DENDRITE-SUPPRESSING ION-CONDUCTORS FROM ARAMID NANOFIBERS WITHSTANDING EXTREME BATTERY CONDITIONS

Figure 1

Abstract: Ion conducting membranes based on aramid nanofibers (ANFs) can be prepared using layer-by-layer assembly, sol-gel processing, evaporation, spin coating, doctor blading, or other methods. Porosity is controlled through choice of additives and processing.
DENDRITE-SUPPRESSING ION-CONDUCTORS FROM ARAMID
NANOFIBERS WITHSTANDING EXTREME BATTERY CONDITIONS

GOVERNMENT SUPPORT

[0001] This invention was made with government support under DE-SC0000957 awarded by the Department of Energy, CBET1036672, CBET0932823, CBET0933384, ECS0601345 and EFRI0938019 awarded by the National Science Foundation. The Government has certain rights in the invention.

INTRODUCTION

[0002] The new generation of high-performance batteries requires ionic conductors that suppress growth of dendrites compromising battery safety. They also must withstand harsh thermal conditions at high currents. Finding a material satisfying a long list of mutually contradictory properties for such ion-conductors is difficult.

[0003] Increasing the energy capacity of batteries represents a bottleneck in the advancement of many technologies, as exemplified by electrical vehicles, solar/wind energy conversion, flexible electronics, and health monitoring devices. Much attention had been paid to maximizing the energy and power densities of the cathode and anode of lithium batteries,\(^1,2\) especially using new forms of nanostructured materials\(^3,4\) and thin polymer films\(^5\). Cathode-anode separators have attracted much less attention although they contribute to desired high capacity, high discharge rate, and lightweight electrical storage.

[0004] Typically, cathode-anode separators or ion-conducting membranes (ICMs) are made from microporous polymer sheets impregnated with solutions of lithium salts in alkylcarbonates. These gel or liquid phases serve as the actual ion-conducting media in many ICMs from microporous polymer sheets. Shortcomings of such ICMs include flammability, fluid leakage, limited operating temperature range, and sporadic internal shorting of cathode and anode leading to battery fires. These shortcomings present acute safety challenges for batteries.

[0005] Materials adequately addressing the current problems are difficult to find because of the extensive list of requirements for ICMs that include high stiffness \((E_{ICM})\), shear modulus \((G_{ICM})\), and ion conductivity \((\Omega_{ICM})\). Moreover, as the charge rate and
power density of the batteries increase, the importance of having adequate ICMs will inevitably increase. The list of requirements for ICM materials thus also becomes longer and increasingly more challenging to satisfy. Although many problems related to the stability of both cathode and anode materials still need to be resolved, the ICM-related challenges due to higher currents and current densities should be anticipated as well. Besides $E_{ICM}$, $G_{ICM}$, and $\Omega_{ICM}$, the new generation of batteries will need ICMs with improved high temperature resilience and reduced brittleness.

[0006] Many of the safety problems of modern batteries are related to dendrite growth and anode expansion in the charged state\textsuperscript{5-9}. Piercing of porous polymer separators, for instance Celgard\textsuperscript{TM} 2400 (Figure 1A), by dendrites (Figure 1B) is the most common mechanism of spontaneous battery failure which can also lead to short circuit and fire. The growth of dendrites is also the key roadblock for the development of batteries with lithium metal anodes, which can approach the theoretical limit for lithium-based storage devices with respect to capacity, power, and weight\textsuperscript{10}. Many different approaches were previously proposed to prevent dendrite formation, including additives to the gel and liquid electrolyte\textsuperscript{11} or composite gel electrolytes with inorganic fillers\textsuperscript{12}, however the dendrite problem still persists. The variety of data presented suggest that improvement of mechanical properties of ICM such as $E_{ICM}$\textsuperscript{13} and/or $G_{ICM}$\textsuperscript{14} could dramatically inhibit their growth. Although formation of metal deposits during battery charging/discharging cycles is a part of normal battery operation, sufficient compressive stress exerted on tips of growing dendrites is expected to inhibit/prevent their growth\textsuperscript{14}. Reduced thickness of the ICM is also of importance in avoiding high internal resistance inside the battery cells that leads both to heating, instability of operation, and energy losses. The fundamental problem in this field is how to combine the high modulus, flexibility, and ion conductivity -- properties that often appear to be mutually exclusive and essentially equates to finding new approaches to the materials engineering of ICMs. Similar difficulties also exist with several other combinations of mechanical and transport properties of materials\textsuperscript{15}. Multiple material combinations and materials engineering approaches have been investigated in the past to make ICMs but each has presented their own unique limitations, eventually translating into alternative safety concerns and/or energy losses. Solid electrolytes based on Li-based ceramics represent one of the most advanced ion conductors at the moment\textsuperscript{16-18}. They combine high mechanical stiffness with E values as high as 80-100 GPa and $\Omega_{ICM}$
values as high as $1.0 \times 10^{-3}$ S/cm$^{16,17}$ and $1.2 \times 10^{-2}$ S/cm$^{18}$. These parameters make them exciting candidates for some high-power applications. However, their brittleness makes it difficult to incorporate Li-based ceramic materials into battery packs and necessitates thicker ICMs with increased internal resistance. Finding new dendrite-suppressing ion-conducting materials and de facto unite the advantages of ion-conducting glasses and polymers, is fundamentally important since dendrite growth is pervasive for virtually all electrochemical devices utilizing different metals and electrolytes.

SUMMARY

[0007] Favorable properties can be engineered in a composite made from aramid nanofibers (ANFs). Ion conducting membranes from ANFs can be prepared using layer-by-layer assembly, sol-gel processing, evaporation, spin coating, doctor blading, or other methods. As one of the components of the membrane ion conducting polymers, such as poly(ethylene oxide) (PEO) can be used. In various embodiments, the porosity of the membranes (15-20 nm) was designed to be smaller than the growth area of the dendrites (e.g. 25-100 nm). Composites exhibit high stiffness, ionic conductivity, and ion flux exceeding those found in other solid electrolytes. Successful suppression of hard copper dendrites by the ion conductors is demonstrated at extreme discharge conditions and in a functional battery with a lithium metal anode. Composites containing ANF also demonstrated exceptional temperature resilience and thus combined advantages of both ion-conducting glasses and polymers.

[0008] In an illustrative example, ANFs with a length of 1 μm and an average diameter of 5-10 nm (Figure 1C) are made by dissolution of bulk Kevlar® fibers in DMSO in the presence of KOH. Notably, the ANFs are insulating, differentiating them from many other ultrastrong metallic and semiconducting nanomaterials (nanotubes, nanowires, etc.), which cannot be used as ICM materials.

[0009] As one embodiment of ANF-based ICMs, ANFs were combined with poly(ethyleneoxide) (PEO) serving as the solid ion-conducting media using the versatile layer-by-layer (LBL) assembly method$^{20}$. In the past, composites made by LBL or other methods have shown exceptional mechanical performance$^{21}$ or ionic conductivity,$^{22,23}$ but not the combination of the two or any dendrite-suppressing capabilities.
DRAWSINGS

[0010] The drawings described herein are for illustrated purposes only of selected embodiments and not all possible implementations, and are not intended to limit the scope of the present disclosure.

[0011] Figure 1 illustrates (A) top view SEM images of copper dendrite penetrating through Celgard™ ICM. (B) SEM image of the tip of a copper dendrite. (C) TEM image of ANF. (D) Top and (E) side view SEM images of (PEO/ANF)_{200}. (F) optical photograph of (PEO/ANF)_{200}.

[0012] Figure 2 illustrates SEM images of copper electrode with (A) no coating; (B) (PEO/ANF)_{10}; (C) (PEO/ANF)_{30}; (D) (PEO/ANF)_{50}. Copper dendrite growth with current density of 10.3 mA/cm² on (E) bare copper electrode; (F) copper electrode coated with (PEO/ANF)_{10}; (G) (PEO/ANF)_{30}; and (H) (PEO/ANF)_{50}. (I), (J), (K), (L) are cross sections of (E), (F), (G), (H) respectively. Total charge transferred = 0.02 C/cm².

[0013] Figure 3 demonstrates (A) Comparative evaluation of stiffness and internal resistance normalized to a standard CR2032 coin cell for (PEO/ANF)_{200} and other ICMs. The corresponding references is given in the SI (PEGDMA = polyethylene glycol dimethacrylate, PEGDME = poly(ethylene glycol)dimethyl ethers, NBR = nitrile rubber, IL = ionic liquids, BPAEDA = bisphenol A ethoxylate diacrylate, PST = polystyrene, PAN = polyacrylonitrile, SN = succinonitrile, PMMA = poly(methyl methacrylate)); (B) Hot solder iron test on (PEO/ANF)_{200} and Celgard™ 2400 PE. (E) DSC and (F) TGA curves for (PEO/ANF)_{200}, neat PEO, and Celgard™ 2400 PE.

[0014] Figure 4 illustrates the UV-Visible spectra of (PEO/ANF)n LBL composite deposited on glass slide with different number of bilayers. Absorbance at 330 nm shows linear growth of the film (inset).

[0015] Figure 5 shows a photograph of (PEO/ANF)n LBL film on a glass slide used as the counter electrode for 2 seconds. This corresponds to approximately 0.02 Coulomb/cm² charge transferred. The sample was then rinsed gently with DMSO and dried under vacuum overnight at room temperature. The sample was then sputtered with
gold in preparation for SEM. For cross-sectional images, the sample was broken in half to expose a cross section after cooling by liquid nitrogen.

[0016] Figure 6 illustrates the experimental setup used in dendrite growth experiments.

[0017] Figure 7 illustrates the stress-strain curve of (PEO/ANF)_{100}; ultimate strength is $\sigma_{ICM} = 169$ MPa. The initial linear region yields a Young’s Modulus of $E = 4.95$ GPa.

[0018] Figure 8 illustrates an AFM image of a PEO-ANF interconnected network.

[0019] Figure 9 illustrates a XRD pattern of (A) neat PEO and (B) (PEO/ANF)_{200}.

[0020] Figure 10 illustrates an FT-IR spectra of (A) neat PEO, (B) (ANF/ANF)_{100}, and (C) (PEO/ANF)_{200}. A distinct peak at 1728.87 cm$^{-1}$ found in the spectrum of the PEO-ANF nanocomposite is assigned to the N-H bending vibration and represents strong hydrogen bonding between PEO and ANF.

**DESCRIPTION**

[0021] In one embodiment, a free standing film comprises alternating layers of aramid nanofibers (ANF) and polyalkylene oxide. In a non-limiting example, the polyalkylene oxide comprises polyethylene oxide (PEO). In various embodiments, the free standing film is characterized as having from 5 to 500 alternating layers of ANF and polyalkylene oxide. In one embodiment, the film has at least 10 alternating layers of ANF and PEO. For use in certain applications, the film is provided having a thickness of 3 microns or greater.

[0022] In another embodiment, an electrode assembly comprises a cathode, and anode, and an ion conducting membrane (ICM) disposed between the cathode and anode, wherein the ICM comprises aramid nanofibers and polyoxyalkylene oxide. For example, the ICM has the structure (PEO/ANF)$_n$, where $n$ is from 5 to 500 and where PEO/ANF represents alternating layers of polyethylene oxide and aramid nanofiber. In various embodiments, at least one of the cathode and anode is a lithium metal electrode. A lithium electrochemical cell is provided that contains such an electrode assembly, and a lithium battery is provided that comprises a plurality of such cells.
[0023] In another embodiment, a free standing membrane contain aramid nanofibers fibers and has a porosity of 20 – 80% or 30 – 60%. The membrane can further contain nanoparticles. In various embodiments, the ratio of weight of the nanoparticles to the nanofibers is from 1:2 to 2:1 or from 1:2:1 to 1:1. In certain embodiments, the nanoparticles are selected from silica, alumina, zirconia, titania, magnesium oxide, and calcium oxide. The thickness of the membranes ranges from 1 micron to about 100 microns, in non-limiting examples. For battery applications it is desired to have a thickness of at least 3 or at least 5 microns, to provide sufficient strength and to avoid shorting from too thin a separator membrane.

[0024] In another embodiment, a method of making a nanofiber membrane involves exposing aramid fibers to base in an aprotic solvent to make a suspension of aramid nanofibers; depositing the suspension of nanofibers on a substrate; exposing the substrate to water, to remove the aprotic solvent and release the deposited suspension from the substrate; and drying the released suspension to form a free standing membrane.

[0025] Depositing is carried by layer-by-layer assemble, by spin coating, by spray coating, by doctor blading, or other suitable methods. A suitable aprotic solvent is dimethyl sulfoxide (DMSO).

[0026] Batteries such as lithium ion batteries, thin film flexible batteries, and redox flow batteries incorporate such membranes as separators or ion conducting membranes.

**Batteries**

[0027] In various embodiments, a thin film battery is provided. The battery contains ion-conducting media, wherein the ion conducting media is made by the methods described herein and comprises aramid nanofibers.) In other embodiments, a similar 18650 type of battery, comprising ion-conducting media based on aramid nanofibers.

[0028] One use of the free standing film is as an ion conducting membrane (or, equivalently, ion conducting medium, both abbreviated as ICM) in a battery such a lithium battery. In this application, the ICM can be abbreviated as ICM) in a battery such a lithium battery. In this application, the ICM can be disposed in an electrode assembly between a cathode and an anode. The electrode assembly is used in conventional fashion to make an electrochemical cell, and a battery (for example a lithium battery) can be made up of a plurality of electrochemical cells. The ICM's made of (PAO/ANF)ₙ have the useful
property of being resistant to puncture or rupture by dendrites formed during operation of the battery or cell.

[0029] The same ICMs can be utilized with other electrode materials represented by but not limited to Na, K, Zn, Mg, Ca, and Cu. Their performance is severely impeded by the dendrites while increase in charge-discharge rates is much needed for large scale energy storage exemplified but not limited to wind/solar farms. The ANF-based ICMs will be LBL deposited, spin-coated, rolled, sprayed, pressed with free-standing ANF-based sheets or otherwise deposited on these electrodes and integrated with other battery components.

[0030] In a redox flow battery (RFB), electroactive species are dissolved in separate liquid electrolytes called the catholyte (cathode) and the anolyte (anode). These liquids are separated by an ion-conducting membrane (ICM) made according to the current teachings. The liquids are stored in separate reservoirs and pumped past electrodes to charge and discharge the cell. Energy is stored and released when the electroactive species are reversibly oxidized and reduced at the electrode surface. Ions from the support electrolytes, such as TBA+ or BF4-, are allowed to travel through the ICM to balance the charge difference created by the redox reactions. The standard potential between the cathodic and anodic reaction, along with the concentration and number of electrons transferred dictates the amount of energy stored. Energy and power are decoupled in this case as power scales with the surface area of the carbon electrodes and energy scales with the active species concentration.

[0031] In another embodiment, a method of making a free standing film comprises layer by layer (LBL) assembly of alternating layers of ANF and polyalkylene oxide.

Aramid nanofibers

[0032] In one aspect, aramid nanofibers are provided that have a diameter of about 1 micron or less, 500 nm or less, or 300 nm or less. In certain embodiments the nanofibers are characterized by a diameter of 3 to 100 nm. In various embodiments, the diameter of the nanofibers is on the order of 3 to 30 nm. In various embodiments, the nanofibers have a high aspect ratio, in that the length of the nanofibers is at least five times, at least ten times, or at least 20 times their diameter. In various embodiments, the nanofibers have lengths of 0.1 to 10 micrometers, for example 1 to 10 micrometers or 5 to 10 micrometers.
In one embodiment, the nanofibers are prepared as suspensions in a suitable solvent such as DMSO. Suspensions contain aramid nanofibers and an aprotic solvent such as DMSO. The suspension optionally further contains water. If water is present in the suspension, it is present in a volume ratio of water to aprotic solvent in a range of 1/1,000 to 1/20, in a non-limiting example.

A process for making a suspension of aramid nanofibers in a solvent is found for example in Arruda et al., United States application US 2013-0288050 published October 31, 2013, the entirety of which is hereby incorporated by reference. An aprotic solvent such as DMSO has been found to be suitable for the synthetic method. As a first step, a conventional aramid fiber (of micro or macro dimensions) is subjected to an optional first step involving exposing the aramid material to ultrasound energy while the aramid material of macro dimensions is in contact with a solvent. N-methylpyrrolidone (NMP) has been found to be a suitable solvent. The aramid material undergoing exposure to the ultrasound energy is made of fibers having a diameter of greater than 1 micrometers, in a non-limiting example.

After pretreatment of the aramid material with ultrasound, the aramid material is removed from the solvent and combined with a solution containing a base and an aprotic solvent. If no ultrasound treatment is applied, aramid fiber is combined directly with the solution containing base and an aprotic solvent. In certain embodiments, the base is KOH and the aprotic solvent is DMSO. Thereafter, the aramid material is reacted in the KOH/DMSO solution, in exemplary fashion at a temperature below 50°C for times sufficient to produce aramid nanofibers having a diameter 3 to 100 nanometers, 3 to 50 nanometers, or the like. The nanofibers are produced in situ and are suspended in the solution. It is found that under these conditions, the aramid material does not proceed to molecular dimensions where it could be considered as having been dissolved in the solvent. Rather, discrete nanofibers can be visualized in the suspension and in films produced from the suspension, which in various embodiments show the nanofibers having diameters less than 100 nm and high aspect ratios as described. The reaction in solution to prepare the suspension is carried out preferably at low temperatures and can be carried out at room temperature or about 20° to 30°, for example, 25°C.

In various embodiments, the KOH/DMSO solution can contain water in a volume ratio of water to DMSO of 1 to 20 to 1 to 1,000. In a non-limiting embodiment,
the reacting solution contains equal parts by weight aramid material and KOH. Further, the aramid material and the base are present in relatively minor amounts in the solution, making up for example about 0.05 percent to about 5 percent by weight of the solution. In one embodiment, the weight of the KOH and the aramid material is about 7.6 percent by weight of the suspension. In other non-limiting embodiments, suspensions are made that contain 2% by weight (a 2% suspension) or that contain 1% by weight (a 1% suspension) nanofibers in the aprotic solvent.

**Aramid Material**

[0037] The aramid material described herein is made of aramid polymers, generally in the form of fibers, threads, or yarns. Aramid fibers of micro or macro dimensions are commercially available. Typically a commercially available aramid fiber is characterized by a diameter in the micro range, for instance by a diameter of one micron or greater. In one aspect, the current disclosure provides methods for transforming the commercially available microsized aramid fibers into aramid nanofibers.

[0038] Aramid polymers are defined as those that contain aromatic groups and amide linkages in the backbone. Normally, the amide groups provide linkages between adjacent aromatic groups. In one aspect, an aramid polymer is characterized as one in which at least 85% of the amide groups in the backbone are directly attached to two aromatic groups, especially where the aromatic groups are phenyl groups.

[0039] Two popular aramids are para-aramid fiber and meta-aramid fiber. The former is well known under the trademark of Kevlar® and others. Its backbone consists of phenyl groups separated by amide linkages, wherein the amides link the phenyl groups in a para configuration. A para-aramid represented by Kevlar® is also called a poly (para-phenylene terephthalamide) (PPTA). Although the synthesis is not limited to reacting the particular monomers, in a simple form, a PPTA can be understood as the reaction product of para-phenylene diamine and terephthaloyl dichloride. In similar fashion, a meta-aramid such as illustrated by Nomex® material can be understood as the product as para-phenylene diamine and isophthaloyl dichloride.

[0040] Besides meta-aramids like Nomex® and para-aramids like Kevlar®, other aramid fibers are available of the copolyamide type. Copolyamides have structures that result from polymerizing other aromatic diamines with terephthaloyl or isophthaloyl
chlorides, alternatively in the presence of para-phenylene diamine. In whichever way the aramid fibers are produced, it is believed that the useful physical properties of the fibers derive from the stiff nature of the polymers and orientation along the fiber direction of the aromatic chains.

[0041] The aramid material can also be obtained from used bullet proof vests, tents, ropes, or other items containing Kevlar/aramid macroscale fibers, or from waste or scrap from the manufacture of the aramid materials. The source materials will be cleaned and dissolved in DMSO following the protocol being used for the pristine aramid fibers. In this way a method of recycling aramid materials is provided. Impurities can be washed out with organic solvents if desired after the nanofiber suspension is produced.

Nanofibers

[0042] Aramid nanofibers are defined by their composition and by their dimensions. Aramid nanofibers are made of aramid material such as discussed above. By nanofibers is meant that the diameter is in the nanometer range, and especially in the range of 3 to 100 nanometers, 3 to 50 nanometers, 4 to 40 nanometers, 3 to 30 nanometers, and 3 to 20 nanometers. In addition to diameters in the nanometer range, the aramid nanofibers are characterized by a high aspect ratio, meaning that the length of the fibers is at least 5 times, at least 10 times, or at least 20 times the diameter. In various embodiments, the length of the aramid nanofibers is greater than 0.1 microns or greater than 1 micron. Non-limiting examples of the length of the aramid nanofibers includes 0.1 to 10 microns and 1 micron to 10 microns.

Making Suspensions Of Aramid Nanofibers

[0043] A process begins with commercially available aramid fibers having macro dimensions. Suitable aramid materials include those represented by the Kevlar® and Nomex® trade names and by aromatic copolyamide materials.

[0044] In a preferred first step, an aramid fiber is treated with ultrasound in a solvent to swell the fiber as a preliminary step in the manufacture of a nanofiber. Examples of ultrasound treatment are given in the examples below. It has been found suitable to sonicate the starting material aramid fiber in a solvent such as NMP to swell the fiber before further reaction. After the ultrasound treatment, the swollen fiber is removed from the NMP solvent and combined in another solvent in the presence of a base. The
fiber is then reacted with the base and the solvent at low to ambient temperatures for a
time until nanofibers are formed. Advantageously, the temperature of reaction is at 50° or
less, at 40° or less, or at 30° or less. In various embodiments, the temperature of reaction is
20 to 50°C, 20 to 40°C, or 20 to 30°C. Reaction can be carried out at or about 20°C or at
or about 25°C. Reaction at 25°C is considered to be at room temperature.

[0045] In a preferred embodiment, the solvent used to prepare the nanofibers is
dimethyl sulfoxide (DMSO) and the base is potassium hydroxide (KOH). Preferably, the
base is provided in stoichiometric excess to the aramid material, and is conveniently
applied in a one-to-one weight ratio. Relative to the amount of solvent, the combined
weight of the base and the aramid material is from about 0.05 to 5%. In an exemplary
embodiment, 500 mL of solvent is used, in which 1.5 grams of KOH are dissolved and in
which 1.5 grams of aramid fiber material is suspended.

[0046] As detailed below, the reaction conditions are sufficient to transform the
macro-dimensioned aramid starting material into aramid nanofibers having dimensions as
discussed above and further exemplified below. The reaction conditions do not lead
completely to dissolution of the aramid material. As a result, the reaction product is a
suspension of nanosized aramid nanofibers in a solvent system that preferably contains a
DMSO.

[0047] In addition to DMSO, the solvent system can contain small amounts of
water, for example wherein the volume ratio of water to the solvent (i.e. an aprotic solvent
such as DMSO) is from 1/20 to about 1/1,000. In various embodiments, it has been
observed that the presence of water leads to production of nanofibers having a smaller
diameter. In this way, the diameter of the nanofibers produced by the method can be
controlled to a desirable extent.

Polyalkylene oxide

[0048] In various embodiments, alternating layers of polyalkylene oxide are used
with layers of aramid nanofibers to make free standing films. Examples include polymers
and copolymers of predominantly low C2-C4 alkylene oxides such as ethylene oxide,
propylene oxide, and butylene oxide. Water soluble polyalkylene oxides are preferred. A
preferred material used in the Examples is polyethylene oxide. Commercially available
PEO can be used having a nominal molecular weight or about 200 to about 10,000.
Examples include those known under the generic names of PEG 200, PEG 400, PEG 800, PEG 1000, PEG, 2000, PEG 4000, PEG 10,000, and the like. Aqueous solutions of PAO are used to build up the ANF ICMs of the present disclosure.

**LBL assembly and Hydrogel Spin Coating**

**[0049]** In one embodiment, free standing films are built up by depositing alternating layers of ANF and PAO on a substrate, then after construction removing the film from the substrate. The process is readily automated, and can also be carried out manually.

**[0050]** One way involves layer by layer assembly. For the (PAO/ANF<sub>m</sub>) films, a first layer of PAO is applied by exposing the substrate (such as a glass slide) to a solution of PAO for a few seconds or a few minutes, removing the slide from the solution, and rinsing. Thereafter the slide containing one layer of PAO is exposed to a solution or suspension of aramid nanofibers, again for a brief time encompassing a few seconds up to a few minutes, followed by rinsing. In this way a bilayer PAO/ANF is laid down, and the process is then repeated or reiterated n times to build up (PAO/ANF<sub>m</sub>). As noted, n is preferably at least 5, at least 10, at least 20, at least 50, or at least 100. In various embodiments, the maximum number of layers is 50, 100, 200, 300, 500, or 1000.

**[0051]** In another embodiment, hydrogels containing ANFs are built up on a slide to provide free standing films useful as ICMs. The ICM in this embodiment is a free standing film comprising multiple layers of ANF hydrogels. In a non-limiting example, 1% Aramid fiber dispersion is dropped onto a glass slide. The glass slide is then spun at 1000 rpm to form a uniform film on top of the glass slide. Deionized water is then gently poured over the ANF film to form the ANF hydrogel. Polymer solutions, such as the polyalkylene oxide and polyethylene oxide described herein, can be used in place of DI water to form an ANF/polymer composite hydrogel. The glass slide is spun again at 1000 rpm to remove excess water/polymer solution. The ANF hydrogel coated glass slide is then dried in a 70°C vacuum oven for 30 minutes. The process is repeated until a desired thickness is reached. For a typical 3μm ANF film, this process is repeated 10 times. The ANF film is then detached from the glass slide using a 0.1% hydrogen fluoride solution.
The ANF is washed with DI water and ethanol repeatedly to remove excess HF and subsequently dried in a 70°C oven.

**Depositing the suspension on the substrate**

[0052] In addition to the layer by layer technique, suitable thicknesses of membrane can be built up faster using other coating techniques such as doctor blading, spin coating, spray coating, and the like. The membrane can be built up in multiple or repeated applications of these techniques, or in a single application, depending on the requirements. For example, a layer by layer process can be “assisted” by spin coating, whereby a plurality of layers are added on top of one another to build up a thick membrane. The thickness is built up in this way much faster than with the conventional LBL technique. Thus 5 to 20, 30, 40, or 50 layers can be deposited to build up a thick membrane.

[0053] Depending on the intended application, the suspension of nanofibers can be deposited on the substrate using doctor blading. Another alternative is spray coating. All of these techniques for putting a composition on a substrate are known and can be adapted.

**Removing the deposited suspension from the substrate**

[0054] Once the suspension has been deposited onto the substrate and built up to a suitable thickness, it can be released by treating it with water. The film undergoes a water/DMSO solvent exchange process and releases from the substrate. After further drying and optional pressing, the membrane is ready for use. For example, the released membrane is dried between sheets of Teflon under compression and under vacuum at a temperature sufficient to remove residual water and other solvent.

**Formulating additives into the nanofiber suspensions**

[0055] Before the suspensions are deposited onto the substrate, additives can be incorporated to provide additional benefits. For example, powder additives can be included in the dispersion before the depositing process by means of a suitable mixer (for example a speed mixer, a flacktek mixer, or a planetary mixer). The dispersion is measured out into a mixer container in addition to the additive powder. Grinding media such as zirconia beads can be added to ensure a smooth mixture. The dispersion is then mixed until a homogenous solution is achieved. The container is then placed under
vacuum to remove any air bubbles trapped in the viscous dispersion. The dispersion is now ready to be deposited onto the substrate.

[0056] One class of additives comprises the inorganic or ceramic nanoparticles. These are characterized by nanosizes on the order of less than a micron; they contribute strength, porosity, and other advantages to the membranes. It is preferred to use nanoparticles with a size less than one micron, for example, from 5 nm to 1000 nm, so as to be able to incorporate the particles into suitably thin membranes. Non-limiting examples include nanopowders of silica, alumina, titania, zirconia, magnesium oxide, and calcium oxide. Other suitable powders are nanosized zeolites and ceramic electrolytes such as lithium phosphorus oxy nitride (LIPON). Such materials are commercially available.

[0057] Other additives include polyelectrolytes that are incorporated into the membrane, for example to provide for ion conduction, either of cations or of anions. Non-limiting examples include polycations such as poly(diallylammonium chloride (PDDA) and polystyrene sulfonate (PSS).

[0058] Another class of additives is materials, usually organic, that sublime at low temperatures, such as 100°C or less under reduced pressure. These are added to the suspensions and lead to porosity in the membrane when the dried membrane containing the material is subjected to sublimation conditions. A useful material is naphthalene, which sublimes under reduced pressure.

[0059] Other additives include polyethylene oxide and related polyalkylene oxides, which can serve to enhance solid state lithium conduction.

[0060] The additives are incorporated at levels suitable for obtaining the desired benefits. For the polyelectrolytes, about 15 – 20%, based on the content of nanofibers has been found suitable. For additives that lead to porosity (e.g. the nanopowders and the subliming material), the amount to be used is varied to achieve the right amount of porosity. Generally, the additives are incorporated at a rate of 10% - 200% relative to the level of the nanofibers.
Porosity and size of the membranes

[0061] In various embodiments, the membranes are characterized by a porosity that makes them suitable for use in battery and other applications. The porosity of the membranes is controlled by the process used for making it, and the additives formulated into the suspensions, as discussed herein. In various embodiments the membranes have a porosity of 10 – 90%, of 20 – 80 %, or of 30 – 70%. In other embodiments, the membranes have a porosity of at least 10% at 20%, at least 25%, at least 33%, at most 90%, at most 75%, at most 60%, at most 50%. Porosity can be determined by determining the volume of a membrane (area times the thickness) and comparing the mass of the membrane to the mass of a block of ANF. The porosity is the mass of the membrane divided by the mass of the block times 100. In this determination, the loss of mass in the membrane is attributed to the presence of pores. In other embodiments, the porosity is determined using the ASTM standard method for porosity D2873, which is a gas absorption method.

[0062] The aramid nanofibers form films and bulk composites with tightly interpenetrating network of the nanoscale fibers. The pore size in these networks can be less than 10 nm which is sufficient for ion transport. At the same time this size pore size is very restrictive for the growth of dendrites whose diameter and growth point exceed 50 nm in size. For dendrite suppression it is preferred to make membranes with pore sizes on the order of about 20 nm or less. For example, pore sizes of 5 nm or less can be achieved making ANF only membranes. The pore size is affected as well by the amount and particle size of additives such as the nanoparticles described herein. Nanoscale pores of the ANF networks suppress the growth of dendrites because the walls of the pores do exhibit mechanical pressure on the growing dendrite and alter conditions of metal deposition at the tip. Pore size is measured using mercury porosimetry. A nitrogen physisorption method such as a BET method can also be used to determine pore size and surface area.

[0063] In contrast, other nonwoven separators and ICMs such as those made from cellulose or even those made from aramid materials (Dreamweather) with pore size larger than the dimensions of the dendrites will not be able to restrict dendrite growth as well as ANF nanoporous networks.
For use in batteries, a minimum thickness of about 5 microns is preferred because of the desire to make a strong membrane that will not short. As a rule, a membrane is made of a thickness that will give it the tear strength needed for the application, but no thicker so as not to waste material. The thickness of the membrane is controlled by how thick a layer of the ANF suspension gets deposited on the substrate during manufacture. This in turn depends on the setting of the doctor blade, or how many individual layers are deposited, for example by LBL or by spin coating assisted LBL.

Further non-limiting aspects of the invention are now described. The linear growth of the (PEO/ANF)ₙ film was indicated via UV-vis spectroscopy by the steady increase in the absorbance at 330 nm as the number of LBL deposition cycles, n, increases. (Figure 4). Free-standing LBL multilayers were obtained by chemical delamination of (PEO/ANF)ₙ films (SI) after the deposition of 10-200 bilayers. Their smoothness, transparency, and strong interference colors indicated their uniform thickness and structural homogeneity, which can be also seen in SEM and optical images (Figure 1D-F). AFM images of (PEO/ANF)₃ display a dense and uniform interconnecting network of thin nanoscale fibers (SI, Figure 8). Such morphology provides structural prerequisites for high ion conductance, stiffness, and efficient distribution of external stresses. The ultimate tensile strength, Young’s modulus, and shear modulus were σICM = 170±5 MPa, EICM = 5.0±0.05 GPa and GICM = 1.8±0.06 GPa, respectively (Figure 7). Given PEO’s value of EICM = 100 MPa, (PEO/ANF)₂₀₀ nanocomposites show a ca. 500-fold increase in the elastic modulus. Their impregnation with lithium triflate (often used in Li batteries) did not change the mechanical nature of the (PEO/ANF)₂₀₀ nanocomposite.

Crystallization of PEO is known to dramatically decrease ionic conductivity of ICMs made by traditional casting or blending. However, in the (PEO/ANF)ₙ composite we do not observe crystalline phase even though the polymer is deposited at room temperature, under which conditions PEO crystallization should spontaneously occur for thermodynamic reasons, suggesting that LBL deposition effectively prevents PEO crystallization. This fact can be confirmed by X-ray diffraction (XRD) (Figure 9) wherein the material displays a diffuse broad band for 2θ between 20° and 30° instead of sharp peaks at 2θ = 19° and 2θ = 23° observed in crystalline PEO (Figure 9). Differential scanning calorimetry data (DSC) also support this conclusion (Figure 3E). Neat PEO shows a sharp endothermic peak around 70°C, which corresponds
to melting of the crystalline polymer, which is completely absent in the DSC curve for 
(PEO/ANF)n (Figure 3E). In FT-IR spectra of the nanocomposites, we observed a strong 
peak at 2860 cm⁻¹ (Figure 10) assigned to intermolecular hydrogen bonds between PEO 
and ANF. The prevention of PEO crystallization and the efficient LBL assembly is 
credited to these bonds.²⁵

[0067] In order to investigate ionic conductivity, free-standing (PEO/ANF)n 
membranes were sandwiched between two lithium metal electrodes and housed in a 
CR2032 coin battery cell. Without any additives or additional treatments, the ionic 
conductivities of (PEO/ANF)₂₀₀ at 25°C and 90 °C were Ω_{ICM,25°C} = 5.0 \times 10^{-6} \text{ S/cm} and 
Ω_{ICM,90°C} = 2.6 \times 10^{-5} \text{ S/cm}, respectively. The (PEO/ANF)₂₀₀ membrane was immersed in a 
1M lithium triflate solution in a propylene carbonate (PC)/dimethyl carbonate (DMC) 
1:1 v/v mixture, followed by overnight drying in a vacuum oven, resulting in a solid 
material. The ionic conductivity of (PEO/ANF)₂₀₀ after that was 5.5 \times 10^{-5} \text{ S/cm}, which is 
comparable with some Li sulfide glasses.¹⁶,¹⁷ To better replicate the actual battery 
conditions and mitigate contact resistance between the electrode and the solid 
(PEO/ANF)₂₀₀ membranes, 150 Ml of a 1M lithium hexafluorophosphate solution in a 
ethylene carbonate (EC)/dimethyl carbonate (DMC) 1:1 v/v mixture was added to each 
side of the membrane. The ionic conductivity of (PEO/ANF)₂₀₀ reached values as high as 
Ω_{ICM,25°C} = 1.7 \times 10^{-4} \text{ S/cm}.

**Batteries**

[0068] One use of the free standing film is as an ion conducting membrane (ICM) 
in a battery such a lithium battery. In this application, the ICM can be disposed in an 
electrode assembly between a cathode and an anode. The electrode assembly is used in 
conventional fashion to make an electrochemical cell, and a battery (for example a lithium 
battery) can be made up of a plurality of electrochemical cells. The ICM’s made of 
(PAO/ANF)n have the useful property of being resistant to puncture or rupture by 
dendrites formed during operation of the battery or cell.

[0069] With respect to dendrite propagation, we have to point out that 
investigation of lithium dendrite growth and suppression is practically complicated due to 
the high reactivity of lithium metal with ambient air and water. Fast oxidation of Li metal 
changes the shape, length, and mechanical properties of the dendrites, making the results
inconclusive. Therefore we decided to carry out an analogous study for copper dendrites, which can serve as a convenient experimental model under ambient conditions. The results obtained for copper do remain relevant for lithium as the Young’s modulus of copper is $E = 129.8$ GPa, while that of lithium is $E = 4.91$ GPa. If an ICM can stop copper dendrites from propagating, it will also suppress the much softer lithium dendrites. In addition, note that copper ion-based batteries are also being considered, and the insights gained into the engineering of materials with a combination of desirable mechanical properties and high ionic flux are also applicable to them (26).

[0070] To design successful dendrite-suppressing ICMs we need to consider the dimensions of dendrites and of ion-conducting pores. The growth zones of dendrites, $d_{\text{dendr}}$, are 50-100 nm in size (Figure 2E & I). The dendrites propagate through ICMs via the path of the least mechanical resistance. Importantly, typical polymeric ICMs are made as heterogeneous membranes to provide high ionic conductivities. Therefore, if a heterogeneous material has soft pores larger than $d_{\text{dendr}}$, the parts with low modulus determine the propagation of dendrites rather than the stiffer parts. If the heterogeneity of an ICM is smaller than $d_{\text{dendr}}$, the growth zone of the dendrite experiences a resistance equal to the averaged modulus of the membrane.

[0071] Many ICMs are strongly heterogeneous at scales much greater than $d_{\text{dendr}}$. Celgard™, for instance, is microscopically stiff with an $E$ value of 1.1 Gpa and a tensile strength of 11.1 Mpa, but it has large pores of ion-conducting gel with sizes of ca. 430 nm (Figure 1A). Consequently, the mechanical properties relevant to dendrite growth are those found in the propylene carbonate and ethylene carbonate loaded with lithium salts\textsuperscript{11}. Being liquids, the electrolytes offer little to-no resistance with regard to blocking dendrite growth. The scale of inhomogeneity and dendrite inhibition in (PEO/ANF)$_n$ is very different. (PEO/ANF)$_n$ exists as a film of tightly interconnected PEO and ANF networks. Pores in the film are ca. 20 nm in diameter (Figure 1C,D). In comparison, we observed that copper dendrites have growth zones with sizes of 50-100 nm and tip diameters of 25 nm (Figure 1B). The growth of dendrites will experience the component-averaged (macroscopic) stiffness of (PEO/ANF)$_n$ since its pores are smaller than the dendrite tips.

[0072] Investigation of dendrite growth was carried out under harsh conditions of high current density (10.3 mA/cm$^2$). This rate is equivalent to 6-7 C extreme charge/discharge rate, at which one could fully charge a battery in less than 10 minutes,
while the typical charging rate for batteries is ca. 0.25 C. Copper electrodes with and without (PEO/ANF)_{10}, (PEO/ANF)_{30}, and (PEO/ANF)_{50} coatings were investigated by SEM (Figure 2) after a constant total charge Q = 0.006 mAh/cm² was transferred. Hemispherical copper dendrites on average 500 nm in diameter were formed on the bare Cu electrode (Figure 2A, E, I). The dendrites were no longer visible on electrodes coated with as few as 10 bilayers, i.e. (PEO/ANF)_{10} (Figure 2B, F, J), corresponding to a film thickness of 162 nm. However, cracks from dendrite growth are observed (Figure 2J) and indicate dendrite formation underneath the (PEO/ANF)_{10} film. Dendrites were completely suppressed for the electrode carrying (PEO/ANF)_{30} (Figure 2C, G, K), corresponding to a film thickness of 486 nm. In this case dendrites could no longer penetrate through or break the film. The dendrites were reduced to an evenly deposited layer at the interface underneath the film, which is exactly the behavior necessary for a successful battery. Deposition of (PEO/ANF)_{30} films with a thickness of 809 nm results in further suppression of dendrite formation (Figure 2D, H, L). We believe that (PEO/ANF)_{n} films suppress the growth of dendritic deposits by exerting a compressive force on them while being able to sustain the ionic flux through the membrane in accord with a previously elaborated theoretical mechanism.14

[0073] Figure 3A summarizes the mechanical and electrochemical properties of current ICMs and (PEO/ANF)_{n}. Popular separators such as Celgard™ monolayer PP, PE, and trilayer PP/PE/PP have thicknesses ranging from 12 to 40 μm, and when infused with electrolyte give an internal resistance of R_1 = 0.25 Ohm. However, the large pores providing the conductive pathways also allow for the uninhibited growth of dendrites because of the softness of the containing gel. Solid electrolytes, such as polymers incorporating inorganic or organic fillers, generally exhibit higher ionic conductivity than their pure polymer forms. These membranes are cast with a thickness of 100-400 μm, which in turn can introduce internal resistance as high as 2000 Ohm. The consummate mechanical properties and ionic conductivity of (PEO/ANF)_{n} makes possible a substantial reduction of thickness of ICMs based on their ability to significantly decrease internal resistance by 2 to 3 orders of magnitude without sacrificing mechanical properties or dendrite suppression. A 486 nm (PEO/ANF)_{30} ICM introduces 0.16 Ohm of resistance into the CR2032 battery cell and still exhibits higher mechanical strength than any polymer-based electrolyte and separator, being even competitive with Li-based ceramics. To
substantiate the practicality of $(\text{PEO/ANF})_{30}$ ICMs and their chemical stability in contact with lithium metal, we assembled a battery cell using $(\text{PEO/ANF})_{200}$, a lithium metal anode, and a LiCoO$_2$ cathode. The cell was studied over 50 cycles at C/4 (39 Ma/g, Figure 3D). The battery exhibited a discharge capacity of over 100 mAh/g and an excellent discharge efficiency of 98%. Although the battery parameters are limited by the stability of LiCoO$_2$ cathode and the charge transfer kinetics at both cathode and anode, which complicate evaluation at extreme charge rates, this test demonstrates that a film as thin as 3μm can perform at least as well as 25μm thick layer of Celgard$^\text{TM}$ and prevent rapid deterioration of the battery due to lithium metal dendrite growth. Further studies were conducted to comparatively investigate the thermal stability of $(\text{PEO/ANF})_n$ nanocomposites which is needed when battery operates under elevated temperatures, high charge density, high discharge rate conditions$^{27,28}$ or with malfunctioning thermal management system. In the hot solder iron test accepted in industry as a standard, a 180°C solder iron tip was placed on both a PEO-ANF film and a Celgard 2400 PE separator for 30 seconds. The Celgard$^\text{TM}$ 2400 PE was burned and a hole formed in it. The PEO-ANF film showed no damage (Figure 3B), which can be attributed to the high temperature stability of Kevlar$^\text{®}$ translating also into ANFs. In the high-temperature oven test, both PEO-ANF and Celgard$^\text{TM}$ 2400 PE were kept at 200°C for 10 minutes. Celgard$^\text{TM}$ PE melted completely. PEO-ANF remained flat, intact, and un-deformed (Figure 3C), indicating that high-temperature shrinkage and deformation are minimal for $(\text{PEO/ANF})_n$ ICMs. Thermal stability tests of the PEO-ANF nanocomposite investigated by DSC and TGA (Figure 3E & F) demonstrated stability exceeding 400°C, which is exceptional among polymeric ICMs and is comparable to Li-based ceramics (17).

[0074] In conclusion, PEO and ANFs can be assembled into ICMs in which amorphous PEO produces ion-conducting channels smaller than $d_{\text{dendr.}}$. $(\text{PEO/ANF})_{30-200}$ films display ionic conductivity as high as $1.7 \times 10^{-4}$ S/cm and are capable of complete suppression of hard copper dendrites at a thickness of less than 500 nm even when operating under extreme charge/discharge rate conditions. Resilience to harsh electrochemical and thermal conditions, high flexibility and high ionic flux accompany these properties, a combination that has been thus far difficult to achieve in other classes of ion-conducting materials, while being essential for high energy density, high charge/discharge rate batteries.

EXAMPLES

Example 1. For 500mL 2% ANF dispersion or 1% ANF dispersion

10g (5g for 1%ANF) of Kevlar yarn is weighed out and placed in a 500mL bottle with a magnetic stir bar. 10g of KOH (5g for 1%ANF) is added to the bottle. 500mL of anhydrous DMSO is then added. The bottle is then sealed and stirred for approx. 28 days or until all visible fibers are dissolved. The resulting solution should be a clear dark red color with no signs of fibers.

Example 2. Incorporation of Additives (Al₂O₃ example)

[00103] A high speed planetary mixer (Flactek Inc.) is used to incorporate the additives into the ANF dispersions. 5g of 2% ANF dispersion is weighed out into a mixing cup followed by 0.01g (50 wt% dry weight, for 50/50 Al₂O₃/ANF separator) of Al₂O₃ nanoparticles (50nm from Sigma Aldrich). The mixture is then mixed at 1500 rpm for 5 minutes. Zirconia based grinding media can be used to improve the particle dispersions if needed. The Al₂O₃/ANF mixture is then placed under vacuum to remove any trapped air bubbles in the mixture. This will ensure a pinhole-free separator. The mixture is then aged for a day and bladed into a separator using the doctor-blading process.

Example 3. Doctor Blading for Lithium ion/Lithium sulfur separators

[00104] A 2% ANF dispersion is prepared using the same DMSO/KOH method as before. The dispersion should be a dark red viscous solution. The dispersion is then poured evenly on a substrate (glass, Teflon, tin foil etc) and spread evenly with an automatic doctor blade machine (blade height=600µm for a 10µm dried separator. The substrate is then removed and immersed into a water bath. The bladed film will then undergo a
DMSO/water solvent exchange process. The bladed film is transformed into a thick yellowish ANF hydrogel and will automatically release from the substrate. The floating substrate is then dried between two sheets of Teflon under compression and under vacuum at 110°C.

Example 4. Preparation of (PEO/ANF)$_n$ nanocomposite ion conductors:

[00105] Multilayers of PEO and ANFs are prepared following the classical LBL deposition process$^{1-5}$ with exception of the use of dimethyl sulfoxide (DMSO) as solvent and rinsing solution for assembly steps involving ANFs. Note also that the film preparation process used here is markedly different than the one used in the previous study by M. Yang et al.$^6$ by the use of partner electrolyte in all of the deposition steps while M. Yang et al.$^6$ used ANF-on-ANF deposition.

[00106] Glass slides are pre-cleaned by piranha solution for 2 hours followed by extensive rinsing with D$_1$ water (18 MΩ) immediately prior to the LBL assembly. The glass slides are dipped in solutions of 0.01% PEO in DI water for 1 minute, rinsed in D$_1$ water for 1 minute, air dried and then dipped in a 0.04% ANF dispersion in DMSO for 10 seconds. The rinsing step after deposition of ANF consisted of a DMSO bath for 30 seconds followed by a 1 minute rinse in D$_1$ water and air drying.

[00107] The growth of a (PEO/ANF)$_n$ LBL composite on glass slides was monitored by UV-visible spectroscopy to ensure the consistency of the deposition. By tracking the absorbance at a wavelength of 330 nm, one can observe steady deposition of PEO and ANFs (Figure S1). This is a very typical build-up process by layer-by-layer assembly as well dispersed polyelectrolytes / nanomaterials are deposited on the substrate surface at nanometer scale.$^{7-12}$ The interactions that enable LBL deposition here are likely to be the strong hydrogen bonds formed between amide -N(H)- groups and -O(\cdot)- groups. Cooperative hydrogen bonding has shown the capability to produce diverse LBL multilayers in several previous studies.$^5,12$

[00108] The macroscale uniformity of the deposited composite can be observed in Figure 5. (PEO/ANF)$_n$ LBL composites are detached from glass slides as continuous
membranes by immersing the slides in 0.1% HF for <3 minutes. Freestanding membranes are rinsed with D$_1$ water until the pH value at the membrane surface becomes neutral (pH 7), and are then dried in a vacuum oven at 80°C.

**Example 5. Ionic conductivity measurements:**

[00109] Free-standing (PEO/ANF)$_n$ membranes were sandwiched between two lithium metal electrodes and housed in a CR2032 coin battery cell. Impedance spectroscopy was performed using an Autolab potentiostat and Solartron 1260 frequency response analyzer. The resulting Nyquist plots are fitted to a equivalent circuit where ionic conductivity is then calculated.

**Example 6. Growth of copper dendrites:**

[00110] 1 μm-thick smooth copper layers deposited on silicon wafer using physical vapor deposition are used as working electrodes. LBL membranes are then deposited onto the copper layer using the procedure described in Section 1. The copper-Si wafer electrode is dipped into a 0.15 M copper chloride solution in anhydrous DMSO with 1 cm$^2$ of submerged surface area (Figure 7). 10.3 mA/cm$^2$ is applied to the electrode with a copper plate.

**Example 7. Preparation of (ANF/ANF)$_n$ film:**

[00111] The (ANF/ANF)$_n$ film used in FTIR experiments was obtained using the procedure describe by Ming Yang et al. (6): A clean piece of glass slide was dipped into a 1% poly(diallyldimethyammonium chloride) (PDDA) solution for 1 min and rinsed with D$_1$ water for 2 mins before air drying. The PDDA-coated glass slide is then dipped into the 0.04% ANF dispersion for 1 min and rinsed with water for 2 mins before air drying. This sequence is repeated 100 times to obtain a free-standing (ANF/ANF)$_{100}$ film.

**Example 8. Preparation of LiCoO$_2$, Coin Cell:**

[00112] A slurry of 88% lithium cobalt oxide (LiCoO$_2$), 6% SuperP Li Carbon and 6% PVdF is made using a planetary mixer. The slurry is then cast onto an aluminum foil substrate using a doctor blade to form an electrode. The electrodes are dried in a vacuum oven overnight at 110°C and then punched out and transferred into an argon-filled
glovebox. The electrodes are then assembled into standard CR2032 coin cells along with the (PEO/ANF)_{300} electrolyte, 150 µL of a 1M LiPF₆ in EC/DMC solution, lithium metal anode, stainless steel spacers and spring washers. The cells are left in the glovebox overnight before being placed onto a Maccor battery tester for charge-discharge experiments.

Example 9. List of References for Figure 3A:

[00113] During the calculation of the internal resistance contribution by different electrolytes, the electrode area was taken to be the area of a typical electrode in a CR2032 coin cell (diameter = 15.6 mm). The elastic modulus (E), ionic conductivity, and thickness of electrolytes were taken from the papers listed below.

[00114] Li10GeP2S12 - N. Kamaya, K. Homma, Y. Yamakawa, M. Hirayama, R. Kanno, M. Yonemura, T. Kamiyama, Y. Kato, S. Hama, K. Kawamoto, A. Mitsui, A lithium superionic conductor, Nature Materials 10, 682-686 (2011). When calculating internal resistance for Li10GeP2S12, the thickness was taken to be 100 µm according to the Ref 9 by T. Inada et al. cited in this publication.

[00124] PEO/Li Triflate/Ceramic filler - C. Leo, Studies on plasticized PEO-lithium triflate–ceramic filler composite electrolyte system, *Solid State Ionics* **148**, 159-171 (2002). Ceramic filler used is Li NaSi compound [Li1.4(Al0.4Ge1.6)(PO4)$_3$].

SUPPLEMENTARY REFERENCES

CLAIMS

We claim:

1. A free standing film, comprising alternating layers of aramid nanofibers (ANF) and polyalkylene oxide.

2. The film of claim 1, wherein the polyalkylene oxide comprises polyethylene oxide (PEO).

3. The film of claim 1 or claim 2, having from 5 to 500 alternating layers of ANF and polyalkylene oxide.

4. The film of claim 2, having at least 10 alternating layers of ANF and PEO.

5. The film according to any of the preceding claims, having a thickness of 3 microns or greater.

6. An electrode assembly, comprising a cathode, anode, and an ion conducting membrane (ICM) disposed between the cathode and anode, wherein the ICM comprises aramid nanofibers and polyoxyalkylene oxide.

7. The electrode assembly of claim 6, wherein the ICM has the structure (PEO/ANF)$_n$, where n is from 5 to 500 and where PEO/ANF represents alternating layers of polyethylene oxide and aramid nanofiber.

8. The electrode assembly of claims 6 or 7, wherein at least one of the cathode and anode is a lithium metal electrode.

9. A lithium cell comprising an electrode assembly according to any of claims 6-8.

10. A lithium battery comprising a plurality of cells according to claim 9.

11. A method of making a free standing film according to any of claims 1 to 5, comprising layer by layer (LBL) assembly of alternating layers of ANF and polyalkylene oxide.

12. A free standing film comprising built up layers of a hydrogel comprising aramid nanofibers.
13. The free standing film of claim 12, wherein the layers of hydrogel comprise aramid nanofibers and polyoxyalkylene.

14. A redox flow battery comprising:
a positive electrode cell comprising a positive electrode and a catholyte solution;
a negative electrode cell comprising a negative electrode and an anolyte solution; and
an ion exchange membrane interposed between the positive electrode cell and the negative electrode cell,
wherein the ion exchange membrane comprises aramid nanofibers and has a porosity of 20 – 80%.

15. A free standing membrane comprising aramid nanofibers fibers and having a porosity of 20 – 80%.

16. The membrane of claim 15, wherein the porosity is 30 – 60%.

17. The membrane of claim 15, further comprising nanoparticles, wherein the ratio of weight of the nanoparticles to the nanofibers is from 1:2 to 2:1.

18. The membrane of claim 17, wherein the ratio is from 1.2:1 to 1:1.

19. The membrane of claim 17, wherein the nanoparticles comprise particles selected from silica, alumina, zirconia, titania, magnesium oxide, and calcium oxide.

20. The membrane of claim 17, having a thickness in the range from 5 microns to 100 microns.

21. The membrane of claim 20, wherein the thickness is about 10 microns.

22. A method of making a nanofiber membrane, comprising:
exposing aramid fibers to base in an aprotic solvent to make a suspension of aramid nanofibers;
depositing the suspension of nanofibers on a substrate;
exposing the substrate to water, to remove the aprotic solvent and release the deposited suspension from the substrate; and
drying the released suspension to form a free standing membrane.

23. The method of claim 22, wherein depositing comprises layer by layer assembly.

24. The method of claim 22, wherein depositing comprises spin coating.

25. The method of claim 22, wherein depositing comprises doctor blading.

26. The method of claim 22, wherein the aprotic solvent comprises dimethyl sulfoxide.

27. The method of claim 22, further comprising treating aramid fibers in a solvent with ultrasound before exposing the fibers to base in an aprotic solvent.
28. The method of claim 22, comprising combining an additive with the suspension before the depositing step.

29. The method of claim 28, wherein the additive comprises a nanoparticle.

30. The method of claim 29, wherein the nanoparticle is selected from silica, alumina, zirconia, titania, magnesium oxide, and calcium oxide.

31. The method of claim 28, wherein the additive comprises a polyelectrolyte.

32. The method of claim 28, wherein the additive comprises a material that sublimes under vacuum at a temperature below 100°C.

33. A battery comprising an ion conductive membrane, wherein the membrane is made by a method according to claim 9.

34. (A thin film battery comprising ANF-based ion-conducting media, wherein the ion conducting media comprises aramid nanofibers.)

35. A 18650 type of battery, comprising ion-conducting media based on aramid nanofibers.

☐ Further documents are listed in the continuation of Box C. ☒ See patent family annex.

* Special categories of cited documents:
  *A* document defining the general state of the art which is not considered to be of particular relevance
  *E* earlier application or patent but published on or after the international filing date
  *L* document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)
  *O* document referring to an oral disclosure, use, exhibition or other means
  *P* document published prior to the international filing date but later than the priority date claimed

*T* later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention

*X* document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone

*Y* document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art

*&#x26; document member of the same patent family

Date of the actual completion of the international search
17 June 2015 (17.06.2015)

Date of mailing of the international search report
18 June 2015 (18.06.2015)

Name and mailing address of the ISA/KR

Form PCT/ISA/210 (second sheet) (January 2015)
**INTERNATIONAL SEARCH REPORT**

**Box No. II  Observations where certain claims were found unsearchable (Continuation of item 2 of first sheet)**

This international search report has not been established in respect of certain claims under Article 17(2)(a) for the following reasons:

1. ☐ Claims Nos.:
   because they relate to subject matter not required to be searched by this Authority, namely:

2. ☒ Claims Nos.: 10, 33, 35
   because they relate to parts of the international application that do not comply with the prescribed requirements to such an extent that no meaningful international search can be carried out, specifically:
   1. Claims 10 and 33 refer to claim 9 which does not comply with PCT Rule 6.4(a).
   2. The term "A 18650 type of battery" of claim 35 is not supported by the description as required by PCT Article 6.

3. ☒ Claims Nos.: 5, 9, 11
   because they are dependent claims and are not drafted in accordance with the second and third sentences of Rule 6.4(a).

**Box No. III  Observations where unity of invention is lacking (Continuation of item 3 of first sheet)**

This International Searching Authority found multiple inventions in this international application, as follows:

1. ☐ As all required additional search fees were timely paid by the applicant, this international search report covers all searchable claims.

2. ☐ As all searchable claims could be searched without effort justifying an additional fees, this Authority did not invite payment of any additional fees.

3. ☐ As only some of the required additional search fees were timely paid by the applicant, this international search report covers only those claims for which fees were paid, specifically claims Nos.:

4. ☐ No required additional search fees were timely paid by the applicant. Consequently, this international search report is restricted to the invention first mentioned in the claims; it is covered by claims Nos.:

**Remark on Protest**

☐ The additional search fees were accompanied by the applicant's protest and, where applicable, the payment of a protest fee.

☐ The additional search fees were accompanied by the applicant's protest but the applicable protest fee was not paid within the time limit specified in the invitation.

☐ No protest accompanied the payment of additional search fees.
