metal oxide, metal oxy-bromide or mixtures of these species to yield metal bromide salt in solution and water which is removed from the scrubber 38 via line 44.

[0048] The residual vapor phase containing olefins, higher molecular weight hydrocarbons or mixtures thereof that is removed as effluent from the scrubber 38 is forwarded via line 39 to dehydrator 50 to remove substantially all water via line 53 from the vapor stream. The water is then removed from the dehydrator 50 via line 53. The dried vapor stream containing olefins, higher molecular weight hydrocarbons or mixtures thereof is further passed via line 51 to product recovery unit 52 to recover olefins, the C₆+ gasoline-range hydrocarbon fraction or mixtures thereof as a liquid product in line 54. Any conventional method of dehydration and liquids recovery, such as solid-bed dessicant adsorption followed by refrigerated condensation, cryogenic expansion, or circulating absorption oil or other solvent, as used to process natural gas or refinery gas streams, and/or to recover olefinic hydrocarbons, as will be evident to a skilled artisan, may be employed in the process of the present invention. The residual vapor effluent from product recovery unit 52 is then split into a purge stream 57 which may be utilized as fuel for the process and a recycled residual vapor which is compressed via compressor 58. The recycled residual vapor discharged from compressor 58 is split into two fractions. A first fraction that is equal to at least 2.5 times the feed gas molar volume is transported via line 62 and is combined with dry liquid bromine conveyed by pump 24, heated in exchanger 26 to vaporize the bromine and fed into first reactor 30. The second fraction is drawn off of line 62 via line 63 and is regulated by control valve 60, at a rate sufficient to dilute the alkyl bromide concentration to reactor 34 and absorb the heat of reaction such that reactor 34 is maintained at the selected operating temperature, preferably in the range of about 300°C to about 450°C in order to maximize conversion versus selectivity and to minimize the rate of catalyst deactivation due to the deposition of carbon. Thus, the dilution provided by the recycled vapor effluent permits selectivity of bromination in the first reactor 30 to be controlled in addition to moderating the temperature in second reactor 34.

[0049] Water containing metal bromide salt in solution which is removed from scrubber 38 via line 44 is passed to hydrocarbon stripper 47 wherein residual dissolved hydrocarbons are stripped from the aqueous phase by contact with incoming feed gas transported via line 11. The stripped aqueous solution is transported from hydrocarbon stripper 47 via line 65 and is cooled to a temperature in the range of about 0°C to about 70°C in heat exchanger 46 and then passed to absorber 48 in which residual bromine is recovered from vent stream in line 67. The aqueous solution effluent from absorber 48 is transported via line 49 to a heat exchanger 40 to be preheated to a temperature in the range of about 100°C to about 600°C, and most preferably in the range of about 120°C to about 180°C, and passed to third reactor 16. Oxygen or air is delivered via line 10 by blower or compressor 13 at a pressure in the range of about ambient to about 5 bar to bromine stripper 14 to strip residual bromine from water. Water is removed from stripper 14 in line 16 and combined with water stream 53 from dehydrator 50 to form water effluent stream in line 56 which is removed from the process. The oxygen or air leaving bromine stripper 14 is fed via line 15 to reactor 16 which operates at a pressure in the range of about ambient to about 5 bar and at a temperature in the range of about 100°C to about 600°C, but most preferably in the range of about 120°C to about 180°C so as to oxidize an aqueous metal bromide salt solution to yield elemental bromine and metal hydroxide, metal oxide, metal oxy-bromide or mixtures of these species. As stated above, although Co(II), Ni(II), Mn(II), V(II), Cr(II) or other transition-metals which form oxidizable bromide salts can be used, the preferred metal of the bromide salt is Fe(II), Cu(II), or Zn(II), or mixtures thereof, as these are less expensive and readily oxidized at lower temperatures in the range of about 120°C to about 180°C, which should allow the use of glass-lined or fluoropolymer-lined equipment. Alternatively, alkaline-earth metals which also form oxidizable bromide salts, such as Ca(II) or Mg(II) could be used.

[0050] Hydrobromic acid reacts with the metal hydroxide, metal oxide, metal oxy-bromide or mixtures of these species so formed to once again yield the metal bromide salt and water. Heat exchanger 18 in reactor 16 supplies heat to vaporize water and bromine. Thus, it is believed that the overall reactions result in the net oxidation of hydrobromic acid produced in first reactor 30 and second reactor 34 to elemental bromine and steam in the liquid phase catalyzed by the metal bromide/metal oxide or metal hydroxide operating in a catalytic cycle. In the case of the metal bromide being Fe(II)Br₃, the reactions are believed to be:

[0051] 1) Fe(3a)+6Br(–a)+3H₂O→3FeOH(3)b+3Br₂(g)+Fe(3a)+6Br(–a)+3H₂O  
[0052] 2) 3FeOH(3)b+3H₂O→3FeO(3)b+3H₂+3Br₂(g)  
[0053] 3) 3FeO(3)b+3Br₂(g)+Fe(3a)+6Br(–a)+3H₂O

In the case of the metal bromide being Cu(II)Br₂, the reactions are believed to be:

[0054] 1) 4Cu(2a)+8Br(–a)+3H₂O→4CuOH(3)b+3Br₂(g)+Cu₂Br₂+3CuOH(3)b  
[0055] 2) 6HBr(3)a+H₂O→6H₂+6Br(–a)+6Br₂(g)  
[0056] 3) 6H₂+6Br(–a)+Cu₂Br₂→6CuBr₂+6H₂O

[0057] The elemental bromine and water and any residual oxygen or nitrogen (if air is utilized as the oxidant) leaving as vapor from the outlet of third reactor 16 via line 19, are cooled in condenser 20 at a temperature in the range of about 0°C to about 70°C and a pressure in the range of about ambient to 5 bar to condense the bromine and water and passed to three-phase separator 22. In three-phase separator 22, since liquid
water has a limited solubility for bromine, on the order of about 3% by weight, any additional bromine which is condensed forms a separate, denser liquid bromine phase. The liquid bromine phase, however, has a notably lower solubility for water, on the order of less than 0.1%. Thus a substantially dry bromine vapor can be easily obtained by condensing liquid bromine and water, decanting water by simple physical separation and subsequently re-vaporizing liquid bromine.

[0058] Liquid bromine is pumped in line 25 from three-phase separator 22 via pump 24 to a pressure sufficient to mix with vapor stream 62. Thus bromine is recovered and recycled within the process. The residual oxygen or nitrogen and any residual bromine vapor which is not condensed exits three-phase separator 22 and is passed via line 23 to bromine scrubber 48, wherein residual bromine is recovered by solution into and by reaction with reduced metal bromides in the aqueous metal bromide solution stream 65. Water is removed from separator 22 via line 27 and introduced into stripper 14.

[0059] In another embodiment of the invention, referring to FIG. 3, a gas stream containing lower molecular weight alkanes, comprised of mixture of a feed gas plus a recycled gas stream at a pressure in the range of about 1 bar to about 30 bar, is transported or conveyed via line, pipe or conduit 162, mixed with dry bromine liquid transported via pump 124 and passed to heat exchanger 126 wherein the liquid bromine is vaporized. The mixture of lower molecular weight alkanes and dry bromine vapor is fed to reactor 130. Preferably, the molar ratio of lower molecular weight alkanes to dry bromine vapor in the mixture introduced into reactor 130 is in excess of 2.5:1. Reactor 130 has an inlet pre-heater zone 128 which heats the mixture to a reaction initiation temperature in the range of about 150° C. to about 300° C. In reactor 130, the lower molecular weight alkanes are reacted exothermically with dry bromine vapor at a relatively low temperature in the range of about 250° C. to about 600° C., and at a pressure in the range of about 1 bar to about 30 bar to produce gaseous alkyl bromides and hydrobromic acid vapors. The upper limit of the operating temperature range is greater than the upper limit of the reaction initiation temperature range to which the feed mixture is heated due to the exothermic nature of the bromination reaction. In the case of methane, the formation of methyl bromide occurs in accordance with the following general reaction:

\[ \text{CH}_4(g) + \text{Br}_2(g) \rightarrow \text{CH}_3\text{Br}(g) + \text{HBr}(g) \]

[0060] This reaction occurs with a significantly high degree of selectivity to methyl bromide. For example, in the case of bromination of methane, a methane to bromine ratio of about 4.5:1 increases the selectivity to the mono-halogenated methyl bromide. Small amounts of dibromomethane and tribromomethane are also formed in the bromination reaction. Higher alkanes, such as ethane, propane and butane, are also readily brominated resulting in mono and multiple brominated species such as ethyl bromides, propyl bromides and butyl bromides. If an alkane to bromine ratio of significantly less than about 2.5 to 1 is utilized, a lower selectivity to methyl bromide occurs and significant formation of undesirable carbon soot is observed. Further, the dry bromine vapor that is feed into first reactor 30 is preferably substantially water-free. Applicant has discovered that elimination of substantially all water vapor from the bromination step in first reactor 30 substantially eliminates the formation of unwanted carbon dioxide thereby increasing the selectivity of alkane bromination to alkyl bromides and eliminating the large amount of waste heat generated in the formation of carbon dioxide from alkanes.

[0061] The effluent that contains alkyl bromides and hydrobromic acid is withdrawn from the first reactor via line 131 and is partially cooled in heat exchanger 132 before flowing to a second reactor 134. The temperature to which the effluent is partially cooled in heat exchanger 134 is in the range of about 150° C. to about 350° C. Where it is desired to convert the alkyl bromides to higher molecular weight hydrocarbons in second reactor 134, or to range of about 150° C. to about 450° C., where it is desired to convert the alkyl bromides to olefins in second reactor 134. In second reactor 134, the alkyl bromides are reacted exothermically over a fixed bed 133 of crystalline alumino-silicate catalyst, preferably a zeolite catalyst. The temperature and pressure employed in second reactor 134, as well as the zeolite catalyst, will determine the product that is formed from the reaction of alkyl bromides occurring in second reactor 134.

[0062] The crystalline alumino-silicate catalyst employed in second reactor 134 is preferably a zeolite catalyst and most preferably a ZSM-5 zeolite catalyst when it is desired to form higher molecular weight hydrocarbons. Although the zeolite catalyst is preferably used in the hydrogen, sodium or magnesium form, the zeolite may also be modified by ion exchange with other alkali metal cations, such as Li, Na, K, Cs, or alkali-earth metal cations, such as Mg, Ca, Sr or Ba, or with transition metal cations, such as Ni, Mn, V, W, or to the hydrogen form. Other zeolite catalysts having varying pore sizes and acidities, which are synthesized by varying the alumina-to-silica ratio may be used in the second reactor 134 as will be evident to a skilled artisan.

[0063] When it is desired to form olefins from the reaction of alkyl bromides in reactor 134, the crystalline alumino-silicate catalyst employed in second reactor 134 is preferably a zeolite catalyst and most preferably an X type or Y type zeolite catalyst. A preferred zeolite is 10 X or Y type zeolite, although other zeolites with differing pore sizes and acidities, which are synthesized by varying the alumina-to-silica ratio may be used in the process of the present invention as will be evident to a skilled artisan. Although the zeolite catalyst is preferably used in a protonic form, a sodium form or a mixed protonic/sodium form, the zeolite may also be modified by ion exchange with other alkali metal cations, such as Li, K, Cs, with alkali-earth metal cations, such as Mg, Ca, Sr or Ba, or with transition metal cations, such as Ni, Mn, V, W, or to the hydrogen form. These various alternative cations have an effect of shifting reaction selectivity. Other zeolite catalysts having varying pore sizes and acidities, which are synthesized by varying the alumina-to-silica ratio may be used in the second reactor 134 as will be evident to a skilled artisan.

[0064] The temperature at which the second reactor 134 is operated is an important parameter in determining the selectivity of the reaction to higher molecular weight hydrocarbons or to olefins.

[0065] When a catalyst is selected to form higher molecular weight hydrocarbons in reactor 134, it is preferred to operate second reactor 134 at a temperature within the range of about 150° C. to 450° C. Temperatures above about 300° C. in the second reactor result in increased yields of light hydrocarbons, such as undesirable methane, whereas lower temperatures yield yields of heavier molecular weight hydrocarbon products. At the low end of the temperature range, with alkyl bromide reacting over ZSM-5 zeolite at temperatures as low as 150° C.
significant methyl bromide conversion on the order of 20% is noted, with a high selectivity towards C2+ products. Notably, in the case of the alkyl bromide reaction over the preferred zeolite ZSM-5 catalyst, cyclization reactions also occur such that the C4+ fractions are composed primarily of substituted aromatics. At increasing temperatures approaching 300°C, methyl bromide conversion increases towards 90% or greater, however selectivity towards C2+ products decreases and selectivity towards lighter products, particularly undesirable methane, increases. Surprisingly, very little ethane or C3-C5 olefin components are formed. At temperatures approaching 450°C, almost complete conversion of methyl bromide to methane occurs. In the optimum operating temperature range of between about 300°C and 400°C, as a byproduct of the reaction, a small amount of carbon will build up on the catalyst over time during operation, causing a decline in catalyst activity over a range of hours, up to hundreds of hours, depending on the reaction conditions and the composition of the feed gas. It is believed that higher reaction temperatures above about 400°C, associated with the formation of methane favor the thermal cracking of alkyl bromides and formation of carbon or coke and hence an increase in the rate of deactivation of the catalyst. Conversely, temperatures at the lower end of the range, particularly below about 300°C, may also contribute to coking due to a reduced rate of desorption of heavier products from the catalyst. Hence, operating temperatures within the range of about 250°C to about 500°C, but preferably in the range of about 300°C to about 450°C in the second reactor 134 balance increased selectivity of the desired olefins and C2+ products and lower rates of deactivation due to carbon formation, against higher conversion per pass, which minimizes the quantity of catalyst, recycle rates and equipment size required.

The catalyst may be periodically regenerated in situ, by isolating reactor 134 from the normal process flow, purging with an inert gas via line 170 at a pressure in the range of about 1 bar to about 5 bar and an elevated temperature in the range of 400°C to 650°C, to remove unreacted material adsorbed on the catalyst insofar as is practical, and then subsequently oxidizing the deposited carbon to CO2 by addition of air or inert gas-diluted oxygen via line 170 to reactor 134 at a pressure in the range of about 1 bar to about 5 bar and an elevated temperature in the range of 400°C to 650°C. Carbon dioxide and residual air or inert gas are vented from reactor 134 via line 175 during the regeneration period.

The effluent which comprises hydrobromic acid and higher molecular weight hydrocarbons, olefins or mixtures thereof is withdrawn from the second reactor 134 via line 135, cooled to a temperature in the range of about 0°C to about 100°C in exchanger 136, and combined with vapor effluent in line 112 from hydrocarbon stripper 147. The mixture is then passed to a scrubber 138 and contacted with a stripped, recirculated water that is transported to scrubber 138 in line 164 by any suitable means, such as pump 143, and is cooled to a temperature in the range of about 0°C to about 50°C in heat exchanger 155. Any liquid hydrocarbon product condensed in scrubber 138 may be skimmed and withdrawn as stream 137 and added to liquid hydrocarbon product 154. Hydrobromic acid is dissolved in scrubber 138 in the aqueous solution which is removed from the scrubber 138 via line 144, and passed to hydrocarbon stripper 147 wherein residual hydrocarbons dissolved in the aqueous solution are stripped out by contact with feed gas 111. The stripped aqueous phase effluent from hydrocarbon stripper 147 is cooled to a temperature in the range of about 0°C to about 50°C in heat exchanger 146 and then passed via line 165 to absorber 148 in which residual bromine is recovered from vent stream 167.

The residual vapor phase containing olefins, higher molecular weight hydrocarbons or mixtures thereof is removed as effluent from the scrubber 138 and forwarded to dehydrator 150 to remove substantially all water from the gas stream. The water is then removed from the dehydrator 150 via line 153. The dried gas stream containing olefins, higher molecular weight hydrocarbons or mixtures thereof is further passed via line 151 to product recovery unit 152 to recover olefins, the C2+ gasoline range hydrocarbon fraction or mixtures thereof as a liquid product in line 154. Any conventional method of dehydration and liquids recovery such as solid-bed dessicant adsorption followed by, for example, refrigerated condensation, cryogenic expansion, or circulating absorption oil, or other solvents as used to process natural gas or refinery gas streams and recover olefinic hydrocarbons, as known to a skilled artisan, may be employed in the implementation of this invention. The residual vapor effluent from product recovery unit 152 is then split into a purge stream 157 that may be utilized as fuel for the process and a recycled residual vapor which is compressed via compressor 158. The recycled residual vapor discharged from compressor 158 is split into two fractions. A first fraction that is equal to at least 2.5 times
the feed gas volume is transported via line 162, combined with the liquid bromine conveyed in line 125 and passed to heat exchanger 126 wherein the liquid bromine is vaporized and fed into first reactor 130. The second fraction which is drawn off line 162 via line 163 and is regulated by control valve 160, at a rate sufficient to dilute the alkyl bromide concentration to reactor 134 and absorb the heat of reaction such that reactor 134 is maintained at the selected operating temperature, preferably in the range of about 300°C to about 450°C in order to maximize conversion vs. selectivity and to minimize the rate of catalyst deactivation due to the deposition of carbon. Thus, the dilution provided by the recycled vapor effluent permits selectivity of bromination in the first reactor 130 to be controlled in addition to moderating the temperature in second reactor 134.

[0070] Oxygen, oxygen enriched air or air 110 is delivered via blower or compressor 113 at a pressure in the range of about ambient to about 5 bar to bromine stripper 114 to strip residual bromine from water which leaves stripper 114 via line 164 and is divided into two portions. The first portion of the stripped water is recycled via line 164, cooled in heat exchanger 155 to a temperature in the range of about 20°C to about 50°C, and maintained at a pressure sufficient to enter scrubber 138 by any suitable means, such as pump 143. The portion of water that is recycled is selected such that the hydrobromic acid solution effluent removed from scrubber 138 via line 144 has a concentration in the range from about 10% to about 50% by weight hydrobromic acid, but more preferably in the range of about 30% to about 40% by weight to minimize the amount of water which must be vaporized in heat exchanger 141 and preheater 119 and to minimize the vapor pressure of HBr over the resulting acid. A second portion of water from stripper 114 is removed from line 164 and the process via line 156.

[0071] The dissolved hydrobromic acid that is contained in the aqueous solution effluent from absorber 148 is transported via line 149 and is combined with the oxygen, oxygen enriched air or air leaving bromine stripper 114 in line 115. The combined aqueous solution effluent and oxygen, oxygen enriched air or air is passed to a first side of heat exchanger 141 and through preheater 119 wherein the mixture is preheated to a temperature in the range of about 100°C to about 600°C and most preferably in the range of about 120°C to about 250°C and passed to third reactor 117 that contains a metal bromide salt or metal oxide. The preferred metal of the bromide salt or metal oxide is Fe(III), Cu(II) or Zn(II) although Co(II), Ni(II), Mn(II), V(II), Cr(II) or other transition-metals which form oxidizable bromide salts can be used. Alternatively, alkaline-earth metals which also form oxidizable bromide salts, such as Ca(II) or Mg(II) could be used. The metal bromide salt in the oxidation reactor 117 can be utilized as a concentrated aqueous solution or preferably, the concentrated aqueous salt solution may be imbibed into a porous, high surface area, acid resistant inert support such as a silica gel. More preferably, the oxide form of the metal in a range of 10 to 20% by weight is deposited on an inert support such as alumina with a specific surface area in the range of 50 to 200 m²/g. The oxidation reactor 117 operates at a pressure in the range of about ambient to about 5 bar and at a temperature in the range of about 100°C to 600°C, but most preferably in the range of about 130°C to 350°C, therein, the metal bromide is oxidized by oxygen, yielding elemental bromine and metal hydroxide, metal oxide or metal oxybromide species or, metal oxides in the case of the supported metal bromide salt or metal oxide operated at higher temperatures and lower pressures at which water may primarily exist as a vapor. In either case, the hydrobromic acid reacts with the metal hydroxide, metal oxy-bromide or metal oxide species and is neutralized, restoring the metal bromide salt and yielding water. Thus, it is believed that the overall reaction results in the net oxidation of hydrobromic acid produced in first reactor 130 and second reactor 134 to elemental bromine and steam, catalyzed by the metal bromide/metal hydroxide or metal oxide operating in a catalytic cycle. In the case of the metal bromide being Fe(III)Br₂ in an aqueous solution and operated in a pressure and temperature range in which water may exist as a liquid the reactions are believed to be:

\[ \text{[0072]} \quad 1) \quad \text{Fe}^{3+} + 3\text{Br}^- + 3\text{H}^+ + \frac{1}{2}\text{O}_2 \rightarrow 3\text{Br}_2 + \text{Fe(OH)}_3 \]

\[ \text{[0073]} \quad 2) \quad 3\text{HBr} + \text{H}_2\text{O} \rightarrow \text{3H}^+ + \text{3Br}^- + 3\text{H}_2\text{O} \]

\[ \text{[0074]} \quad 3) \quad \text{3H}^+ + 3\text{Br}^- + \text{Fe(OH)}_3 \rightarrow \text{Fe}^{3+} + 3\text{H}_2\text{O} \]

In the case of the metal bromide being Cu(II)Br₂ in an aqueous solution and operated in a pressure and temperature range in which water may exist as a liquid the reactions are believed to be:

\[ \text{[0075]} \quad 1) \quad 4\text{Cu}^{2+} + 8\text{Br}^- + 3\text{H}_2\text{O} \rightarrow 3\text{CuBr}_2 + 3\text{Cu(OH)}_2 \]

\[ \text{[0076]} \quad 2) \quad 6\text{HBr} + \text{H}_2\text{O} \rightarrow 6\text{H}^+ + 6\text{Br}^- + 3\text{H}_2\text{O} \]

\[ \text{[0077]} \quad 3) \quad 6\text{H}^+ + 6\text{Br}^- + \text{CuBr}_2 \rightarrow 3\text{Cu(OH)}_2 \rightarrow 4\text{Cu}^{2+} + 8\text{Br}^- + 6\text{H}_2\text{O} \]

In the case of the metal bromide being Cu(II)Br₂ supported on an inert support and operated at higher temperature and lower pressure conditions at which water primarily exists as a vapor, the reactions are believed to be:

\[ \text{[0078]} \quad 1) \quad 2\text{Cu(II)Br}_2 \rightarrow 2\text{Cu(I)Br} + \text{Br}_2 \]

\[ \text{[0079]} \quad 2) \quad 2\text{Cu(I)Br} + \text{O}_2 \rightarrow \text{Br}_2 + 2\text{Cu(II)O} \]

\[ \text{[0080]} \quad 3) \quad 2\text{HBr} + \text{Cu(II)O} \rightarrow \text{Cu(II)Br}_2 + \text{H}_2\text{O} \]

[0081] The elemental bromine and water and any residual oxygen or nitrogen (if air or oxygen enriched air is utilized as the oxidant) leaving as vapor from the outlet of third reactor 117, are cooled in the second side of exchanger 141 and condenser 120 to a temperature in the range of about 0°C to about 70°C wherein the bromine and water are condensed and passed to three-phase separator 122. In three-phase separator 122, since liquid water has a limited solubility for bromine, on the order of about 3% by weight, any additional bromine which is condensed forms a separate, denser liquid bromine phase. The liquid bromine phase, however, has a notably lower solubility for water, on the order of less than 0.1%. Thus, a substantially dry bromine vapor can be easily obtained by condensing liquid bromine and water, decanting water by simple physical separation and subsequently re-vaporizing liquid bromine. It is important to operate at conditions that result in the near complete reaction of HBr so as to avoid significant residual HBr in the condensed liquid bromine and water, as HBr increases the miscibility of bromine in the aqueous phase, and at sufficiently high concentrations, results in a single ternary liquid phase.

[0082] Liquid bromine is pumped from three-phase separator 122 via pump 124 to a pressure sufficient to mix with vapor stream 162. Thus the bromine is recovered and recycled within the process. The residual air, oxygen enriched air or oxygen and any bromine vapor which is not condensed exits three-phase separator 122 and is passed via line 123 to bromine scrubber 148 wherein residual bromine is recovered by dissolution into hydrobromic acid solution stream conveyed.
to scrubber 148 via line 165. Water is removed from the three-phase separator 122 via line 129 and passed to stripper 114.

[0083] The elemental bromine vapor and steam are condensed and easily separated in the liquid phase by simple physical separation, yielding substantially dry bromine. The absence of significant water allows selective bromination of alkanes, without production of CO₂ and the subsequent efficient and selective reactions of alkyl bromides to primarily C₂ to C₄ olefins, heavier products, the C₅⁺ fraction of which contains substantial branched alkanes and substituted aromatics, or mixtures thereof. Byproduct hydrobromic acid vapor from the bromination reaction and subsequent reaction in reactor 134 are readily dissolved in an aqueous phase and neutralized by the metal hydroxide or metal oxide species resulting from oxidation of the metal bromide.

[0084] In accordance with another embodiment of the process of the present invention illustrated in FIG. 4A, the alkyl bromination and alkyl bromide conversion stages are operated in a substantially similar manner to those corresponding stages described with respect to FIGS. 2 and 3 above. More particularly, a gas stream containing lower molecular weight alkanes, comprised of mixture of a feed gas and a recycled gas stream at a pressure in the range of about 1 bar to about 30 bar, is transported or conveyed via line, pipe or conduits 262 and 211, respectively, and mixed with dry bromine liquid in line 225. The resultant mixture is transported via pump 224 and passed to heat exchanger 226 wherein the liquid bromine is vaporized. The mixture of lower molecular weight alkanes and dry bromine vapor is fed to reactor 230. Preferably, the molar ratio of lower molecular weight alkanes to dry bromine vapor in the mixture introduced into reactor 230 is in excess of 2.5:1. Reactor 230 has an inlet pre-heater zone 228 which heats the mixture to a reaction initiation temperature in the range of 250° C. to 400° C. In first reactor 230, the lower molecular weight alkanes are reacted exothermically with dry bromine vapor at a relatively low temperature in the range of about 250° C. to about 600° C., and at a pressure in the range of about 1 bar to about 30 bar to produce gaseous alkyl bromides and hydrobromic acid vapors. The upper limit of the operating temperature range is greater than the upper limit of the reaction initiation temperature range to which the feed mixture is heated due to the exothermic nature of the bromination reaction. In the case of methane, the formation of methyl bromide occurs in accordance with the following general reaction:

\[
\text{CH}_4(g) + \text{Br}_2(g) \rightarrow \text{CH}_3\text{Br}(g) + \text{HBr}(g)
\]

This reaction occurs with a significantly high degree of selectivity to methyl bromide. For example, in the case of bromine reacting with a molar excess of methane at a temperature to bromine ratio of 4.5:1, a high selectivity to the mono-halogenated methyl bromide occurs. Small amounts of dibromomethane and tribromomethane are also formed in the bromination reaction. Higher alkanes, such as ethane, propane and butane, are also readily bromoninated resulting in mono and multiple brominated species such as ethyl bromides, propyl bromides and butyl bromides. If an alkane to bromine ratio of significantly less than 2.5 to 1 is utilized, substantially lower selectivity to methyl bromide occurs and significant formation of undesirable carbon soot is observed. Further, the dry bromine vapor that is fed into first reactor 230 is substantially water-free. Applicant has discovered that elimination of substantially all water vapor from the bromination step in first reactor 230 substantially eliminates the formation of unwanted carbon dioxide thereby increasing the selectivity of alkane bromination to alkyl bromides and eliminating the large amount of waste heat generated in the formation of carbon dioxide from alkanes.

[0085] The effluent that contains alkyl bromides and hydrobromic acid is withdrawn from the first reactor via line 231 and is partially cooled in heat exchanger 232 before flowing to a second reactor 234. The temperature to which the effluent is partially cooled in heat exchanger 234 is in the range of about 150° C. to about 350° C. When it is desired to convert the alkyl bromides to higher molecular weight hydrocarbons in second reactor 234, or to range of about 150° C. to about 450° C. when it is desired to convert the alkyl bromides to olefins a second reactor 234. In second reactor 234, the alkyl bromides are reacted exothermically over a fixed bed 235 of crystalline aluminosilicate catalyst, preferably a zeolite catalyst. The temperature and pressure employed in second reactor, as well as the zeolite catalyst, will determine the product that is formed from the reaction of alkyl bromides occurring in second reactor 234.

[0086] The crystalline aluminosilicate catalyst employed in second reactor 234 is preferably a zeolite catalyst and most preferably a ZSM-5 zeolite catalyst when it is desired to form higher molecular weight hydrocarbons. Although the zeolite catalyst is preferably used in the hydrogen, sodium or magnesium form, the zeolite may also be modified by ion exchange with other alkali metal cations, such as Li, Na, K or Cs, with alkali-earth metal cations, such as Mg, Ca, Sr or Ba, or with transition metal cations, such as Ni, Mn, V, W, or to the hydrogen form. Other zeolite catalysts having varying pore sizes and acidities, which are synthesized by varying the aluminia-to-silica ratio may be used in the second reactor 234 as will be evident to a skilled artisan.

[0087] When it is desired to form olefins from the reaction of alkyl bromides in reactor 234, the crystalline aluminosilicate catalyst employed in second reactor 234 is preferably a zeolite catalyst, and most preferably an X type or Y type zeolite catalyst. A preferred zeolite is 10 X or Y type zeolite, although other zeolites with differing pore sizes and acidities, which are synthesized by varying the aluminia-to-silica ratio may be used in the process of the present invention as will be evident to a skilled artisan. Although the zeolite catalyst is preferably used in a protonic form, a sodium form or a mixed protonic/sodium form, the zeolite may also be modified by ion exchange with other alkali metal cations, such as Li, K or Cs, with alkali-earth metal cations, such as Mg, Ca, Sr or Ba, or with transition metal cations, such as Ni, Mn, V, W, or to the hydrogen form. These various alternative cations have an effect of shifting reaction selectivity. Other zeolite catalysts having varying pore sizes and acidities, which are synthesized by varying the aluminia-to-silica ratio may be used in the second reactor 234 as will be evident to a skilled artisan.

[0088] The temperature at which the second reactor 234 is operated is an important parameter in determining the selectivity of the reaction to higher molecular hydrocarbons, or to olefins.

[0089] Where a catalyst is selected to form higher molecular weight hydrocarbons in reactor 234, it is preferred to operate second reactor 234 at a temperature within the range of about 150° C. to 450° C. Temperatures above about 300° C. in the second reactor result in increased yields of light hydrocarbons, such as undesirable methane, whereas lower temperatures increase yields of heavier molecular weight hydro-
carbon products. At the low end of the temperature range, with methyl bromide reacting over ZSM-5 zeolite at temperatures as low as 150°C, significant methyl bromide conversion on the order of 20% is noted, with a high selectivity towards C4+ products. Notably, in the case of the alkyl bromide reaction over the preferred zeolite ZSM-5 catalyst, cyclization reactions also occur such that the C7+ fractions are composed primarily of substituted aromatics. At increasing temperatures approaching 300°C, methyl bromide conversion increases towards 90% or greater, however selectivity towards C4+ products decreases and selectivity towards lighter products, particularly undesirable methane, increases. Surprisingly, very little ethene or C2-C5 olefin components are formed. At temperatures approaching 450°C, almost complete conversion of methyl bromide to carbon occurs. In the optimum operating temperature range of between about 300°C and 400°C, as a byproduct of the reaction, a small amount of carbon will build up on the catalyst over time during operation, causing a decline in catalyst activity over a range of hours, up to hundreds of hours, depending on the reaction conditions and the composition of the feed gas. It is believed that higher reaction temperatures above about 400°C, associated with the formation of methane favor the thermal cracking of alkyl bromides and formation of carbon or coke and hence an increase in the rate of deactivation of the catalyst. Conversely, temperatures at the lower end of the range, particularly below about 300°C, may also contribute to coke due to a reduced rate of desorption of heavier products from the catalyst. Hence, operating temperatures within the range of about 250°C to about 500°C, but preferably in the range of about 300°C to about 450°C in the second reactor 234 balance increased selectivity of the desired olefins and C4+ products and lower rates of deactivation due to carbon formation, against higher conversion per pass, which minimizes the quantity of catalyst, recycle rates and equipment size required.

[0091] The catalyst may be periodically regenerated in situ by isolating reactor 234 from the normal process flow, purging with an inert gas via line 270 at a pressure in the range of about 1 bar to about 5 bars and maintained temperature in the range of about 400°C to about 650°C to remove unreacted material adsorbed on the catalyst insofar as is practical, and then subsequently oxidizing the deposited carbon to CO2 by addition of air or inert gas-diluted oxygen via line 270 to reactor 234 at a pressure in the range of about 1 bar to about 5 bars and an elevated temperature in the range of about 400°C to about 650°C. Carbon dioxide and residual air or inert gas are vented from reactor 234 via line 275 during the regeneration period.

[0092] The effluent which comprises hydrobromic acid and higher molecular weight hydrocarbons, olefins or mixtures thereof is withdrawn from the second reactor 234 via line 235 and cooled to a temperature in the range of about 100°C to about 600°C in exchanger 236. As illustrated in FIG. 4A, the cooled effluent is transported via lines 235 and 241 with valve 238 in the opened position and valves 239 and 243 in the closed position and introduced into a vessel or reactor 240 containing a bed 298 of a solid phase metal oxide. The metal of the metal oxide is selected from magnesium (Mg), calcium (Ca), vanadium (V), chromium (Cr), manganese (Mn), iron (Fe), cobalt (Co), nickel (Ni), copper (Cu), zinc (Zn), or tin (Sn). The metal is selected for the impact of its physical and thermodynamic properties relative to the desired temperature of operation, and also for potential environmental and health impacts and cost. Preferably, magnesium, copper and iron are employed as the metal, with magnesium being the most preferred. These metals have the property of not only forming oxides but bromide salts as well, with the reactions being reversible in a temperature range of less than about 500°C. The solid metal oxide is preferably immobilized on a suitable attrition-resistant support, for example a synthetic amorphous silica, such as Davicat Grade 57, manufactured by Davison Catalysts of Columbia, Md. Or more preferably, an alumina support with a specific surface area of about 50 to 200 m²/g. In reactor 240, hydrobromic acid is reacted with the metal oxide at temperatures below about 600°C and preferably between about 100°C to about 500°C in accordance with the following general formula wherein M represents the metal:

\[ 2\text{HBr} + M\text{O} \rightarrow M\text{Br}_2 + \text{H}_2\text{O} \]

The steam resulting from this reaction is transported together with olefins and/or the high molecular hydrocarbons in line 244, 218 and 216 via opened valve 219 to heat exchanger 220 wherein the mixture is cooled to a temperature in the range of about 0°C to about 70°C. This cooled mixture is forwarded to dehydrator 250 to remove substantially all water from the gas stream. The water is then removed from the dehydrator 250 via line 253. The dried gas stream containing olefins,
higher molecular weight hydrocarbons or mixtures thereof is further passed via line 251 to product recovery unit 252 to recover olefins, the C₃+ fraction, or mixtures thereof as a liquid product in line 254. Any conventional method of dehydration and liquids recovery such as solid-bed desiccant adsorption followed by, for example, refrigerated condensation, cryogenic expansion, or circulating absorption oil or other solvent, as used to process natural gas or refinery gas streams and recover olefinic hydrocarbons, as known to a skilled artisan, may be employed in the implementation of this invention. The residual vapor effluent from product recovery unit 252 is then split into a purge stream 257 that may be utilized as fuel for the process and a recycled residual vapor which is compressed via compressor 258. The recycled residual vapor is discharged from compressor 258 to split into two fractions. A first fraction that is equal to at least 1.5 times the feed gas volume is transported via line 262, combined with the liquid bromine and feed gas conveyed in line 225 and passed to heat exchanger 226 wherein the liquid bromine is vaporized and fed into first reactor 230 in a manner as described above. The second fraction which is drawn off line 262 via line 263 and is regulated by control valve 260, at a rate sufficient to dilute the alkyl bromide concentration to reactor 234 and absorb the heat of reaction such that reactor 234 is maintained at the selected operating temperature, preferably in the range of about 300°C to about 450°C in order to maximize conversion vs. selectivity and to minimize the rate of catalyst deactivation due to the deposition of carbon. Thus, the dilution provided by the recycled vapor effluent permits selectivity of bromination in the first reactor 230 to be controlled in addition to moderating the temperature in second reactor 234.

Oxygen, oxygen enriched air or air 210 is delivered via blowor or compressor 213 at a pressure in the range of about ambient to about 10 bar to bromine via line 214, line 215 and valve 249 through heat exchanger 215, wherein oxygen, oxygen enriched air or air is preheated to a temperature in the range of about 100°C to about 500°C to a second vessel or reactor 246 containing a bed 299 of a solid phase metal bromide. Oxygen reacts with the metal bromide in accordance with the following general reaction wherein M represents the metal:

\[ \text{MBr}_3 + 1/2 \text{O}_2 \rightarrow \text{MO}_2 \text{Br}_2 \]

In this manner, a dry, substantially HBr free bromine vapor is produced thereby eliminating the need for subsequent separation of water or hydrobromic acid from the liquid bromine. Reactor 246 is operated below 600°C, and more preferably between about 300°C to about 500°C. The resultant bromine vapor is transported from reactor 246 via line 247, valve 248 and line 242 to heat exchanger or condenser 221 wherein the bromine is condensed into a liquid. The liquid bromine is transported via line 242 to separator 222 wherein liquid bromine is removed via line 225 and transported via line 225 to heat exchanger 226 and first reactor 230 by any suitable means, such as by pump 224. The residual air or unreacted oxygen is transported from separator 222 via line 227 to a bromine scrubbing unit 223, such as venturi scrubbing system containing a suitable solvent, or suitable solid adsorbent medium, as selected by a skilled artisan, wherein the remaining bromine is captured. The captured bromine is desorbed from the scrubbing solvent or adsorbent by heating or other suitable means and the thus recovered bromine transported via line 212 to line 225. The scrubbed air or oxygen is vented via line 229. In this manner, nitrogen and any other substantially non-reactive components are removed from the system of the present invention and thereby not permitted to enter the hydrocarbon-containing portion of the process; also loss of bromine to the surrounding environment is avoided.

One advantage of removing the HBr by chemical reaction in accordance with this embodiment, rather than by simple physical solubility, is the substantially complete scavenging of the HBr to low levels at higher process temperatures. Another distinct advantage is the elimination of water from the bromine removed thereby eliminating the need for separation of bromine and water phases and for stripping of residual bromine from the water phase.

Reactors 240 and 246 may be operated in a cyclic fashion. As illustrated in FIG. 4A, valves 238 and 219 are operated in the open mode to permit hydrobromic acid to be removed from the effluent that is withdrawn from the second reactor 234, while valves 248 and 249 are operated in the open mode to permit air, oxygen enriched air or oxygen to flow through reactor 246 to oxidize the solid metal bromide contained therein. Once significant conversion of the metal oxide and metal bromide in reactors 240 and 246, respectively, has occurred, these valves are closed. At this point, bed 299 in reactor 246 is a bed of substantially solid metal bromide, while bed 298 in reactor 240 is substantially solid metal oxide. As illustrated in FIG. 5A, valves 245 and 243 are then opened to permit oxygen, oxygen enriched air or air to flow through reactor 240 to oxidize the solid metal bromide contained therein, while valves 239 and 217 are opened to permit effluent which comprises olefins, the higher molecular weight hydrocarbons and/or hydrobromic acid that is withdrawn from the second reactor 234 to be introduced into reactor 246. The reactors are operated in this manner until significant conversion of the metal oxide and metal bromide in reactors 246 and 240, respectively, has occurred and then the reactors are cycled back to the flow schematic illustrated in FIG. 4A by opening and closing valves as previously discussed.

When oxygen is utilized as the oxidizing gas transported in via line 210 to the reactor being used to oxidize the solid metal bromide contained therein, the embodiment of the process of the present invention illustrated in FIGS. 4A and 5A can be modified such that the bromine vapor produced from either reactor 246 (FIG. 4B) or 240 (FIG. 5B) is transported via lines 242 and 225 directly to first reactor 230. Since oxygen is reactive and will not build up in the system, the need to condense the bromine vapor to a liquid to remove unreactive components, such as nitrogen, is obviated. Compressor 213 is not illustrated in FIGS. 4B and 5B as substantially all commercial sources of oxygen, such as a commercial air separator unit, will provide oxygen to line 210 at the required pressure. If not, a compressor 213 could be utilized to achieve such pressure as will be evident to a skilled artisan.

In the embodiment of the present invention illustrated in FIG. 6A, the beds of solid metal oxide particles and solid metal bromide particles contained in reactors 240 and 246, respectively, are fluidized and are connected in the manner described below to provide for continuous operation of the beds without the need to provide for equipment, such as valves, to change flow direction to and from each reactor. In accordance with this embodiment, the effluent which comprises olefins, the higher molecular weight hydrocarbons and/or hydrobromic acid is withdrawn from the second reactor 234 via line 235, cooled to a temperature in the range of about 100°C to about 500°C in exchanger 236, and introduced...
into the bottom of reactor 240 which contains a bed 298 of solid metal oxide particles. The flow of this introduced fluid should induce the particles in bed 298 to move upwardly within reactor 240 as the hydrobromic acid is reacted with the metal oxide in the manner as described above with respect to FIG. 4A. At or near the top of the bed 298, the particles which contain substantially solid metal bromide on the attrition-resistant support due to the substantially complete reaction of the solid metal oxide with hydrobromic acid in reactor 240 are withdrawn via a weir or cyclone or other conventional means of solid/gas separation, flow by gravity down line 259 and are introduced at or near the bottom of the bed 299 of solid metal bromide particles in reactor 246. In the embodiment illustrated in FIG. 6A, oxygen, oxygen enriched air or air 210 is delivered via blower or compressor 213 at a pressure in the range of about ambient to about 10 bar, transported via line 214 through heat exchanger 215, wherein the oxygen, oxygen enriched air or air is preheated to a temperature in the range of about 100°C to about 500°C and introduced into second vessel or reactor 246 below bed 299 of a solid phase metal bromide. Oxygen reacts with the metal bromide in the manner described above with respect to FIG. 4A to produce a dry, substantially HBr free bromine vapor. The flow of this introduced gas should induce the particles in bed 299 to flow upwardly within reactor 246 as oxygen is reacted with the metal bromide. At or near the top of the bed 298, the particles which contain substantially solid metal oxide on the attrition-resistant support due to the substantially complete reaction of the solid metal oxide with oxygen in reactor 246 are withdrawn via a weir or cyclone or other conventional means of solid/gas separation, flow by gravity down line 264 and are introduced at or near the bottom of the bed 298 of solid metal oxide particles in reactor 240. In this manner, reactors 240 and 246 may be operated continuously without changing the parameters of operation.

In the embodiment illustrated in FIG. 6B, oxygen is utilized as the oxidizing gas and is transported in via line 210 to reactor 246. Accordingly, the embodiment of the process of the present invention illustrated in FIG. 6A is modified such that the bromine vapor produced from reactor 246 is transported via lines 242 and 225 directly to first reactor 230. Since oxygen is reactive and will not build up in the system, it is believed that the need to condense the bromine vapor to a liquid to remove unreactive components, such as nitrogen, should be obviated. Compressor 213 is not illustrated in FIG. 6B as substantially all commercial sources of oxygen, such as a commercial air separator unit, will provide oxygen to line 210 at the required pressure. If not, a compressor 213 could be utilized to achieve such pressure as will be evident to a skilled artisan.

In accordance with another embodiment of the process of the present invention that is illustrated in FIG. 7, the alkyl bromination and alkyl bromide conversion stages are operated in a substantially similar manner to those corresponding stages described in detail with respect to FIG. 4A, except as discussed below. Residual air or oxygen and bromine vapor emanating from reactor 246 is transported via line 247, valve 248 and line 242 and valve 300 to heat exchanger or condenser 221 wherein the bromine-containing gas is cooled to a temperature in the range of about 30°C to about 300°C. The bromine-containing gas is then transported via line 242 to vessel or reactor 320 containing a bed 322 of a solid phase metal bromide in a reduced valence state. The metal of the metal bromide in a reduced valence state is selected from copper (Cu), iron (Fe), or molybdenum (Mo). The metal is selected for the impact of its physical and thermodynamic properties relative to the desired temperature of operation, and also for potential environmental and health impacts and cost. Preferably, copper or iron are employed as the metal, with copper being the most preferred. The solid metal bromide is preferably immobilized on a suitable attrition-resistant support, for example a synthetic amorphous silica, such as Davicat Grade 57, manufactured by Davison Catalysts of Columbia, Md. More preferably the metal is deposited in oxide form in a range of about 10 to 20 wt % on an alumina support with a specific surface area in the range of about 50 to 200 m²/g. In reactor 320, bromine vapor is reacted with the solid phase metal bromide, preferably retained on a suitable attrition-resistant support at temperatures below about 300°C. and preferably between about 200°C to about 200°C. In accordance with the following general formula wherein $M^+$ represents the metal:

$$2M^+Br_{2x+1} \rightarrow 2M^+Br_x + Br_2$$

In this manner, bromine is stored as a second metal bromide, i.e. $2M^+Br_{x+1}$, in reactor 320 while the resultant vapor containing residual air or oxygen is vented from reactor 320 via line 324, valve 326 and line 318.

The gas stream containing lower molecular weight alkanes, comprised of mixture of a feed gas (line 211) and a recycled gas stream, is transported or conveyed via line 262, heat exchanger 352, wherein the gas stream is preheated to a temperature in the range of about 150°C to about 600°C, valve 304 and line 302 to a second vessel or reactor 310 containing a bed 312 of a solid phase metal bromide in an oxidized valence state. The metal of the metal bromide in an oxidized valence state is selected from copper (Cu), iron (Fe), or molybdenum (Mo). The metal is selected for the impact of its physical and thermodynamic properties relative to the desired temperature of operation, and also for potential environmental and health impacts and cost. Preferably, copper or iron are employed as the metal, with copper being the most preferred. The solid metal bromide in an oxidized state is preferably immobilized on a suitable attrition-resistant support, for example a synthetic amorphous silica such as Davicat Grade 57, manufactured by Davison Catalysts of Columbia, Md. More preferably the metal is deposited in an oxide state in a range of 10 to 20 wt % supported on an alumina support with a specific surface area of about 50 to 200 m²/g. The temperature of the gas stream is from about 150°C to about 600°C, and preferably from about 200°C to about 450°C. In second reactor 310, the temperature of the gas stream thermally decomposes the solid phase metal bromide in an oxidized valence state to yield elemental bromine vapor and a solid metal bromide in a reduced state in accordance with the following general formula wherein $M^+$ represents the metal:

$$2M^+Br_{x+1} \rightarrow 2M^+Br_x + Br_2$$

The resultant bromine vapor is transported with the gas stream containing lower molecular weight alkanes via lines 314, 315, valve 317, line 330, heat exchanger 226 prior to being introduced into alkyl bromination reactor 230.

Reactors 310 and 320 may be operated in a cyclic fashion. As illustrated in FIG. 7, valve 304 is operated in the open mode to permit the gas stream containing lower molecular weight alkanes to be transported to the second reactor 310, while valve 317 is operated in the open mode to permit this gas stream with bromine vapor that is generated in reactor 310
to be transported to alkyl bromination reactor 230. Likewise, valve 306 is operated in the open mode to permit bromine vapor from reactor 246 to be transported to reactor 320, while valve 326 is operated in the open mode to permit residual air or oxygen to be vented from reactor 320. Once significant conversion of the reduced metal bromide and oxidized metal bromide in reactors 320 and 310, respectively, to the corresponding oxidized and reduced states has occurred, these valves are closed as indicated in FIG. 8. At this point, bed 322 in reactor 320 is a bed of substantially metal bromide in an oxidized state, while bed 312 in reactor 310 is substantially metal bromide in a reduced state. As illustrated in FIG. 8, valves 304, 317, 306 and 326 are closed, and then valves 308 and 332 are opened to permit the gas stream containing lower molecular weight alkanes to be transported or conveyed via lines 262, heat exchanger 352, wherein the gas stream is heated to a range of about 150° C. to about 600° C. valve 308 and line, 309 to reactor 320 to thermally decompose the solid phase metal bromide in an oxidized valence state to yield elemental bromine vapor and a solid metal bromide in a reduced state. Valve 332 is also opened to permit the resultant bromine vapor to be transported with the gas stream containing lower molecular weight alkanes via lines 324 and 330 and heat exchanger 226 prior to being introduced into alkyl bromination reactor 230. In addition, valve 300 is opened to permit bromine vapor emanating from reactor 246 to be transported via line 242 through exchanger 221 into reactor 310 wherein the solid phase metal bromide in a reduced valence state react with bromine to effectively store bromine as a metal bromide. In addition, valve 316 is opened to permit the resulting gas, which is substantially devoid of bromine to be vented via lines 314 and 318. The reactors are operated in this manner until significant conversion of the beds of reduced metal bromide and oxidized metal bromide in reactors 310 and 320, respectively, to the corresponding oxidized and reduced states has occurred and then the reactors are cycled back to the flow schematic illustrated in FIG. 7 by opening and closing valves as previously discussed.

[0102] In the embodiment of the present invention illustrated in FIG. 9, the beds 312 and 322 contained in reactors 310 and 320, respectively, are fluidized and are connected in the manner described below to provide for continuous operation of the beds without the need to provide for equipment, such as valves, to change flow direction to and from each reactor. In accordance with this embodiment, the bromine-containing gas withdrawn from the reactor 246 via line 242 is cooled to a temperature in the range of about 30° C. to about 300° C. in exchangers 370 and 372, and introduced into the bottom of reactor 320 which contains a moving solid bed 322 in a fluidized state. The flow of this introduced fluid should induce the particles in bed 322 to flow upwardly within reactor 320 as the bromine vapor is reacted with the reduced metal bromide entering the bottom of bed 322 in the manner as described above with respect to FIG. 7. At or near the top of the bed 322, the particles which contain substantially oxidized metal bromide on the attrition-resistant support due to the substantially complete reaction of the reduced metal bromide with bromine vapor in reactor 320 are withdrawn via a weir, cyclone or other conventional means of solid/gas separation, flow by gravity down line 359 and are introduced at or near the bottom of the bed 312 in reactor 310. In the embodiment illustrated in FIG. 9, the gas stream containing lower molecular weight alkanes, comprised of mixture of a feed gas (line 211) and a recycled gas stream, is transported or conveyed via line 262 and heat exchanger 352 wherein the gas stream is heated to a range of about 150° C. to about 600° C. and introduced into reactor 310. The heated gas stream thermally decomposes the solid phase metal bromide in an oxidized valence state present entering at or near the bottom of bed 312 to yield elemental bromine vapor and a solid metal bromide in a reduced state. The flow of this introduced gas should cause the particles in bed 312 to flow upwardly within reactor 310 as the oxidized metal bromide is thermally decomposed. At or near the top of the bed 312, the particles which contain substantially reduced solid metal bromide on the attrition-resistant support due to the substantially complete thermal decomposition in reactor 310 are withdrawn via a weir or cyclone or other conventional means of gas/solid separation and flow by gravity down line 364 and introduced at or near the bottom of the bed 322 of particles in reactor 310. In this manner, reactors 310 and 320 may be operated continuously with changing the parameters of operation.

[0103] It is believed that the process of the present invention should be less expensive than conventional process since it operates at low pressures in the range of about 1 bar to about 30 bar and at relatively low temperatures in the range of about 20° C. to about 600° C. for the gas phase, and preferably about 20° C. to about 180° C. for the liquid phase. It is believed that these operating conditions should permit the use of less expensive equipment of relatively simple design that are constructed from readily available metal alloys or glass-lined equipment for the gas phase and polymer-lined or glass-lined vessels, piping and pumps for the liquid phase. It is believed that the process of the present invention also should be more efficient because less energy should be required for operation and the production of excessive carbon dioxide as an unwanted byproduct is minimized. The process is capable of directly producing a mixed hydrocarbon product containing various molecular-weight components in the liquefied petroleum gas (LPG), olefin, and motor gasoline fuels range that have substantial aromatic content thereby significantly increasing the octane value of the gasoline-range fuel components.

[0104] The following examples demonstrate the practice and utility of the present invention, but are not to be construed as limiting the scope thereof.

EXAMPLE 1

[0105] Various mixtures of dry bromine and methane are reacted homogeneously at temperatures in the range of 459° C. to 491° C. at a Gas Hourly Space Velocity (GHSV) which is the gas flow rate in standard liters per hour divided by the gross reactor catalyst-bed volume, including catalyst-bed porosity, in liters) of approximately 7200 hr⁻¹. The results of this example indicate that for molar ratios of methane to bromine greater than 4.5:1 selectivity to methyl bromide is in the range of 90 to 95%, with near-complete conversion of bromine.

EXAMPLE 2

[0106] FIG. 13 and FIG. 14 illustrate two exemplary PONA analyses of two C₆+ liquid product samples that are recovered during two test runs with methyl bromide and methane react-
ing over ZSM-5 zeolite catalyst. These analyses show the substantially aromatic content of the C6+ fractions produced.

EXAMPLE 3

[0107] Methyl bromide is reacted over a ZSM-5 zeolite catalyst at a Gas Hourly Space Velocity (GHSV) of approximately 94 hr⁻¹ over a range of temperatures from about 100°C to about 460°C at approximately 2 bar pressure. As illustrated in FIG. 10, which is a graph of methyl bromide conversion and product selectivity for the oligomerization reaction as a function of temperature, methyl bromide conversion increases rapidly in the range of about 200°C to about 350°C. Lower temperatures in the range of about 100°C to about 250°C favor selectivity towards higher molecular weight products however conversion is lower. Higher temperatures in the range of about 250°C to about 350°C show higher conversions in the range of 50% to near 100%, however increasing selectivity to lower molecular weight products, in particular undesirable methane is observed. At higher temperatures above 350°C selectivity to methane rapidly increases. At about 450°C, almost complete conversion to methane occurs.

EXAMPLE 4

[0108] Methyl bromide, hydrogen bromide and methane are reacted over a ZSM-5 zeolite catalyst at approximately 2 bar pressure at about 250°C and also at about 260°C at a GHSV of approximately 76 hr⁻¹. Comparison tests utilizing a mixture of only methyl bromide and methane without hydrogen bromide over the same ZSM-5 catalyst at approximately the same pressure at about 250°C and at about 260°C at a GHSV of approximately 73 hr⁻¹ were also run. FIG. 11, which is a graph that illustrates the comparative conversions and selectivities of several example test runs, shows only a very minor effect due to the presence of HBr on product selectivities. Because hydrobromic acid has only a minor effect on conversion and selectivity, it is not necessary to remove the hydrobromic acid generated in the bromination reaction step prior to the conversion reaction of the alkyl bromides, in which additional hydrobromic acid is formed in any case. Thus, the process can be substantially simplified.

EXAMPLE 5

[0109] Methyl bromide is reacted over a ZSM-5 zeolite catalyst at 230°C. Dibromomethane is added to the reactor. FIG. 12, which is a graph of product selectivity, indicates that reaction of methyl bromide and dibromomethane results in a shift in selectivity towards C4+ products versus methyl bromide alone. Thus, these results demonstrate that dibromomethane is also reactive and therefore very high selectivity to bromomethane in the bromination step is not required in the process of the present invention. It has been observed, however, that the presence of dibromomethane increases the rate of catalyst deactivation, requiring a higher operating temperature to optimize the tradeoff between selectivity and deactivation rate, as compared to pure methyl bromide.

EXAMPLE 6

[0110] A mixture of 12.1 mol % methyl bromide and 2.8 mol % propyl bromide in methane are reacted over a ZSM-5 zeolite catalyst at 295°C and a GHSV of approximately 260 hr⁻¹. A methyl bromide conversion of approximately 86% and a propyl bromide conversion of approximately 98% is observed.

[0111] Thus, in accordance with all embodiments of the present invention set forth above, the metal bromide/metal hydroxide, metal oxy-bromide or metal oxide operates in a catalytic cycle allowing bromine to be easily recycled within the process. The metal bromide is readily oxidized by oxygen, oxygen enriched air or air either in the aqueous phase or the vapor phase at temperatures in the range of about 100°C to about 600°C and most preferably in the range of about 120°C to about 180°C to yield elemental bromine vapor and metal hydroxide, metal oxy-bromide or metal oxide. Operation at temperatures below about 180°C is advantageous, thereby allowing the use of low-cost corrosion-resistant fluoropolymer-lined equipment. Hydrobromic acid is neutralized by reaction with the metal hydroxide or metal oxide yielding steam and the metal bromide.

[0112] While the foregoing preferred embodiments of the invention have been described and shown, it is understood that the alternatives and modifications, such as those suggested and others, may be made thereto and fall within the scope of the invention.

1 claim:
1. A process comprising: separating hydrobromic acid from a gaseous stream comprising hydrobromic acid and hydrocarbons; converting said hydrobromic acid to at least bromine; and contacting said bromine with gaseous alkane to form bromination products comprising alkyl bromides.
2. The process of claim 1 wherein said step of separating said hydrobromic acid from said hydrocarbons comprises: contacting said gaseous stream with water.
3. The process of claim 2 wherein said step of contacting said gaseous stream with said water comprises: neutralizing said hydrobromic acid to form an aqueous solution comprising said water and a metal bromide salt, the metal of said metal bromide salt being selected from the group consisting of Cu, Zn, Fe, Co, Ni, Mn, Ca or Mg bromide.
4. The process of claim 3 wherein said step of converting comprises: oxidizing said aqueous solution containing said metal bromide salt to form at least said bromine and a reaction product selected from the group consisting of a metal hydroxide, a metal oxy-bromide species and combinations thereof; and separating said bromine from said reaction product.
5. The process of claim 4 wherein said water that contacts said gaseous stream comprises said reaction product.
6. The process of claim 2 wherein said hydrobromic acid dissolves into said water forming a hydrobromic acid solution, said process further comprising: vaporizing said hydrobromic acid solution; and reacting said vaporized hydrobromic acid solution with a metal oxide to form a reaction product comprising a metal bromide salt, the metal of said metal bromide salt being selected from the group of Cu, Zn, Fe, Co, Ni, Mn, Ca or Mg.
7. The process of claim 6 wherein said step of converting comprises: oxidizing said metal bromide salt to form oxidation products comprising said bromine and said metal oxide; and separating said bromine from said metal oxide.
8. The process of claim 6 wherein said metal bromide salt is contained on a porous support.
9. The process of claim 1 wherein said step of separating hydrobromic acid from hydrocarbons comprises reacting said hydrobromic acid with a metal oxide to form reaction products comprising a metal bromide and steam.
10. The process of claim 9 wherein the metal of said metal oxide is magnesium, calcium, vanadium, chromium, manganese, iron, cobalt, nickel, copper, zinc or tin.
11. The process of claim 10 wherein said metal oxide is supported on a solid carrier.
12. The process of claim 11 wherein said metal oxide is contained in a bed in a vessel.
13. The process of claim 9 wherein said step of converting comprises:
   reacting said metal bromide with an oxygen containing gas to obtain reaction products comprising said metal oxide and said bromine.
14. The process of claim 1 wherein said bromine from the reaction of said metal bromide with said oxygen containing gas is recycled to said step of contacting said gaseous alkanes to form alkyl bromides.
15. The process of claim 1 further comprising:
   reacting said alkyl bromides in the presence of said hydrobromic acid and a synthetic crystalline alumino-silicate catalyst to form reaction products comprising said hydrocarbons.
16. A process comprising:
   contacting a gaseous stream comprising hydrobromic acid and hydrocarbons with a aqueous solution comprising a base selected from the group consisting of a metal hydroxide, a metal oxy-bromide species, and combinations thereof such that the hydrobromic acid is neutralized to form a metal bromide salt in the aqueous solution;
   oxidizing said aqueous solution containing said metal bromide salt to form oxidation products comprising bromine and said base;
   separating said bromine from said aqueous solution comprising said base; and
   contacting said bromine with gaseous alkanes to form alkyl bromides.
17. The process of claim 16 further comprising:
   reacting said alkyl bromides in the presence of said hydrobromic acid and a synthetic crystalline alumino-silicate catalyst to form said hydrocarbons.
18. A process comprising:
   contacting a gaseous stream comprising hydrobromic acid and hydrocarbons with water, wherein said hydrobromic acid dissolves in said water to form an aqueous solution comprising said water and said hydrobromic acid;
   neutralizing said hydrobromic acid to form a metal bromide salt;
   oxidizing said metal bromide salt to form an oxidation product comprising bromine; and
   contacting said bromine with gaseous alkanes to form bromination products comprising alkyl bromides.
19. The process of claim 18 further comprising:
   reacting said alkyl bromides in the presence of said hydrobromic acid and a synthetic crystalline alumino-silicate catalyst to form reaction products comprising said hydrocarbons.
20. A process comprising:
   reacting hydrobromic acid with a metal oxide to form reaction products comprising a metal bromide and steam, wherein said hydrobromic acid is contained in a gaseous stream comprising said hydrobromic acid and hydrocarbons;
   reacting said metal bromide with a gas comprising oxygen to form reaction products comprising bromine and said metal oxide; and
   contacting said bromine with gaseous alkanes to form bromination products comprising alkyl bromides.
21. The process of claim 19 further comprising:
   reacting said alkyl bromides in the presence of said hydrobromic acid and a synthetic crystalline alumino-silicate catalyst to form reaction products comprising said hydrocarbons.
