Title: REBOUND-DAMPENING AND ENERGY ABSORBING HEADGEAR LINERS WITH POSITIONING FEATURE

Abstract: A liner adapted to be interposed between the interior surface of a protective headgear and a wearer's head includes a plurality of networked fluid cells adapted to distribute and dissipate an impact force to the liner, and/or headgear with which the liner is used, across a larger area of the wearer's head as compared with the impact location, and also to dampen the tendency of the wearer's head from rebounding back from the impact location by transferring fluid through the network from fluid cells at the impact location to those in an opposed region. Discrete fluid cells Interspersed among the networked fluid cells maintain the liner and/or the headgear in a predetermined orientation on the wearer's head. Fluid flow within the liner may be restricted or directed by configuring the fluid passageways. A liner may further include means for moving fluid into or out of the fluid cells.
REBOUND-DAMPENING AND ENERGY ABSORBING HEADGEAR LINERS WITH POSITIONING FEATURE

Related Applications

[0001] This application claims the benefit of U.S. Provisional Patent Application, Serial No. 61325707, filed on April 19, 2010, and of U.S. Nonprovisional Patent Application. Serial No. 13023440, filed on February 8, 2011. the entire disclosures of which is incorporated herein by reference for all purposes.

Technical Field

[0002] The disclosure relates to personal protective equipment, and in particular to fluid-containing liners adapted for use with a wide variety of designs of protective headgear.

Background

[0003] Liners are used in conjunction with protective headgear, such as helmets designed for use with various sports and other outdoor activities, primarily to be interposed generally between the interior surface of the headgear and a wearer's head. Most liners are configured for wearer comfort, but some may also or alternatively serve a protective function, such as by including cushions, pads, or other materials to soften or prevent the impact of the wearer's head against the interior of the headgear, such as when the headgear exterior is subject to an impact or other force.

[0004] Many head or brain injuries incurred while wearing protective headgear, however, are caused or exacerbated by what may be referred to as a "rebound effect": in the event of a sudden force delivered to the headgear, the wearer's head will tend to initially lurch toward the point of impact and then recoil or rebound from the headgear interior (or cushioning system) away from the point of impact, in certain instances, it is the energy associated with the rebound effect, sometimes regardless of whether the initial impact is cushioned, that is primarily responsible for the severity of head injuries sustained while wearing headgear.

[0005] Headgear liners or protective systems that include a plurality of fluid-filled cushions or chambers may be found, for example, in US5720051, US4566137, US4375108, US43707S4, US4354284, US7774866. and US428761. In some of these disclosures, the fluid-filled cushions are joined together to allow the flow of fluid from one cushion to an adjoining one, such as to absorb and/or distribute the energy from an impact to the headgear over a large area of the wearer's head. However.
none address the rebound effect as explained above. Moreover, although the headgear with which some
of these liners are used may employ a chinstrap or other device b orient the headgear on a wearer's
head, none of the liners themselves include such a feature. The complete disclosures of the
aforementioned publications are hereby incorporated by reference for all purposes.

Summary

[0006] Illustrative embodiments of liners adapted for use with headgear, generally in a manner in
which the liner is interposed between the interior surface of the headgear and a wearer's head received
therein, include a plurality of fluid cells formed from a flexible, fluid-impermeable material, each fluid cell
adapted b receive and store fluid, such as air, the plurality of fluid cells further including a group of
networked fluid cells which each communicate with at least one other via a fluid passageway, and a
group of discrete, non-networked fluid cells interspersed among the networked fluid cells. In such
embodiments, when the fluid pressure in the fluid cells is at least a predetermined minimum value, such
as equivalent to atmospheric pressure, the discrete fluid cells are configured b position the headgear on
a wearer's head and to maintain an initial spaced relationship between the user's head and the interior
surface of the headgear, and the fluid passageways are configured to equalize fluid pressure across the
networked fluid cells of the group responsive to a force delivered thereto, such as to distribute and
thereby dissipate such a force over a larger region of the wearer's head than that corresponding to the
initial point or location of impact In such embodiments, the networked, or interconnected, fluid cells are
adapted b dampen the tendency of the wearer's head to rebound from an impact location by laterally
distributing fluid from the networked cells at or near the impact location (or at or near the portion of the
liner corresponding b the impact location on the headgear) to other networked fluid cells that are
disposed at one or more locations on the liner that are generally opposed b the impact location.

[0007] In some embodiments, the liner is formed from two or more superimposed plies of a
flexible, fluid-impermeable material, with the adjacent surfaces thereof being sealed at regions internally
of their peripheries b form the fluid cells and passageways. In some embodiments, the fluid cells are
arranged in a single layer. In such embodiments, each of the discrete fluid cells may be laterally
encompassed by at least one networked cell, or a combination of at least two networked cells and the
fluid passageways) interconnecting them. In some embodiments, the cross-sectional height of the
discrete fluid cells, as defined by the extent to which the discrete fluid cells protrude into the concavity formed by the liner, is greater than that of the networked fluid cells, such as b maintain a spaced relationship between the wearer's head and the headgear, or even between the wearer's head and the networked cells.

[0008] In some embodiments, some of the fluid cells may be configured b release fluid responsive to a predetermined threshold fluid pressure, such as by rupturing, by transferring fluid via a passageway or valve configured b only allow fluid transfer once the threshold fluid pressure is reached, and so forth. Some embodiments may include reserve fluid cells that are initially empty, but are configured b accept fluid transferred from other fluid cells responsive to the threshold fluid pressure.

[0009] In some embodiments, some of the fluid passageways may be provided with means to restrict fluid flow b a predetermined flow rate, or b establish preferential fluid transfer between certain networked cells, such as cells in opposed regions of the liner, for example b facilitate the rebound-dampening effect of the liner.

[0010] The fluid cells in some liners may be completely sealed from the ambient atmosphere, whereas some liner embodiments may be valved, such as by including one or more valve members adapted to allow fluid to flow into or out of one or more fluid cells. Such embodiments may further include pressurizing means for selective fluid movement into or out of the liner, such as by means of an integral or removably attachable pump.

[0011] In some embodiments, a liner is attached to the interior surface of a helmet having an impact-resistant exterior surface and adapted b be disposed between the interior surface and a wearer's head. In such embodiments, the liner may be removably positionable within the helmet via a plurality of fasteners, which may optionally be arranged in a configuration defining a predetermined orientation for positioning the liner relative to the helmet.

[0012] The concepts and components listed above are clarified with reference to the accompanying drawings and detailed description below.
Brief Description of the Drawings

[0013] FIG. 1 shows a side view of an illustrative embodiment of a headgear liner constructed in accordance with the present disclosure, partially cut away to show the interior surface and a cross-section thereof.

[0014] FIG. 2 shows a detail view of a portion of the fluid cell pattern on the interior surface of the headgear liner of FIG. 1.

[0015] FIG. 3 shows a detail view of another configuration of a fluid cell pattern of another illustrative embodiment of a headgear liner constructed in accordance with the present disclosure.

[0016] FIG. 4 shows a cross-sectional view of the liner of FIG. 1 incorporated into a helmet that is worn by a user.

[0017] FIG. 5 shows a cross-sectional view similar to that shown in FIG. 4, but in which the user's head has moved forward inside the helmet, such as in response to an impact force delivered to the front exterior surface thereof.

[0018] FIG. 6 shows a detail view of a configuration of a fluid cell pattern of another illustrative embodiment of a headgear liner constructed in accordance with the present disclosure, in which some of the fluid passageways are adapted to provide a preferential fluid flow pathway.

[0019] FIG. 7 shows a detail view of a configuration of a fluid cell pattern of another illustrative embodiment of a headgear liner constructed in accordance with the present disclosure, in which some of the fluid passageways include fluid restricting means.

[0020] FIG. 8 shows a three-dimensional view of an illustrative embodiment of a headgear liner constructed in accordance with the present disclosure, in which the liner is provided with pressurizing means.

Detailed Description

[0021] The protective liner of the present disclosure may find utility in several areas and design emphasis may shift depending on the application. For example, the liner is generally adapted for use with a protective headgear, such as a helmet, to be interposed between the interior surface of the headgear and a wearer's head received therein. In such embodiments, the liner may take a form appropriate to the interior configuration of the headgear, such as to provide coverage of the areas and/or portion of the
wearer’s head that the headgear covers or protects. Liners constructed in accordance with this disclosure may, in some embodiments, be suitable for use with other pieces or types of personal protective gear, such as those used in sports or other activities to protect other parts of the wearer's body. Therefore, it is intended that although the illustrative embodiments of a liner described herein may be for use with a specific type of protective helmet or other headgear used in connection with a particular activity, the present invention has application in other areas and may be adapted to such applications without departing from the scope of this disclosure.

[0022] Referring initially to FIG. 1, an illustrative embodiment of a liner for protective headgear constructed in accordance with the present disclosure is indicated generally at 10, and is shown to comprise a plurality of fluid cells 20 that are each adapted to receive and store a fluid, such as air, therein, and also a plurality of fluid passageways 22 that join some of the cells 20. The cells 20 and passageways 22 are at least partially formed from a flexible, fluid-impermeable material and are shown to be arranged in a single layer generally defining a shape having a concavity suitable to receive at least a portion of a wearer's head.

[0023] In particular, the cells 20 and passageways 22 of the illustrative liner 10 are formed from two superimposed plies 24, 26 of such a material, with the adjacent surfaces thereof sealed at regions internally of their peripheries to form the fluid cells and passageways. Although other configurations having two or more plies are possible, in the liner 10, the "inner" ply 24 forms the interior surface of the liner 10 which forms the concavity, and includes the fluid cells 20 and passageways 22, which protrude or project generally into the concavity. The "outer" ply 26 forms a generally smooth exterior surface of the liner 10.

[0024] As is evident from the shape and context, the liner 10 is configured for use with protective headgear, such as any of various types of helmets suitable for a range of sports and other activities, including football helmets, baseball helmets, motorcycle or motocross helmets, bicycle helmets, skiing and snowboarding helmets, military helmets, and so forth. Liner 10 may be incorporated into a helmet or other headgear, generally to be interposed between the wearer's head and the helmet's interior. As such, either or both of the exterior and interior surfaces of the liner may be provided with additional components or features as appropriate to the application. For example, the liner in some embodiments may be
removably positionable within a helmet or permanently affixed thereto, such as via one or more fastening systems that secure the liner directly to the interior surface of the helmet and/or to a secondary cushioning system on the helmet interior, such as hook-and-loop fasteners, adhesives, snaps, and so forth. Although the liner may be worn with the interior surface (or portions thereof) directly contacting the wearer’s head, the interior surface of the liner may optionally be provided with a cover or fabric liner, for example for user comfort b absorb perspiration, b prevent slipping, and so forth.

[0025] The sheet material may be any suitable material having flexibility and fluid-impermeability. In the illustrative liner 10, the material is a plastic, specifically polyethylene. Polyethylene and other plastics typically retain their flexible and impermeable properties through a range of material thickness, making them ideal for production processes that may stretch or otherwise thin the material relative to its starting thickness. For example, a 15-mil sheet of polyethylene that was used to form a prototype liner, having a fluid cell configuration similar to that shown in FIG. 1, thinned to approximately 6 mils through the production process used b form the liner. However, a wide variety of sheet materials, or combinations of two or more materials, may be used, as suitable b the application, production method, and so forth. The selection of the material (and characteristics of the chosen material, such as thickness) may optionally depend, b some extent, on the fluid (or fluids) used with the fluid cells of the liner. In the illustrative embodiments discussed and shown herein, the fluid is ambient or pressurized air, but different gases or gas mixtures, or liquids, or other fluid mixtures, may be used. The material (or materials) may also be selected based on the material's yield strength, the production process, and so forth. For an example of the former, in some embodiments, the material and/or its characteristics (such as thickness) may be selected in order b tear or otherwise fail upon being subjected b a predetermined fluid pressure or other force, such as may result from an impact or collision, in particular a catastrophic impact or collision.

[0026] As evident from FIG. 1, the plurality of fluid cells 20 is shown b include two types: those that are interconnected by fluid passageways 22, and those that are not. In other words, some of the fluid cells 20 are networked and form one or more groups of networked fluid cells, whereas some of the fluid cells 20 are discrete, or separate from and unconnected b other fluid eels. As such, celis of the former type are referred b herein as networked fluid cells (or networked cells) 30, and the latter type as discrete
fluid cells (or discrete cells) 32. As explained in greater detail below, when the fluid cells are at least partially filled with fluid, or in other words when the fluid pressure in the fluid cells is at least a predetermined minimum value, the discrete fluid cells 32 function to properly position and/or orient the headgear on the wearer's head, and the fluid passageways 22 equalize and transfer the fluid pressure across the networked fluid cells 30 of a group responsive to a force delivered thereto, such as may result from an impact to the exterior surface of the headgear with which the liner is used. In the prototype liner mentioned above, the predetermined minimum value of the air pressure in both the networked and the discrete fluid cells is substantially equivalent to atmospheric pressure.

[0027] For simplicity, the networked fluid cells 30 of the illustrative liner 10 are shown to form one group of networked cells; in other words, each of the networked fluid cells 30 of liner 10 is interconnected, via one or more intermediate fluid passageways 22 (and possibly via one or more intermediate networked cells), each other networked cell of the liner. However, other embodiments may include two or more separate groups of networked cells.

[0028] The discrete fluid cells 32 are interspersed among the networked fluid cells 30. In the illustrative embodiment in which the fluid cells 20 of the liner 10 are arranged in a single layer, "interspersed" indicates that each discrete fluid cell 32 is laterally encompassed by at least one networked fluid cell or by a combination of two (or more) networked fluid cells and the one (or more) fluid passageways connecting them, as is perhaps best illustrated in FIG. 2, which shows a detail view of some of the fluid cells 20 formed by the inner ply 24 of the liner 10.

[0029] In the illustrative liner of FIGS. 1 and 2, all of the fluid cells 20 (both the networked cells 30 and the discrete cells 32) are shown to have a substantially constant, substantially round cross-section as they protrude inward; in other words, the fluid cells are substantially cylindrical in shape. Further, the networked and discrete cells are all shown to be substantially the same size as others of the same type, with the diameter of the networked cells greater than that of the discrete cells. In particular, in an illustrative prototype example having a fluid cell configuration similar to that shown in FIGS. 1 and 2, the networked fluid cells have a diameter of approximately 30 mm. and the discrete cells have a diameter of approximately 12 mm.
[0030] Of course, the three-dimensional shape of the fluid cells may be considered to be somewhat of a function of whether the cell contains any fluid, and/or the fluid pressure therein. Although not required by all embodiments, in the illustrative embodiments shown and discussed herein it is assumed that the fluid cells each contain air that is approximately the same or greater than atmospheric pressure, which is generally sufficient to inflate the fluid cells and initially adopt the shapes (or shapes) discussed herein.

[0031] The fluid passageways may assume any suitable shape and cross sectional size. In FIGS. 1 and 2, the fluid passageways 22 are each shown to have a much smaller cross section than the fluid cells, and to describe a generally straight pathway between the fluid cells they interconnect. However, as explained in further detail herein, differently sized and configured passageways may be incorporated into a liner, for example to facilitate or restrict fluid flow between or among certain fluid cells.

[0032] The shapes, dimensions, dimension ratio, and other characteristics of the fluid cells and fluid passageways shown in FIGS. 1 and 2 are not required by all embodiments. For example, alternate configurations may include a range of differently sized networked and/or discrete cells, differently shaped fluid cells, and so forth. One alternate configuration is shown in FIG. 3, in which the networked cells assume a ring shape, with each networked cell 30 encompassing a discrete cell 32. In some liner embodiments, the fluid cells may be arranged in different configurations, for example in different areas of the liner. Indeed, a wide range of fluid cell dimensions, shapes, network configurations, and interspersed patterns may be employed for different activities, different levels of fit, comfort, energy impact absorption, method of manufacture, and so forth.

[0033] In the illustrative liner 10, the discrete fluid cells are not only isolated from other fluid cells, but are sealed from the ambient atmosphere by the material from which they are formed. In some embodiments, in a somewhat similar manner, each group of networked cells, although interconnected by its fluid passageways, may also be sealed from the ambient atmosphere. Such a configuration may be thought of as a completely sealed configuration.

[0034] However, although not required by all embodiments, the illustrative liner 10 is shown in FIG. 1 to include a valve member 34 configured to allow movement of fluid into or out of the group of networked fluid cells, such as via transfer of ambient air from the atmosphere or via pressurizing means.
(not shown) such as attachable pump device. As such, because the discrete cells are sealed, whereas
the group of networked cells is valved, the illustrated configuration may be thought of as a partially sealed
configuration, or alternatively, as a valved configuration. Of course, other configurations, or variants of
these configurations, are also possible, such as those that include multiple groups of networked cells,
some of which are sealed and some of which are valved; those in which some of the discrete cells are
sealed whereas other discrete cells are valved, and so forth. Moreover, a valved configuration may
include more than one valve per group of networked cells, and so forth.

[0035] In a partially or completely sealed configuration, a predetermined amount of fluid, or fluid
pressure, may be introduced or otherwise contained in the fluid cells during the production process. For
example, in the prototype liner mentioned above, a first ply of polyethylene was vacuum-pressed into a
substantially dome-shaped mold that includes a number of depressions and raised areas that collectively
define the shapes of the various fluid cells and fluid passageways. The ambient air in the volumes formed
by the fluid cell and fluid passageway depressions was sealed into the prototype liner upon the
application of a second ply of material applied and adhered to the raised areas of the first ply. Of course,
other methods of manufacture may be employed. For example, air (or other fluid) at any desired pressure
may be sealed into the fluid cells of the liner by carrying out the manufacturing process described above
in a fluid-pressurized chamber.

[0036] The valve members, such as valve member 34, may be configured as desired. For
example, even if the production process for a liner traps or seals an initial quantity or volume of ambient
air in fluid cells that are valved, a valve member such as valve member 34 may allow a user to increase
or decrease the fluid pressure in such cells (or in the networked group to which such cells are connected),
such as by opening the valve to the ambient atmosphere, by attaching a pressurizing means such as a
pump, and so forth. Some manufacturing processes, such as the one outlined above, produce a liner in
which the fluid cells are all at least partially filled with fluid or, in other words, in which the fluid pressure in
the fluid cells is at least a predetermined minimum value; in others, fluid may need to be introduced into
the valved fluid cells prior to use. Some embodiments may be configured to allow the user to adjust the
fluid pressure in some or all of the fluid cells to achieve a desired comfort and/or safety level. In some
embodiments, a valve member may be designed to vent pressure to the ambient atmosphere.
automatically responsive to a predetermined threshold fluid pressure, such as in the case of an impact to a piece of protective headgear with which the liner is used.

[0037] The fluid pressure in the fluid cells, either as provided during manufacture or as set by a user, is generally less than the maximum fluid pressure that a given cell can contain before rupturing, so that the cell may accept additional fluid displaced from another networked cell, to deform responsive to a force, and so forth.

[0038] Referring again to the illustrative liner as shown in FIG. 1, the fluid cells are configured so that when the fluid cells are at least partially filled with fluid and/or when the fluid pressure therein is at least a predetermined minimum value, the height of the discrete cells 32, as defined, for example, by the extent to which a discrete cell protrudes into the concavity formed by the liner (or alternatively the extent to which a discrete cell projects from the inner ply 24 forming the interior surface of the liner), is greater than that of the networked cells 30. However, in other examples the height of the discrete cells is less than or substantially equal to the height of the networked cells. In a sealed configuration, the amount of fluid in each of the discrete cells remains more or less constant through use of the liner, for example unless the material defining a particular discrete cell ruptures. Also, unless the material from which it is formed is distended by some force, the height of a discrete fluid cell also remains constant.

[0039] However, the amount of fluid and/or fluid pressure in each of the networked cells may vary, such as if a networked cell is compressed upon the application of some force, in which case the fluid contained therein is transferred to another networked cell or cells in the group in order to equalize the pressure across the group. As such, the height of each networked cell will selectively vary depending on the fluid volume in the group, the pressure applied to a given networked cell in a group, and so forth.

[0040] In the aforementioned prototype liner, the height of a discrete fluid cell in a neutral, resting state (that is, when no more than ambient atmospheric pressure, or nominal pressure from resting against a wearer's head, is applied to any of the fluid cells of the liner) is approximately 30 mm, and the height of a networked fluid cell is approximately 30 mm. Although the respective heights may vary among embodiments, the substantially constant greater height of the discrete cells help to space the wearer's head from the networked cells. This spacing helps initially position and orient, and maintain proper positioning of, the headgear on the wearer's head during use. The positioning system provided by the
discrete fluid cells also helps avoid inadvertent compression of the networked cells due to improper positioning of the headgear on the wearer’s head, so as to ensure an even initial fluid distribution across the groups of networked cells of the liner. As explained below, an even initial fluid distribution allows the networked cells to more effectively distribute and dissipate a force, such as due to an impact of the headgear.

[0041] Although the range may vary among embodiments, the height of the networked fluid cells of the prototype liner vary between about 5 mm and about 100 mm, such as when the liner or a portion thereof is in an impacted state in which the fluid cells may be compacted or distended (that is, when one or more forces are applied to one or more networked cells, such as responsive to an impact delivered to the exterior of the headgear with which the liner is used).

[0042] As a simple example illustrating of these concepts, FIGS. 4 and 5 show a liner constructed in accordance with this disclosure and incorporated into a conventional helmet, which is generally indicated at 40, worn on a wearer’s head, which is generally indicated at 50. The helmet has an impact-resistant, shell-like exterior surface, and an interior surface defining a concavity adapted to receive a wearer’s head therein. As shown, the liner is removably positionable within the helmet to be interposed between the wearer’s head and the interior surface 42 of the helmet, such as via a number of fasteners 44 between the exterior surface of the liner and the interior surface 42. Fasteners 44 are shown as hook-and-loop style fasteners, but any suitable manner of fasteners may be used. Moreover, the configuration of the fasteners 44, such as the manner in which the fasteners are disposed on the interior surface of the helmet, may define a predetermined orientation for positioning the liner relative thereto, such as by forming a pattern to match up a corresponding fastener pattern on the exterior surface of the liner.

[0043] FIG. 4 represents the liner in a neutral, resting state, in which the discrete fluid cells 32 of the liner are shown to directly contact the wearer’s head 50, maintaining correct orientation of the helmet 40 and initially spacing the wearer’s head from the interior surface 42 of the helmet. FIG. 5, however, represents the liner in an impacted state, in particular one in which a force is delivered to the front portion of the exterior surface 46 of the helmet, such as if the front portion of the helmet impacts an object

[0044] As noted above, in the event of a sudden force delivered to the helmet, the wearer’s head tends to initially lurch toward the point of impact, as shown in FIG. 5, wherein the wearer’s head is
shown to have moved forward relative to the helmet 40. Responsive to this movement, the fluid cells between the wearer's head and the interior of the helmet are compressed. Specifically, the discrete fluid cells in the portion of the liner between the wearer's head and the front portion of the helmet, which are either in contact with the wearer's head or, due to their height, are encountered by the wearer's head as it moves forward toward the interior surface of the helmet, initially absorb some of the impact energy and decelerate the wearer's head.

[0045] As the discrete fluid cells are compressed and the wearer's head moves further toward the helmet interior, the wearer's head next encounters the networked cells, which provide further cushioning and deceleration. Depending on the configuration of the discrete cells and the nature of the force, the discrete cells may distend under compression, or rupture or otherwise release fluid. However, the networked fluid cells 30 of the liner are configured to distribute and thereby dissipate the impact force by transferring fluid from the compressed networked cells to others in the group via the fluid passageways 22. As a result, the impact force is distributed over a larger area of the wearer's head compared to that corresponding to the helmet's point of impact.

[0046] Additionally, FIG. 5 shows that the networked fluid cells 30 of the portion of the liner opposite b those compressed between the user's head and the helmet (in other words, those b the rear of the wearer's head) are inflated as compared with their neutral state, having accepted fluid transferred from the compressed networked cells in the front portion of the liner, to the point that the inflated networked cells may contact the rear portion of the wearer's head. In this condition, the inflated cells may serve b restrict or even prevent the wearer's head from rebounding from the point of impact, which may in turn reduce or even eliminate the occurrence and/or severity of head or brain injuries that would otherwise result from the rebound effect.

[0047] As such, an even initial fluid distribution may ensure an effective fluid transfer among networked cells, such as those that are compressed as a result of an impact force, when the liner is in an impacted state. On the other hand, an uneven initial fluid distribution, such as if some cells are compressed and/or distended when the liner is not in an impacted state, may reduce the capacity of some cells to transfer fluid or accept fluid transferred from other cells. As such, the positioning of the liner relative to a wearer's head that is achieved by the discrete fluid cells, in that such spacing may help to
avoid inadvertent cell compression due to incorrect orientation in a neutral state, facilitates the liner’s ability to dissipate and distributed a force through the networked fluid cells.

[0048] The liner 10, as shown in FIGS. 1, 4, and 5, may be thought of as including several more or less continuous regions shaped and configured to protect corresponding portions of a wearer’s head, such as a crown, opposed front and back, and opposed right and left regions that are positioned to protect, respectively, those portions of the area of the wearer’s head covered by the liner. Of course, other embodiments may assume different shapes, such as that include separate and/or discontinuous regions to protect respective head portions, and/or may have greater or lesser head coverage than as shown with liner 10. Optionally, some embodiments may include more than one layer of fluid cells to protect certain regions.

[0049] The liner 10 may be configured to preferentially direct fluid displaced from one region to another responsive b a force, such as an impact force, delivered b some of the networked cells 30. Such preferential fluid transfer may result in faster or more direct fluid transfer from certain designated networked cells to other certain designated networked cells, and/or from the networked cells in one region of the liner to those in another specific region, such as from the front region to the rear region. Faster or more direct fluid transfer may in turn ensure that even in sudden impacts, the networked fluid cells preventing or restricting the head from rebounding from the point of impact are inflated quickly, dampening the rebound effect Further, in circumstances in which the headgear with which the liner is used is subject to a succession of impact forces, preferential fluid transfer may facilitate the quick dissipation of each of such impact forces, even if delivered to different parts of the headgear.

[0050] Preferential fluid transfer may be accomplished in a variety of manners. As mentioned above, the networked fluid cells 30 of the illustrative liner 10 are all interconnected, either directly by means of an intermediate fluid passageway or indirectly by means of multiple intermediate passageways and/or other networked cells; in other words, the illustrative liner 10 includes one group of networked cells. Other embodiments may include several networked groups that are separate from each other, such as a first group of networked cells configured specifically b transfer fluid between the front and back regions of the liner and a separate, second group configured specifically b transfer fluid between the left and right regions, and so forth. Such separate networked groups may be formed in a liner consisting of
two superimposed plies of material forming a single layer of fluid cells and fluid passageways, a liner formed from three or more plies to create one or more superimposed layers of fluid cells and fluid passageways, and so forth.

[0051] Another (additional or alternative) manner in which preferential fluid transfer may be accomplished is via the physical configuration and/or the arrangement of the various fluid passageways that interconnect the networked cells. For a simple example, when all other variables are held constant, a networked cell connected to a second via one fluid passageway and to a third via two fluid passageways, all of the same cross-sectional area, will transfer fluid to the second cell at a faster rate than to the third. Similarly, and again when all other variables are held constant, a networked cell connected to a second one via a fluid passageway having a greater cross-section than a fluid passageway connecting it to a third will transfer fluid to the second at a faster rate than to the third. Still other configurations and arrangements of fluid passageways interconnecting networked fluid cells will result in different relative rates of fluid transfer, allowing preferential fluid transfer between certain networked cells even among those in the same group.

[0052] FIG. 6 illustrates this concept in a partial view of a liner 10 having an example configuration of fluid cells 20 and passageways 22. In FIG. 6, the fluid cell configuration of the liner is similar to those shown in FIGS. 1-5, in that it includes a number of networked fluid cells 30 interconnected by the fluid passageways 22, and a number of discrete fluid cells 32 interspersed among the networked fluid cells. However, in FIG. 6, some of the fluid passageways, indicated at 222, are shown to have a larger cross-section as compared with others, such as indicated at 224. As mentioned above, all other variables held constant, fluid will flow through passageways 222 at a greater rate than through passageways 224. Of course, some fluid will flow through the smaller cross-section passageways 222, but at a comparatively slower rate. As such, this configuration provides a fluid transfer pathway generally defined by the larger fluid passageways 222 and the networked fluid cells they connect, and indicated in FIG. 6 at 60. The fluid transfer pathway 60 indicates the direction of preferred fluid flow through the networked cells in the represented portion of liner 10.

[0053] Thus, in a liner that includes several regions, such as a crown, opposed front and back, and opposed left and right regions shaped, respectively, to protect the crown, front, back, left, and right
portions of a wearer’s head, the networked fluid cells may be adapted to preferentially direct fluid from one or more of the front, back, left, and right regions toward the opposed region responsive to a force delivered thereto, such as to achieve a faster fluid transfer in order to dampen or even prevent the rebound effect resulting from a sudden impact to a particular portion of the headgear. Of course, preferential fluid transfer means may be used to direct transferred fluid from certain networked cells to others in the same group in liners that may not include defined regions.

[0054] Preferential fluid transfer may be thought of, conversely, as being accomplished by selectively restricting some fluid transfer, such as by configuring some of the fluid passageways to restrict the rate at which fluid is transferred. All other variables held constant, fluid will flow along the path of least resistance: thus, between a fluid passageway incorporating some fluid restricting means and one that does not, preferential fluid transfer is accomplished via the latter.

[0055] Fluid restricting means may optionally be used other than to achieve preferential fluid transfer, however. For example, the energy absorbing capacity of a networked cell may be facilitated by limiting or otherwise restricting the rate at which fluid may be displaced from it. Slowing the transfer of fluid from a networked cell may increase the energy absorbed by the cell due to more compression energy and/or time required to move the fluid through the fluid restricting means.

[0056] A variety of fluid restricting means with different levels of restricting capacity may be incorporated into the fluid passageways 22 of liner 10, such as baffles, narrowed fluid passageways or portions thereof, plugs, portions of increased friction, valves, such as one-way valves, circuitous passageways, and so forth. FIG. 7 illustrates this concept in a partial view of a liner 10 having another example configuration of fluid cells 20 and passageways 22. In FIG. 7, the fluid cell configuration of the liner is similar to those shown in FIGS. 1-6, in that it includes a number of networked fluid cells 30 interconnected by the fluid passageways 22, and a number of discrete fluid cells 32 interspersed among the networked fluid cells. In the configuration shown in FIG. 7, the networked cells 30 are ring-shaped, and each of the discrete cells 32 is, respectively, encompassed thereby. However, some of the fluid passageways, particularly those connecting the networked fluid cell indicated at 302 b its neighboring networked fluid cells, are each shown to describe a circuitous. S-shaped pathway between fluid cell 302 and its neighboring networked cells; such passageways are indicated at 226. Other fluid passageways.
such as indicated at 228, describe straight, direct pathways between the fluid cells they interconnect. Comparatively speaking, the S-shaped passageways 228 facilitate the energy-absorbing capacity of fluid cell 302 due to the greater amount of force required to move the fluid contained in the cell through the passageways 228 to its neighboring networked cells.

[0057] Depending on the configuration, the fluid restricting means incorporated into a liner may be adapted only to allow fluid transfer responsive to a predetermined threshold pressure. One example of this is by use of a pressure-responsive valve member (such as a one-way valve) disposed in a fluid passageway connecting a first fluid cell to a second. Such a valve member may be configured to allow fluid be transferred, for example from the first cell to the second, only when the fluid pressure in the first cell reaches a predetermined threshold value.

[0058] Use of such a valve member or other such means is one way in which the fluid cells in a liner may be configured to release fluid responsive to a predetermined threshold fluid pressure. In some situations, such as when an impact force to the headgear is very sudden and of great magnitude, the fluid in some of the fluid cells absorbing the impact energy may reach a very high pressure if the fluid is not able to be rapidly transferred to neighboring networked cells. Rapid fluid transfer may be facilitated by an initial even fluid distribution, as mentioned above. However, some of the fluid cells in some liner embodiments may be provided with means in which the fluid contained therein may be released responsive to a predetermined threshold fluid pressure, in some cases in addition to normal fluid transfer, such as from one networked cell to others in a group. A simple method, of course, is by using a material designed to rupture responsive to such a fluid pressure, for example to release the contained fluid to the atmosphere. Arranging the fluid cells to be spaced away from each other, such as in the illustrative liners shown and described herein, allows a volume of void space between a wearer's head and the helmet interior into which fluid may be released in the case of material rupture. However, in embodiments in which the liner is intended for repeated use, it may be preferable to employ means of relieving high fluid pressure in a manner that avoids cell rupture, such as by incorporating the aforementioned valve members.

[0059] Optionally, although not shown in the drawings, a liner may include one or more reserve fluid cells adapted to accept fluid released from a fluid cell responsive to a predetermined threshold fluid
pressure (such as via a one-way valve). Such reserve fluid cells may initially be empty of fluid, or contain less fluid (or fluid at a comparatively lower pressure) than as compared to the fluid cells in communication therewith, such as to be able to more quickly accept fluid than if initially containing more fluid (or fluid at a comparatively higher pressure). Some liner embodiments may include a number of different pressure-relief means (in addition to normal fluid transfer, such as among other networked cells of a group), such as some cells that are adapted to rupture responsive to a predetermined threshold fluid pressure, some that are adapted to release fluid to one or more reserve cells, and so forth.

[0060] As a further optional configuration, the liner may include a mix of cells configured restrict fluid to different degrees and therefore to absorb energy from different magnitudes of impacts. For example, the liner may include a first set of cells, a second set of cells, and a third set of cells, where the first set restricts fluid from flowing to a connected cell to a lesser degree than the second set restricts fluid flow and the third set restricts fluid flow to a greater degree than either the first or second set. In this example, the first set may readily transfer fluid and absorb energy from relatively minor impacts whereas the second set may require a greater amount of compression energy from an impact before it will transfer fluid. Likewise, the third set may require an even greater amount of impact energy before it will transfer fluid between cells. Any combination of the fluid restriction means discussed above may be employed to restrict fluid to different degrees in each set of cells.

[0061] Continuing the prior example, the first, second, and third set of cells may be differentiated by height or may be mounted in different layers of the liner. For example, the first set of cells may be a first height, the second set of cells be a second height less than the first height, and the third set of cells may be a third height less than the second height. In this configuration, the first set of cells will be closest to the wearer’s head and be the first to compress in an impact. If the impact is sufficient to compress the first set of cells to a height less than or equal to the second height, then the second set of cells will begin to compress and absorb energy by transferring fluid. Finally, if the impact is sufficient to compress the first and second set of cells to a height less than or equal to the third height, then the third set of cells will begin to compress and absorb energy by transferring fluid as well, in this manner, the liner absorbs energy in successive levels.
Additionally or alternatively, the first set of cells, the second set of cells, and the third set of cells may be disposed in different layers. In one example, the first set of cells is disposed in a top layer closest to the wearer's head, the second set of cells is disposed in a middle layer, and the third set of cells is disposed in a bottom layer closest to the helmet. When helmet impacts an object, the first set of cells in the top layer are the first to compress and transfer fluid. When the first set of cells transfer a selected amount of fluid and/or a threshold impact energy is reached, the second set of cells in the second layer begin to transfer fluid and absorb energy. Likewise, when the first and second set of cells transfer a selected amount of fluid and/or a threshold impact energy is reached, the third set of cells in the inner layer begin to transfer fluid and absorb energy.

Some liner embodiments may optionally include pressurizing means disposed on the liner for selectively moving fluid into and out of the fluid cells, such as through a valve member (such as valve member 34, as shown in FIG. 1). FIG. 8 shows an illustrative example liner 10 that includes pressurizing means, generally indicated at 70, and shown in the form of a pump mechanism 72 that communicates with a networked fluid cell 30 via a pump channel 74, when actuated via an actuator 76 (shown as a button). The pressurizing means is shown to be positioned on the wearer's right side of the liner b descend generally forward of the wearer's ear, but such means may be disposed in any appropriate location (or locations) on the liner.

Further, in the example shown in FIG. 8, the fluid may be air that is moved from the ambient atmosphere into the cells of the liner 10, but, as mentioned above, the fluid in other embodiments may be a different gas or gas mixture, or a liquid or liquid mixture. In such embodiments, the pressurizing means may also communicate with a reserve volume of fluid, such as a reservoir or pressurized tank. Optionally, the pressurizing means may be adapted b selectively pressurize the liner with a variety of different fluids, such as by selectively attaching the pressurizing means b a fluid reservoir or allowing the pressurizing means to draw in ambient air as the fluid.

In embodiments in which the pressurizing means incorporates a pump mechanism, the pump may be integrated into the liner, otherwise secured thereto, or selectively attachable thereto, such as by removably coupling with an integrated valve member incorporated into the liner.
Pressurizing means may allow a user to adjust the fit, comfort, and/or protective capabilities of the liner, such as by pumping different amounts of fluid into one or more fluid cells or groups of networked cells. For example, the more fluid that is pumped into a fluid cell or a group of networked fluid cells, the more such cells expand. As mentioned above, in the illustrated embodiments, the discrete fluid cells generally protrude into the concavity formed by the liner further than the networked cells, such that the discrete fluid cells are generally the fluid cells in contact with the wearer's head. In vaived configurations in which some of the discrete fluid cells are provided with a valve, a user may tighten or loosen the fit of the headgear used with the liner by adjusting the fluid pressure or level of such discrete fluid cells.

In vaived configurations in which one or more of the groups of the networked fluid cells are provided with a valve, the cells may be expanded to the point at which they contact the wearer's head, so that a tighter fit may be achieved. As mentioned above, however, when the fluid pressure across a group of networked fluid cells is higher, each individual networked cell in the group may have decreased capacity to absorb energy by accepting fluid transferred from others. Thus, depending on the configuration of the fluid cells of a liner, a user may set the fluid pressure(s) at a desired value (or values) to optimize comfort and protection. Further, a user may choose to add or remove fluid during the course of an activity, for example if the user's head expands or contracts due to changing heat and blood flow, such as from different levels of physical exertion.

Industrial Applicability

The inventions described in this application may be made by a variety of industrial processes, including by various molding industrial methods, and may be used in a wide variety of industries that utilize protective headgear, such as helmets, including manufacturing, construction, engineering, recreation, and sporting industries.

The inventions described above may be alternatively described according to the following non-limiting embodiments:

In an embodiment for a liner for protective headgear adapted to be interposed between the interior surface thereof and a wearer's head received therein, the liner may include, but is not limited to a plurality of fluid cells. The fluid cells may be formed from a flexible, fluid-impermeable material. Each fluid
cell may be adapted to receive and store fluid therein. The plurality of fluid cells may further including a group of networked fluid cells which each communicate with at least one other via a fluid passageway extending therebetween. The plurality of fluid cells may include a group of discrete, non-networked fluid cells interspersed among the networked fluid cells.

[0071] In some examples, when the fluid pressure in the fluid cells is at least a predetermined minimum value, at least some of the discrete fluid cells are configured to position the headgear on a wearer's head and maintain an initial spaced relationship between the user's head and the interior surface of the headgear. In some further examples, the fluid passageways are configured to equalize fluid pressure across the networked fluid cells of the group responsive to a force delivered thereto.

[0072] The fluid cells may be arranged in a single layer. In some examples where the fluid cells are arranged in a single layer, the material is formed such that the layer in which the fluid cells are arranged has an exterior side that faces the interior surface of the headgear, and an interior side forming a concavity adapted to receive a user's head, wherein the interior side defines a surface from which the fluid cells project and wherein, when the fluid pressure in the fluid cells is at least a predetermined minimum value, the discrete fluid cells project into the concavity from the surface to a greater extent than the networked fluid cells.

[0073] In some examples, each of the group of discrete fluid cells are laterally encompassed either by at least one networked cell or a combination of at least two networked cells and a fluid passageway extending therebetween.

[0074] In some embodiments, at least some of the fluid cells may be configured to release fluid responsive to a predetermined threshold fluid pressure. The fluid cells may be configured to rupture responsive to the predetermined threshold fluid pressure. The liner may further include at least one reserve fluid cell communicating with at least one such fluid cell, the reserve fluid cell configured to accept fluid released from the fluid cell responsive to the predetermined threshold fluid pressure.

[0075] The fluid-impermeable material may be formed such that the liner includes crown, opposed front and back, and opposed left and right regions shaped to protect the respective crown, front, back, left, and right portions of the user's head, wherein the plurality of fluid cells includes at least one group of networked cells adapted to dampen the tendency of the wearer's head from rebounding from a location
on the liner in response to a force delivered thereto by distributing fluid from one or more of the front, back, left, and right regions toward the respective one or more opposed regions.

[0076] In some examples, the fluid pressure in the plurality of fluid cells is at least the predetermined minimum value. In such examples, the fluid in at least some of the fluid cells may be air.

[0077] At least some of the fluid passageways may include fluid restricting means configured to limit the rate at which fluid is transferred therethrough. In some examples, the adjacent surfaces of two superimposed sheets of said material are sealed at regions internally of their peripheries to form the plurality of fluid cells and fluid passageways.

[0078] In some examples, the liner may include pressurizing means disposed on said liner for selectively moving fluid into and out of the plurality of fluid cells. The pressurizing means may include an integrated pump or a valve member configured to be attached to a pump.

[0079] In another embodiment for a liner for protective headgear adapted to be interposed between the interior surface thereof and a wearer's head received therein, the liner may include, but is not limited to two superimposed plies of a flexible, fluid-impermeable material, the adjacent surfaces thereof being sealed at regions internally of their peripheries to form a single layer of fluid cells at least partially filled with fluid, and fluid passageways interconnecting at least some of the fluid cells. At least some of the interconnected fluid cells may be adapted to dampen the tendency of the wearer's head from rebounding from an impact location on the headgear in response to a force delivered thereto by laterally distributing fluid from the interconnected fluid cells corresponding to the impact location toward other interconnected fluid cells disposed at one or more locations generally opposed to the impact location. At least some of the fluid cells that are not interconnected may be adapted to maintain the liner in a predetermined orientation on the wearer's head. At least some of the fluid cells that are not interconnected may be interspersed among the interconnected fluid cells. In some examples, the fluid is air.

[0080] In an embodiment for an article of protective headgear, the article of protective headgear may include, but is not limited to a helmet having an impact-resistant exterior surface and an interior surface defining a concavity adapted to receive a wearer's head therein, and a liner attached to the interior surface and adapted to be disposed between the interior surface and a wearer's head, the liner including a plurality of fluid cells arranged in a single layer and a plurality of fluid passageways interconnecting at
least some of the fluid cells, the fluid cells arranged in the liner such that the fluid cells that are not interconnected are interspersed among the fluid cells that are interconnected. The interconnected fluid cells may be adapted to laterally distribute and dissipate an impact force delivered to the exterior surface of the helmet among the other interconnected fluid cells via the fluid passageways. At least some of the fluid cells that are not interconnected may be adapted to maintain the helmet in a predetermined orientation on the wearer's head.

[0081] In some examples, the liner is removably positionable within the helmet via a plurality of fasteners. The configuration of the fasteners may define a predetermined orientation for positioning the liner relative to the interior surface of the helmet.

[0082] Although the present invention has been shown and described with reference to the foregoing operational principles and illustrated examples and embodiments, it will be apparent to those skilled in the art that various changes in form and detail may be made without departing from the spirit and scope of the invention. The present invention is intended to embrace all such alternatives, modifications and variances that fall within the scope of the appended claims.
I CLAIM:

1. A liner for protective headgear adapted to be interposed between the interior surface thereof and a wearer's head received therein, the liner comprising:

   a plurality of fluid cells formed from a flexible, fluid-impermeable material, each fluid cell adapted to receive and store fluid therein, the plurality of fluid cells further including a group of networked fluid cells which each communicate with at least one other via a fluid passageway extending therebetween, and a group of discrete, non-networked fluid cells interspersed among the networked fluid cells:

   wherein, when the fluid pressure in the fluid cells is at least a predetermined minimum value, at least some of the discrete fluid cells are configured to position the headgear on a wearer's head and to maintain an initial spaced relationship between the user's head and the interior surface of the headgear, and the fluid passageways are configured to equalize fluid pressure across the networked fluid cells of the group responsive to a force delivered thereto.

2. The liner of claim 1, wherein the fluid cells are arranged in a single layer.

3. The liner of claim 2, wherein each of the group of discrete fluid cells are laterally encompassed either by at least one networked cell or a combination of at least two networked cells and a fluid passageway extending therebetween.

4. The liner of claim 2, wherein the material is formed such that the layer in which the fluid cells are arranged has an exterior side that faces the interior surface of the headgear, and an interior side forming a concavity adapted to receive a user's head:

   wherein the interior side defines a surface from which the fluid cells project: and

   wherein, when the fluid pressure in the fluid cells is at least a predetermined minimum value, the discrete fluid cells project into the concavity from the surface to a greater extent than the networked fluid cells.
5. The liner of claim 1, wherein at least some of the fluid cells are configured to release fluid responsive to a predetermined threshold fluid pressure.

6. The liner of claim 5, wherein such fluid cells are configured to rupture responsive to the predetermined threshold fluid pressure.

7. The liner of claim 5, further including at least one reserve fluid cell communicating with at least one such fluid cell, the reserve fluid cell configured to accept fluid released from the fluid cell responsive to the predetermined threshold fluid pressure.

8. The liner of claim 1, wherein the material is formed such that the liner includes crown, opposed front and back, and opposed left and right regions shaped to protect the respective crown, front, back, left, and right portions of the user's head; and

   wherein the plurality of fluid cells includes at least one group of networked cells adapted to dampen the tendency of the wearer's head from rebounding from a location on the liner in response to a force delivered thereto by distributing fluid from one or more of the front, back, left, and right regions toward the respective one or more opposed regions.

9. The liner of claim 1, wherein the fluid pressure in the plurality of fluid cells is at least the predetermined minimum value.

10. The liner of claim 9, wherein the fluid in at least some of the fluid cells is air.

11. The liner of claim 1, wherein at least some of the fluid passageways include fluid restricting means configured to limit the rate at which fluid is transferred therethrough.

12. The liner of claim 1, further including pressurizing means disposed on said liner for selectively moving fluid into and out of the plurality of fluid cells.
13. The liner of claim 12, wherein the pressurizing means includes an integrated pump.

14. The liner of claim 12, wherein the pressurizing means includes a valve member configured to be attached to a pump.

15. The liner of claim 16, wherein the adjacent surfaces of two superimposed sheets of said material are sealed at regions internally of their peripheries to form the plurality of fluid cells and fluid passageways.

16. A liner for protective headgear adapted to be interposed between the interior surface thereof and a wearer’s head received therein, the liner comprising:
   
   two superimposed plies of a flexible, fluid-impermeable material, the adjacent surfaces thereof being sealed at regions internally of their peripheries to form a single layer of fluid cells at least partially filled with fluid, and fluid passageways interconnecting at least some of the fluid cells;
   
   wherein at least some of the interconnected fluid cells are adapted to dampen the tendency of the wearer's head from rebounding from an impact location on the headgear in response to a force delivered thereto by laterally distributing fluid from the interconnected fluid cells corresponding to the impact location toward other interconnected fluid cells disposed at one or more locations generally opposed to the impact location;
   
   wherein at least some of the fluid cells that are not interconnected are adapted to maintain the liner in a predetermined orientation on the wearer's head; and
   
   wherein at least some of the fluid cells that are not interconnected are interspersed among the interconnected fluid cells.

17. The liner of claim 16, wherein the fluid is air.
18. An article of protective headgear, comprising:

a helmet having an impact-resistant exterior surface and an interior surface defining a concavity adapted to receive a wearer's head therein: and

a liner attached to the interior surface and adapted to be disposed between the interior surface and a wearer's head, the liner including a plurality of fluid cells arranged in a single layer and a plurality of fluid passageways interconnecting at least some of the fluid cells, the fluid cells arranged in the liner such that the fluid cells that are not interconnected are interspersed among the fluid cells that are interconnected;

wherein the interconnected fluid cells are adapted to laterally distribute and dissipate an impact force delivered to the exterior surface of the helmet among the other interconnected fluid cells via the fluid passageways;

wherein at least some of the fluid cells that are not interconnected are adapted to maintain the helmet in a predetermined orientation on the wearer's head.

19. The article of protective headgear of claim 18, wherein the liner is removably positionable within the helmet via a plurality of fasteners.

20. The article of protective headgear of claim 19, wherein the configuration of the fasteners defines a predetermined orientation for positioning the liner relative to the interior surface of the helmet.
