(54) Title: PHYSICAL LAYER PROCESSING FOR A WIRELESS COMMUNICATION SYSTEM USING CODE DIVISION
MULTIPLE ACCESS

(57) Abstract: The invention includes various embodiments for use in physical layer processing. One embodiment determines the address mapping of bits in the physical channel buffer from the address of bits in the first interleaver buffer (82). The physical channel buffer addresses (84) are determined corresponding to addresses of the bits after rate matching (88), bit scrambling (90), second interleaving (92) and physical channel mapping (94). The bits are directly read (78) from the first interleaver buffer (82) and written to the physical channel buffer (84) using the determined physical channel buffer addresses. Another embodiment determines the address mapping of bits in the first interleaver buffer (82) from the address of bits in the physical channel buffer (84). The first interleaver buffer addresses are determined corresponding to addresses of the bits after reverse rate matching (88), reverse bit scrambling (90), reverse second interleaving (92) and reverse physical channel mapping (94). The bits are directly read from the determined first interleaver buffer addresses (82) and written to the physical channel buffer addresses (84).

PHYSICAL LAYER PROCESSING FOR A WIRELESS COMMUNICATION
SYSTEM USING CODE DIVISION MULTIPLE ACCESS

[0001] BACKGROUND

[0002] This application claims priority from U.S. Provisional Patent Application No. 60/284,062, filed on April 16, 2001.

[0003] The invention generally relates to wireless time division duplex (TDD) communication systems using code division multiple access (CDMA). In particular, the invention relates to processing data at the physical layer for such systems.

[0004] In CDMA communication systems, communications are transmitted in the same frequency spectrum over a wireless air interface, distinguished by their channelization codes. To further increase the utilization of the spectrum, CDMA/TDD communication systems time divide the spectrum into repeating frames having a fixed number of time slots, such as fifteen (15) time slots per frame. In TDD, each time slot is only used exclusively for the uplink or downlink.

[0005] Prior to transmission, data for transfer over the air interface is processed by the Universal Mobile Telecommunications System (UMTS) Terrestrial Radio Access Network (UTRAN). A simplified wireless communication system is illustrated in Figure 1. Wireless users (user equipments) 38_1 - 38_N (38) communicate with base stations 36_1 - 36_N (36). Typically, a Node-B 34_1 - 34_N (34) controls a group of base stations 36. A radio

network controller (RNC) 32_1 - 32_N (32) controls a group of Node-Bs 34. The RNCs 32, Node-Bs 34 and other associated components are part of the UTRAN 30. The UTRAN 30 communicates to other users through the core network 40.

[0006] Data processing within the UTRAN 30 is standardized, such as by the third Generation Partnership Project (3GPP), UMTS terrestrial radio access (UTRA) TDD system. The UTRAN 30 processes transport channels for transfer over the air interface. Figure 2 is a block diagram of this UTRAN processing.

[0007] Transport blocks arrive for transport over the air interface. The transport blocks arrive in sets (transport block sets). The sets are received in a specified time interval (transmission time interval (TTI)). For 3GPP UTRA TDD, the possible TTI lengths are 10ms, 20ms, 40ms and 80ms, which correspond to 1, 2, 4 and 8 radio frames respectively.

[0008] A circular redundancy code (CRC) attachment block 42 attaches CRC bits to each transport block. The CRC bits are used for error detection at the receiver. The CRC bit length is signaled from higher layers.

[0009] The transport blocks (TrBks) are serially concatenated by the TrBk concatenation/code block segmentation block 44. If the number of bits of the concatenated blocks is larger than the maximum size allowed for a code block, the concatenated blocks are segmented. The size of the code blocks is based on the type of error correction coding to be used, such as convolutional coding (maximum of 504 bits), turbo coding (maximum of 5114 bits) or no coding (unlimited). The concatenated blocks

are segmented into a minimum number of equal sized segments (code blocks). If the original number of concatenated bits is not an even multiple of the minimum number of segments, filler bits are used to assure the segments are of equal size.

[0010] A channel coding block 46 error correction encodes the code blocks, such as by convolutional coding, turbo coding or no coding. After encoding, the code blocks are concatenated together. If the concatenated code blocks can not be segmented into a minimum number of equal sized segments (frames), Radio Frame equalization is performed by concatenating additional arbitrary bits.

[0011] A first interleaver 48 interleaves all the concatenated data. Subsequently, the interleaved data is segmented into radio frames by a radio frame segmentation block 50. A rate matching block 52 punctures or repeats bits. The puncturing and repeating assures data transmitted on each physical channel (resource unit) equals the maximum bit rate for that channel. The rate matching attributes for each transport channel (TrCH) is signaled by higher layers.

[0012] The TrCH multiplexing block 54 receives one frame's data for each transport channel. The received data for each TrCH is serially multiplexed onto a coded composite transport channel (CCTrCH). A bit scrambling block 56 scrambles the CCTrCH bits.

[0013] A physical channel block 58 maps the scrambled data onto the physical channels. A second interleaver 60 interleaves the scramble data over the entire radio frame or over each time slot. Higher layers dictate the type of interleaving utilized. After second interleaving, the interleaved data is segmented into the physical channels for

transport over the air interface by a physical channel mapping block 62. The physical channel data is subsequently transmitted, such as from a base station 36 or UE 38. At the receiver, such as at a UE 38 or base station 36, the same process is performed in reverse to recover the transmitted data.

[0014] To process data as shown in Figure 2, various levels of buffering (buffers 64, 66, 68, 70, 72) are required, such as after the first interleaver 48, the rate matching block 52, the transport channel multiplexing block 68, the bit scrambling block 56 and the second interleaver 60. This extensive buffering is undesirable. It requires heavy memory utilization and additional application specific integrated circuit (ASIC) space for memory to accommodate the buffering.

[0015] Accordingly, it is desirable to have alternate data processing schemes.

[0016] SUMMARY

[0017] The invention includes various embodiments for use in physical layer processing. One embodiment determines the address mapping of bits in the physical channel buffer from the address of bits in the first interleaver buffer. The physical channel buffer addresses are determined corresponding to addresses of the bits after rate matching, bit scrambling, second interleaving and physical channel mapping. The bits are directly read from the first interleaver buffer and written to the physical channel buffer using the determined physical channel buffer addresses. Another embodiment determines the address mapping of bits in the first interleaver buffer from the address of bits in the

physical channel buffer. The first interleaver buffer addresses are determined corresponding to addresses of the bits after reverse rate matching, reverse bit scrambling, reverse second interleaving and reverse physical channel mapping. The bits are directly read from the determined first interleaver buffer addresses and written to the physical channel buffer addresses.

[0018] BRIEF DESCRIPTION OF THE DRAWING(S)

[0019] Figure 1 is an illustration of a wireless TDD/CDMA communication system.

- [0040] Figure 22 is an example of “pull” reverse second interleaving.
- [0041] Figure 23 is a flow chart for “pull” reverse rate matching.
- [0042] Figures 24 and 25 are flow charts for two approaches to “pull” reverse rate matching for punctured turbo code sequences.
- [0043] Figure 26 is a flow chart of an embodiment of “pull” reverse bit scrambling.
- [0044] Figure 27 is a simplified diagram of an alternate embodiment of the “pull” approach.
- [0045] Figure 28 is a flow chart of the alternate embodiment of “pull” bit scrambling.
- [0046] Figure 29 is a diagram for “reduced first interleaver buffering.”
- [0047] Figures 30A and 30B are examples of “reduced first interleaver buffering” for a TTI of 10 ms.
- [0048] Figures 31A and 31B are examples of “reduces first interleaver buffering” for a TTI of 80 ms.

[0049] DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT(S)

[0050] Although the preferred embodiments are explained in context of the preferred application in a 3GPP UTRA TDD communication system, the embodiments are applicable to other standards, such as code division multiple access 2000 (CDMA2000), time division synchronous code division multiple access (TDSCDMA) and frequency division duplex code division multiple access (FDD/CDMA), and applications. The preferred embodiments are described in three general approaches: a “push”, “pull” and “reduced first interleaver buffering” approach. However, the embodiments of the engines for each approach may be adapted for use in the other approaches or other applications.

[0051] One approach to physical channel processing is referred to as the “push” approach, as shown in the flow chart of Figure 3 and the block diagram of Figure 4. In the “push” approach on the transmit side, each bit output from the first interleaver output buffer 82 is mapped (step 74) and written (step 76) to a bit of a physical channel buffer 84. Data in the physical channel buffer 84 is sent to chip rate processing for transmission over the air interface. To illustrate, a given bit of the first interleaver buffer 82 is mapped to no location, one location or multiple locations in the physical channel buffer 84, as shown in Figure 4. After the bit is mapped, it is inserted into the physical channel buffer 84 in the corresponding locations. On the receive side, bits are read from the physical channel buffer 84 and written to the first interleaver buffer 82. As a result, the transmit side “push” approach is performed in the reverse order of the “push” approach on the receive side. In the following, the “push”

approach is primarily described from the transmit side. The receive side is performed in an analogous reverse order.

[0052] Figure 4 is a block diagram of an embodiment of the push approach. For bits in the first interleaver buffer 82, a push address generating engine 86 determines its destination address in a resource unit of the physical channel buffer 84. One frame's worth of bits are processed at a time. If the TTI is greater than 10 ms, the other frames bits are taken sequentially after the first frame, such as from frame 1 to frame 2 to frame 3 and so on. The bits may be taken one at a time or in groups, such 8 bits, 16 bits or 32 bits. The push address generating engine 86 determines the one, multiple or no address to write each bit to in the physical channel buffer 84. The push address generating engine 86 uses control parameters, which are either standardized or signaled, to determine the proper address.

[0053] The push address generating engine 86 sends a control signal to a read/write controller 78. The read/write controller 78 reads a bit or bits from the corresponding address in the first interleaver buffer 82 and writes bit/bits to the address or addresses as directed by the push address generating engine 86. All of these operations are controlled by the physical mapping controller 104, which also uses the control parameters to oversee the physical layer processing operation.

[0054] The push address generating engine 86 has four primary sub-engines: a rate matching engine 88, a bit scrambling engine 90, a second interleaving engine 92 and a physical channel mapping engine 94.

[0055] Three other sub-engines feed information to the four primary engines: a radio frame segmentation calculation engine 96, a TrCH multiplexing (MUX) calculation engine 98 and a physical channel segmentation calculation engine 100. These three sub-engines do not functionally change the order of bits during physical layer processing. These engines effectively mark bits.

[0056] The radio frame segmentation engine 96 determines which bit addresses of the first interleaver buffer 82 are to be sent in each frame. The TrCH MUX engine 98 determines which of that frames data is sent in which CCTrCH. The physical channel segmentation engine 100 determines which bits of the CCTrCH are sent in which physical channel (resource unit). Although these three engines 96, 98, 100 are shown in Figure 1 as being functionally performed immediately prior to the step requiring the information, they may actually be performed earlier and, possibly, prior to operation of any of the primary engines 88, 90, 92, 94.

[0057] The four primary engines 88, 90, 92, 94 operate in the order indicated in Figure 3 on the transmit side. Rate matching is performed first. Subsequently, bit scrambling is performed, followed by second interleaving. Finally, physical channel mapping is performed.

[0058] In rate matching, bits are punctured and repeated to both minimize the number of required channels and to assure each channel is fully utilized. To illustrate, if a channel has 110 bits in the first interleaver buffer, but the channel is required to have 100 bits due to the physical channel allocation. 10 bits are punctured. By contrast, if the same channel had

only 90 bits in the buffer, 10 bits would need to be repeated. Due to puncturing and repeating, some first interleaver buffer bits may be written to no address, one address or multiple addresses.

[0059] The rate matching engine 88 determines addresses that each bit of the first interleaver buffer will be in after rate matching and is described using Figure 5. Rate matching primarily uses three variables: e-ini, e-plus and e-minus. e-ini is an initial value for e in the rate matching algorithm. e-plus is an increment to e in the rate matching algorithm. e-minus is a decrement to e in the rate matching algorithm.

[0060] The rate matching engine 88 selects step 108 or step 110, depending on whether a particular channel is convolutionally coded or turbo coded (step 106). This choice is signaled by control information. If the channel is non-turbo coded, the bits are treated as one sequence (step 110). Turbo coding tags each bit with one of three types : systematic (S), parity 1 (P1) and parity 2 (P2). Puncturing is not performed on systematic bits. The rate matching engine treats each of these types of bits as a separate sequences (step 108). Treating these bits as separately eliminates the explicit need for bit separation and bit collection as described in the standard.

[0061] A preferred rate matching algorithm for Push address mapping is as follows (step 112).

Parameter Definitions:

e_{ini}	initial error between current and desired puncturing ratio
e_{minus}	Decrement of variable e
e_{plus}	Increment of variable e
X	Number of bits before rate matching (transmit perspective)

- p Address to map bit to after puncturing or repeating
- u Address of bit before rate matching (transmit perspective)
- e Temporary variable which holds the "error" as identified in the standards
- i The sequence identifier (i.e. S, P1, or P2)
- f Function representing remainder of Push processing engines which further resolve address p and writes bit u to the appropriate physical channel

If puncturing is to be performed, the following algorithm is used.

```

 $e_i = e_{ini,i}$ 
 $p = 0$ 
 $u = 0$ 
while  $u < X$ 
     $e_i = e_i - e_{minus,i}$ 
    if  $e_i > 0$  then                                -- normal no puncture bit
        perform function  $f(u, p)$ 
         $u = u + 1$ 
         $p = p + 1$ 
    else                                           -- else puncture
         $u = u + 1$ 
         $e_i = e_i + e_{plus,i}$ 
    end if
end while

```

If repeating is to be performed, the following algorithm is used.

```

 $e_i = e_{ini,i}$ 
 $p = 0$ 
 $u = 0$ 
while  $u < X$ 
     $e_i = e_i - e_{minus,i}$ 

```

```

    if  $e_i > 0$  then                                -- normal no repeat bit
        perform function  $f(u, p)$ 
         $u = u + 1$ 
         $p = p + 1$ 
    else                                              -- else this is a repeat bit
        perform function  $f(u, p)$ 
         $p = p + 1$ 
         $e_i = e_i + e_{plus, i}$ 
    end if
end while

```

[0062] Although “push” rate matching is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as in a UE, base station or Node-B used with a TDD/CDMA, FDD/CDMA and TDSCDMA system.

[0063] The next step in the process is bit scrambling. In bit scrambling the order of the bits are rearranged to remove a DC bias. The bit scrambling engine determines a bit scrambled address for the address output by the rate matching engine.

[0064] In bit scrambling, the bits are scrambled using a scrambling code. The scrambling of the bits is used to remove a DC bias. The bits prior to bit scrambling are represented, such as by $h_1, h_2, h_3, \dots, h_S$. S is the number of bits in a CCTrCH, otherwise referred to as a scrambling block. A k^{th} bit of the S bits is determined per Equations 1 and 2.

$$s_k = h_k \oplus p_k, \text{ where } k = 1, 2, \dots, S \quad \text{Equation 1}$$

$$p_k = \left(\sum_{i=1}^{16} g_i \cdot p_{k-i} \right) \bmod 2; p_k = 0 \text{ for } k < 1; p_i = 1; g = \{0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 1, 1, 0, 1\}$$

[0065] p_k is a k^{th} bit of the scrambling code. g_i is an i^{th} bit of g .

[0066] The process of bit scrambling is explained in conjunction with the flow chart of Figure 6. Using the position, k , of a bit in the CCTrCH, a corresponding bit in the scrambling code p_k is determined, step 300. The bit, h_k , is scrambled, such as by exclusive-oring the bit with p_k , step 302.

[0067] In an alternate embodiment as shown in Figures 7 and described with the flow chart of Figure 8, the bit scrambling engine 90 is located after the other engines 88, 92, 94 (rate matching, second interleaving and physical channel mapping). This embodiment allows for the all of the address mapping to be performed prior to any manipulation of the value of the bits. The bit scrambling engine determines the address of a given bit after rate matching, step 304. Using the address of the given bit after rate matching, the p_k to scramble the bit is determined, step 306. The given bit is scrambled, such as by exclusive-oring, using the determined p_k , step 308.

[0068] Although “push” bit scrambling is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as preferably in a UE, base station or Node-B of a TDD/CDMA system.

[0069] A second interleaver engine 92 is used to interleave the bits after rate matching. Initially, the second interleaver engine 92 needs to know whether second interleaving is to be performed over an entire CCTrCH or a single time slot of the CCTrCH. This information is signaled in from higher layers. In second interleaving, the bits are read in row wise, such as

over 30 columns. After being read into the array, the columns are permuted. The bits are subsequently read out of the permuted columns.

[0070] Second interleaving is described in conjunction with Figures 9 and 10. The address, u , for a bit prior to second interleaving (after bit scrambling) is used to determine the address, p , after second interleaving. Using the known number of columns for the array, such as 30 columns, the column and row of the bit in the array is determined (step 114). To illustrate using Figure 10, a bit at address, 58, after bit scrambling is to be analyzed. By dividing the address and rounding down, the row of the bit is determined, (row 1: $58/30 = 1$ remainder 29). The column is determined from the remainder of the division. In this illustration, the column is determined by subtracting one from the remainder, column 28 ($29-1$). Using the known column permutations, the new column for the bit is determined (step 116). For this illustration, column 28 is permuted to column 11. The number of bits in the CCTrCH or CCTrCH time slot and the column offsets determine the address, p , of the bit after second interleaving (step 118). In this illustration, 7 columns prior to column 11 have 3 bits and four columns have 2 bits. As a result, the bit is at address 30 after second interleaving.

[0071] Although “push” second interleaving is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as in a UE, base station or Node-B used with a TDD/CDMA, FDD/CDMA and TDSCDMA system.

[0072] After second interleaving, the bits for each CCTrCH are mapped into the physical channels/resource units. Physical channel mapping is described in conjunction with Figure 11. Physical channel mapping uses a different mapping approach for four different cases. In

the first case, a time slot has only one resource unit for the CCTrCH. In the second case, more than one resource unit is used in a time slot for the downlink. In a third case, more than one resource unit is used in the uplink and the spreading factor of data in the first resource unit is greater than or equal to the spreading factor of the second resource unit. In a fourth case, more than one resource unit is used in the uplink and the spreading factor of the first resource unit is less than the spreading factor of the second resource unit. In the uplink, only two resource units can be used for a CCTrCH in a time slot. The physical channel mapping engine 100 categorizes the address, u , of the input bit into one of the four categories (step 120).

[0073] For the first case (single resource unit in a time slot), bits are sequentially assigned to the resource unit. Accordingly, the address, u , of the bit after second interleaving directly corresponds to the address, p , in the resource unit (step 122).

[0074] For the second case (downlink for multiple resource units), bits are assigned to each resource unit in sequence. A first bit is assigned to resource unit 1, a second bit to resource unit 2 and so on until the last resource unit is reached. When the last resource unit is reached, the next bit is assigned to resource unit 1.

[0075] The assigning to each resource unit can be viewed as a modulo counting. Using the illustration of Figure 12, there are three resource units. Filling the resource units is a modulo 3 counting. In general for N resource units, the resource units are filled using a modulo N counting.

[0076] Odd resource units are filled from left to right and even resource units are filled in reverse order, from right to left. As shown in Figure 12, resource units 1 and 3 are filled from left to right and resource unit 2 is filled from right to left.

[0077] The bits are filled in this manner until one of the resource units is filled. This point is referred to as the switch point. At the switch point, the modulus drops by the number of filled resource units. Using Figure 12 as an illustration, resource unit one is filled at bit 681. After the remaining resource units are filled, resource units 2 and 3 are filled using a modulo 2 counting, starting at bit 684 (the switch point).

[0078] The physical channel mapping engine classifies bits into one of four categories: forward before the switch point, reverse before the switch point, forward after the switch point and reverse after the switch point (step 124). Forward indicates that the bits are filled from left to right and reverse indicates that the bits are filled from right to left. The address for a bit is determined based on its category (step 126).

[0079] The switch point is derived from the length of the shortest resource unit and multiplying that length by the number of resource units. Using Figure 12, the first resource unit is 228 bits long. The switch point is 228×3 resource units or 684. After the switch point is determined, whether the bit is forward or reverse is determined. For bits prior to the switch point, the remainder of dividing the bit address by the modulus determines the address. To illustrate using address 682, 682 divided by the modulus, 3, equals 227, remainder 1. Since the resource units are numbered from one to three and not from zero to

two, one is added to the remainder to result in the bit being in resource unit 2. For classification, bits in odd resource units are forward and even are reverse.

[0080] After the switch point, a similar approach is used. The switch point is subtracted from the bit address and the remainder of that result divided by the new modulus is used to determine the bits resource unit.

[0081] After the bit has been categorized, one of four formulas are used to determine its address. For forward before the switch point, Equation 3 is used.

$$p = \text{Start} + u / \text{mod}$$

Equation 3

Start is the first address in that resource unit, such as bit 0. u is the address of the bit after physical channel mapping. p is the determined resource unit address. mod is the modulus number, such as 3 in the example, prior to the switch point.

[0082] For reverse before the switch point, Equation 4 is used.

$$p = \text{End} - u / \text{mod}$$

Equation 4

End is last address in that resource unit.

[0083] For forward after the switch point, Equation 5 is used.

$$p = \text{Start} + \text{SP}/\text{mod} + (u - \text{SP})/\text{mod}_{\text{SP}}$$

Equation 5

SP is the switch point and mod_{SP} is the modulus after the switch point.

[0084] For reverse after the switch point, Equation 6 is used.

$$p = \text{End} - \text{SP}/\text{mod} - (u - \text{SP})/\text{mod}_{\text{SP}} - 1$$

Equation 6

[0085] For case 3 (uplink where the first resource unit has a higher spreading factor than the second resource unit), the bits are filled into the resource units using a modulus based on the two resource units spreading factors. Equation 7 is used to determine the modulus.

$$\text{mod} = 1 + \max((SF1, SF2) / \min(SF1, SF2))$$

Equation 7

SF1 is the spreading factor for resource unit 1 and *SF2* is the spreading factor for resource unit 2.

[0086] To illustrate using Figure 13, resource unit 1 has a spreading factor of 16 and resource unit 1 has a spreading factor of 4. As a result, the resource units are filled using a modulo 5 counting. Accordingly, resource unit 1 has bits 0 and 5 and resource unit 2 has bit 1 to 4. After resource unit 1 is filled, the remaining bits are sequentially filled in resource unit 2. The point where resource unit 1 is filled is the switch point. Resource unit 1 is always filled left to right and resource unit 2 is filled in reverse.

[0087] The physical channel mapping engine classifies bits into one of three categories: forward before the switch point, reverse before the switch point, and reverse after the switch point (step 128). The address for a bit is determined based on its category (step 130).

[0088] The switch point is derived from the length of the first resource unit per Equation 8.

$$\text{SP} = \text{mod} * \text{length of first resource unit}$$

Equation 8

[0089] After the switch point is determined, whether the bit is forward or reverse is determined. For bits prior to the switch point, if there is a remainder of dividing the bit address by the modulus, that bit is in the second resource unit. To illustrate for bit 4, 4 divided by the modulus, 5, results in a remainder of 4. As shown in Figure 10, bit 4 is in resource unit 2 as expected. If there is no remainder, the bit is in the first resource unit. After the switch point, all bits are in the second resource unit.

[0090] After the bit has been categorized, one of three formulas are used to determine its address. For forward before the switch point, Equation 9 is used.

$$p = \text{Start} + u / \text{mod}$$

Equation 9

[0091] For reverse before the switch point, Equation 10 is used.

$$p = \text{End} - ((\text{mod}-1) * (u / \text{mod}) - \text{BN}\% \text{mod})$$

Equation 10

BN%mod is the bit number modulo by the value for mod. To illustrate for a mod = 5, BN%mod is mod₅ (bit number).

[0092] For reverse after the switch point, Equation 11 is used.

$$p = \text{End} - \text{mod} * \text{SP} / (\text{mod} + 1) - (u - \text{SP})$$

Equation 11

[0093] For case 4 (uplink where first resource unit has a lower spreading factor than the second resource unit), the bits are also filled into the resource units using a modulus based on the two resource units spreading factors. Equation 7 is also used to determine the modulus.

[0094] To illustrate using Figure 14, resource unit 2 has a spreading factor of 16 and resource unit 1 has a spreading factor of 4. As a result, the resource units are filled using a modulo 5 counting. Accordingly, resource unit 1 has bits 0 to 3 and resource unit 2 has bit 4.

After resource unit 1 is filled, the remaining bits are sequentially filled in resource unit 2. The point where resource unit 1 is filled is the switch point. Resource unit 1 is always filled left to right and resource unit 2 is filled in reverse.

[0095] The physical channel mapping engine classifies bits into one of three categories: forward before the switch point, reverse before the switch point, and reverse after the switch point (step 132). The address for a bit is determined based on its category (step 134).

[0096] The switch point is derived from the length of the first resource unit per Equation 12.

$$SP = \text{mod} * \text{length of first resource unit} / (\text{mod} - 1)$$

Equation 12

[0097] After the switch point is determined, whether the bit is forward or reverse is determined. For bits prior to the switch point, if there is a remainder of dividing the bit address plus one by the modulus, that bit is in the first resource unit. Otherwise, it is in the second resource unit. After the switch point, all bits are in the second resource unit.

[0098] After the bit has been categorized, one of three formulas are used to determine its address. For forward before the switch point, Equation 13 is used.

$$p = \text{Start} + ((\text{mod} - 1) * (u / \text{mod})) + \text{BN} \% \text{mod}$$

Equation 13

[0099] For reverse before the switch point, Equation 14 is used.

$$p = \text{End} - u / \text{mod}$$

Equation 14

[00100] For reverse after the switch point, Equation 15 is used.

$$p = \text{End} - \text{SP}/(\text{mod} + 1) - (u - \text{SP})$$

Equation 15

[00101] Using these equations for the four cases, the physical channel mapping engine 94 determines the resource unit address, p , for a particular address, u , prior to physical channel mapping.

[00102] Although “push” channel mapping is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as preferably in a UE, base station or Node-B of a TDD/CDMA system.

[00103] Another approach to physical channel processing is referred to as the “pull” approach, as shown in Figure 15. In the “pull” approach on the transmit side, each bit to be input to the physical channel buffer 146 is mapped to a bit or bits of the first interleaver buffer 144 (step 136). To illustrate, an address in the physical channel buffer 146 is mapped to an address in the first interleaver buffer 144. After the bit is mapped, it is inserted into the physical channel buffer 146 by reading the corresponding location in the first interleaver buffer 144 (step 138). Data in the physical channel buffer 146 is sent to chip rate processing for transmission over the air interface. On the receive side, bits are read from the physical channel buffer 146 and written to the first interleaver buffer 144. As a result, the “pull”

approach on the receive side is the reverse of the transmit side. In the following, the “pull” approach is primarily described from the transmit side. The receive side is performed in an analogous reverse order.

[00104] Figure 16 is a block diagram of an embodiment of the “pull” approach. A pull address generating engine 148 determines bits to be written to the physical channel buffer 146. An advantage of the “pull” approach is that resource units can be filled as needed eliminating the need to buffer physical channel data over multiple timeslots. To illustrate, if only one resource unit is transmitted in the first time slot of a frame, the “pull” approach can selectively only “pull” bits for that resource unit. As a result, the pull approach can be used to reduce physical channel buffering to only a single time slot.

[00105] The bits in the “pull” approach may be taken one at a time or in groups, such as 8 bits, 16 bits or 32 bits. The bits are preferably taken in sequence from the first bit to the last bit of a resource unit, although the bits may be taken in other sequences. The pull address generating engine 148 determines the address to read the bit from in the first interleaver buffer 144. The pull address generating engine 148 uses control parameters, which are either standardized or signaled, to determine the proper address.

[00106] The pull address generating engine 148 sends a control signal to a read/write controller 140. The read/write controller 140 reads a bit from the determined address in the first interleaver buffer 144 and writes that bit to the address of the physical channel buffer 146. These operations are controlled by the physical mapping controller 166, which also uses the control parameters to oversee the physical layer processing operation.

[00107] Similar to the “push” approach, the pull address generating engine 148 has four primary sub-engines: a rate matching engine 150, a bit scrambling engine 152, a second interleaving engine 154 and a physical channel mapping engine 156.

[00108] Also, three other sub-engines feed information to the four primary engines: a radio frame segmentation calculation engine 158, a TrCH multiplexing (MUX) calculation engine 158 and a physical channel segmentation calculation engine 162.

[00109] In contrast to the “push” approach, the four primary engines 150, 152, 154, 156 operate in the order indicated in Figure 16 on the transmit side. Reverse physical channel mapping is performed first. Subsequently, reverse second interleaving is performed, followed by reverse bit scrambling. Finally, reverse rate matching is performed.

[00110] The physical channel mapping engine 156 performs a reverse physical channel mapping. For each bit address in a resource unit, a corresponding address prior to physical channel mapping is determined.

[00111] Physical channel mapping using a different mapping approach for four different cases. Physical channel mapping is described in conjunction with Figure 17. In the first case, a time slot has only one resource unit for the CCTrCH. In the second case, more than one resource unit is used in a time slot for the downlink. In a third case, more than one resource unit is used in the uplink and the spreading factor of data in the first resource unit is greater than or equal to the spreading factor of the second resource unit. In a fourth case, more than one resource unit is used in the uplink and the spreading factor of the first resource unit is less than the spreading factor of the second resource unit.

[00112] The physical mapping engine 156 determines which case applies to each resource unit bit address (step 168). For the first case (single resource unit in a time slot), bits are sequentially assigned to the resource unit. Accordingly, the address, p , of the bit in the resource unit directly corresponds to the address, u , prior to physical channel mapping (step 170). For the second case (downlink for multiple resource units). The physical channel mapping engine 156 classifies bits into one of four categories: forward before the switch point, reverse before the switch point, forward after the switch point and reverse after the switch point (step 172). Forward indicates that the bits are filled from left to right and reverse indicates that the bits are filled from right to left. The address for a bit is determined based on its category (step 174).

[00113] The switch point for odd resource units is the length of the shortest resource unit. Using the example of Figure 18, the switching point is 228 (the length of the shortest resource unit). For even resource units, the switch point is the last address in the resource unit less the length of the shortest resource unit number. After the switch point is determined, whether the bit is forward or reverse is determined, based on its resource unit. Odd resource units are forward and even are reverse.

[00114] After the bit has been categorized, one of four formulas are used to determine its address. For forward before the switch point, Equation 16 is used.

$$u = p * \text{mod} + ru \% \text{mod}$$

Equation 16

u is the address of the bit as reverse physical channel mapped. p is the resource unit address.

mod is the modulus counting prior to the switch point. $ru \% mod$ is the resource unit bit number modulo of the value of mod .

[00115] For reverse before the switch point, Equation 17 is used.

$$u = \text{End} - p * mod + 1$$

Equation 17

End is the last address in that resource unit.

[00116] For forward after the switch point, Equation 18 is used.

$$u = SP * mod + (p - SP) * (mod_{SP})$$

Equation 18

SP is the switch point and mod_{SP} is the modulus after the switch point.

[00117] For reverse after the switch point, Equation 19 is used.

$$u = SP * mod - (\text{End} - SP - p) * (mod_{SP} - 1) + RU - 2$$

Equation 19

RU is the resource unit number of the bit.

[00118] For case 3 (uplink where first resource unit has a higher spreading factor than the second resource unit), the bits are filled into the resource units using a modulus based on the two resource units spreading factors as previously described.

[00119] The physical channel mapping engine 156 classifies bits into one of three categories: forward before the switch point, reverse before the switch point, and reverse after the switch point (step 176). The address for a bit is determined based on its category (step 178).

[00120] Two switch points are used for case 3 physical channel mapping: a forward switch point (SPF) and a reverse switch point (SPR). The forward switch point is the switch point of the first resource unit, which is equal to its length, such as 228 in Figure 19. The reverse switch point is the switch point of the second resource unit, which is determined per Equation 20.

$$SPR = \text{End} - (\text{mod} - 1) * SPF$$

Equation 20

End is the last address in resource unit 2.

[00121] After the bit has been categorized, one of three formulas are used to determine its address. For forward before the switch point, Equation 21 is used.

$$u = \text{mod} * p$$

Equation 21

[00122] For reverse before the switch point, Equation 22 is used.

$$u = \text{mod} * \text{INT}((\text{LP2} - \text{ruPOS}) / (\text{mod} - 1) + \text{MOD}(\text{LP2} - \text{ruPOS}, (\text{mod} - 1)) + 1$$

Equation 22

INT is the integer operator. MOD is the modulo operator. LP2 is the last point in resource unit 2. ruPOS is the bit position number of the bit in the resource unit.

[00123] For reverse after the switch point, Equation 23 is used.

$$u = \text{mod} + \text{SPF} + \text{SPR} - p - 1$$

Equation 23

[00124] For case 4 (uplink where first resource unit has a lower spreading factor than the second resource unit), the bits are also filled into the resource units using a modulus based on the two resource units spreading factors, as previously described.

[00125] The physical channel mapping engine 156 classifies bits into one of three categories: forward before the switch point, reverse before the switch point, and reverse after the switch point (step 180). The address for a bit is determined based on its category (step 182).

[00126] Only a reverse switch point (SPR) is used for case 4 physical channel mapping. The reverse switch point is the switch point of the second resource unit, which is determined per Equation 24.

$$\text{SPR} = \text{End} - \text{length of the resource unit} / (\text{mod} - 1)$$

Equation 24

End is the last address in resource unit 2.

[00127] After the bit has been categorized, one of three formulas are used to determine its address. For forward before the switch point, Equation 25 is used.

$$u = \text{mod} * \text{INT}(p/(\text{mod}-1)) + \text{ruPOS} \% (\text{mod} - 1)$$

Equation 25

$\text{ruPOS} \% (\text{mod} - 1)$ is the bit position in the resource unit modulo by the value of $(\text{mod}-1)$.

[00128] For reverse before the switch point, Equation 26 is used.

$$u = \text{mod} * (\text{LP2} - p) + (\text{mod} - 1)$$

Equation 26

[00129] For reverse after the switch point, Equation 27 is used.

$$u = \text{mod} * (\text{LP2} - \text{SPR} + 1) + (\text{LP2} - p) \% \text{modMinus1}$$

Equation 27

[00130] Using these equations for the four cases, the physical channel mapping engine 156 determines the resource unit address, p , for a particular second interleaver bit address, u .

[00131] Although “pull” physical channel mapping is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as in a UE, base station or Node-B of a TDD/CDMA system.

[00132] A second interleaving engine 154 is used to reverse interleave the bits after physical channel mapping. Initially, the second interleaving engine 154 needs to know whether second interleaving is to be performed over an entire CCTrCH or is performed for a single timeslot of the CCTrCH. This information is signaled in from higher layers.

[00133] Second interleaving is described in conjunction with Figure 21. The particular address, p , of the bit after physical channel mapping is used to determine the address, u , after reverse second interleaving. Using the total number of bits in the CCTrCH or CCTrCH time slot and the column offsets, a number of bits in each column is determined. Using the address p , the column and row of the bit in the permuted array are determined (step 184). To illustrate using the example of Figure 22, a bit at address $p=61$ in the physical channel buffer is analyzed. Using the total number of bits and the column offsets, it is known that column 0 has five bits and the other columns have four bits. Using the known number of bits for each column, the column and row for the bit is determined (column 12, row 1).

[00134] Using the known column permutations, the non-offset column is determined (step 186). For the above illustration, offset column 12 corresponds to non-offset column 1. Using the column and row of the bit in the non-offset array, the address for the bit is determined (step 188). For the prior illustration, the address of the bit is address 6.

[00135] Although “pull” second interleaving is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as in a UE, base station or Node-B used with a TDD/CDMA, FDD/CDMA and TDSCDMA system.

[00136] As previously described, in rate matching, bits are punctured and repeated to both minimize the number of required channels and to assure each channel is fully utilized. The rate matching engine 150 determines addresses that each bit of the first interleaver buffer will be in after reverse rate matching. Rate matching primarily uses three variables: e-ini, e-plus and e-minus. e-ini is an initial value for e in the rate matching algorithm. e-plus is an increment to e in the rate matching algorithm. e-minus is a decrement to e in the rate matching algorithm.

[00137] Rate matching is described in conjunction with the flow charts of Figures 23-25. The rate matching engine 150 determines whether data for a particular channel is non-turbo coded, such as convolutional coded, or turbo coded. If the channel is non-turbo coded, the bits are treated as one sequence.

[00138] Turbo coding uses three types of bits: systematic (S), parity 1 (P1) and parity 2 (P2). Puncturing is not performed on systematic bits. The rate matching engine 150 treats each of these types of bits as a separate string (step 190). By treating these bits as separate

strings eliminates the explicit need for bit separation and bit collection as described in the standard. This functionality is dealt with by separately handling each sequence.

[00139] The address calculation for the sequences, excluding when turbo coding puncturing (step 192) is required, is functionally performed by Equation 28 for puncturing and Equation 29 for repeating (step 194).

$$u = \left\lfloor \frac{pe^+ - e^{ini} + e^-}{e^+ - e^-} \right\rfloor + 1$$

Equation 28

$$u = \left\lfloor \frac{e^{ini} + pe^+}{e^- - e^+} \right\rfloor$$

Equation 29

u is the calculated address for the bit in the first interleaver buffer. p is the address of the bit prior to reverse rate matching.

[00140] Puncturing of turbo coded sequences is treated differently. Two general approaches can be used to determine the address for these bits, as shown in Figures 24 and 25. In a first approach as shown in Figure 24, the sequences of S, P1 and P2 are treated independently. As a result, a large system of linear indeterminate equations results. These equations can be solved using the particular constraints on the unknown variable (step 198), mainly that the addresses u and p are constrained to integer values. Using the constraints, the solution space is narrowed such that only one u solution exists for any given p. To implement this approach,

the number of punctures prior to the u address is approximated (step 200). A search is conducted having a sufficient space around the approximation to determine the valid solution. The valid solution is determined using the known constraints on the intermediate variables (step 202).

[00141] The following is a preferred technique for applying the first approach. Systematic bits (S) are never punctured. Equation 30 describes the state of the “ e ” variable at any given address, u , in the puncturing operation for P1 bits.

$$e_1 = e_1^{ini} - u_1 e_1^- + n_1 e_1^+$$

Equation 30

e_1 is the variable e for P1. Similarly, e_1^{ini} , e_1^- and e_1^+ are the e^{ini} , e^- and e^+ for, respectively, for P1. u_1 is the number of bits of the P1 sequence prior to the address u being determined. n_1 is the number of punctured bits prior to the current value of u_1 in the P1 sequence.

[00142] Equation 31 describes the state of the “ e ” variable at any given address, u , in the puncturing operation for P2 bits.

$$e_2 = e_2^{ini} - u_2 e_2^- + n_2 e_2^+$$

Equation 31

e_2 is the variable e for P2. Similarly, e_2^{ini} , e_2^- and e_2^+ are the e^{ini} , e^- and e^+ for, respectively, for P2. u_2 is the number of bits of the P2 sequence prior to the address u being determined. n_2 is the number of punctured bits prior to the current value of u_2 in the P2 sequence.

[00143] For a given p , Equation 32 is used.

$$u - p = n_1 + n_2$$

Equation 32

[00144] Equations 33 and 34 are known to be true from inspection of the rate matching algorithm in the standards.

$$0 < e_1 \leq e_1^+$$

Equation 33

$$0 < e_2 \leq e_2^+$$

Equation 34

[00145] The above linear inequalities consist of three equations and five unknowns (u , e_1 , e_2 , n_1 , n_2). To determine the solutions of these equations, values for n_1 and n_2 are approximated. A sufficient space around this approximation is searched. The solution is determined based on the constraints of Equations 33 and 34.

[00146] The approximation of n_1 and n_2 is determined by replacing u in Equation 32 per Equation 35.

$$u = \frac{p}{\gamma}$$

Equation 35

[00147] Equation 36 results.

$$n_1 + n_2 = \left(\frac{p}{\gamma} - p \right)$$

Equation 36

[00148] γ is the puncturing ratio, which is determined per Equation 37.

$$\gamma = 1 - \frac{e_1^-}{3e_1^+} - \frac{e_2^-}{3e_2^+}$$

Equation 37

[00149] The rate matching parameter determination algorithm per the standard distributes puncturing of P1 and P2 bits evenly, except when odd number of punctures is requested.

When an odd number of punctures is requested, P1 gets one more puncture. The rate matching algorithm also allows for no more than two P1 punctures in a row without a P2 puncture. Additionally, no more than two P2 punctures can occur with a P1 puncture.

Accordingly, Equations 38 and 39 result.

$$n_1 - n_2 \leq 3$$

Equation 38

$$n_2 - n_1 \leq 2$$

Equation 39

[00150] Using Equations 38, 39 and 36, Equations 40 and 41 result.

$$\frac{p\left(\frac{1}{\gamma} - 1\right) - 2}{2} \leq n_1 \leq \frac{p\left(\frac{1}{\gamma} - 1\right) + 3}{2}$$

Equation 40

$$\frac{p\left(\frac{1}{\gamma} - 1\right) - 3}{2} \leq n_2 \leq \frac{p\left(\frac{1}{\gamma} - 1\right) + 2}{2}$$

Equation 41

These equations are used to determine a small subspace which contains the solution.

[00151] For any p in which the corresponding write address u is to be determined, the bit at that address is not punctured (or it would not end up in the physical channel mapping buffer).

Accordingly, the value of e must be greater than e^- and Equation 42 results.

$$e_x^- < e_x \leq e_x^+$$

Equation 42

The subscript x is used generally, since the inequality is true for both x = 1 or 2 (for P1 or P2). Using Equations 30 and 31, Equation 43 results.

$$0 < e_x^{ini} - (u_x + 1)e_x^- + n_x e_x^+ \leq e_x^+ - e_x^-$$

Equation 43

[00152] Equation 43 is only true when u is a P_x bit. If u is not a P_x bit, Equation 44 applies.

$$0 < e_x^{ini} - (u_x + 1)e_x^- + n_x e_x^+ \leq e_x^+$$

Equation 44

[00153] To identify a valid solution, Equations 45 and 46 are used.

$$\tilde{e}_1 = e_s^{ini} - (u_2 + 1)e_2^- + n_2 e_2^+$$

Equation 45

$$\tilde{e}_2 = e_s^{ini} - (u_2 + 1)e_2^- + n_2 e_2^+$$

Equation 46

[00154] Subsequently, a range check is performed. If u is a P1 bit, Equation 47 is used.

$$(0 < \tilde{e}_1 \leq e_1^+ - e_1^-) \quad \text{and} \quad (0 < \tilde{e}_2 \leq e_2^+)$$

Equation 47

[00155] If u is a P2 bit, Equation 48 is used.

$$(0 < \tilde{e}_1 \leq e_1^+) \quad \text{and} \quad (0 < \tilde{e}_2 \leq e_2^+ - e_2^-)$$

Equation 48

[00156] If u is an S bit, Equation 49 is used.

$$(0 < \tilde{e}_1 \leq e_1^+) \quad \text{and} \quad (0 < \tilde{e}_2 \leq e_2^+)$$

Equation 49

[00157] The second approach, as shown in Figure 25, is as follows. Based on the u position, the rate matching input bit position, p, is determined. A systematic ratio is determined (step 204). The systematic ratio is based on the puncture ratio for the P1 and P2 sequences. The number of systematic bits S_{bits} is estimated, such as per Equation 50 (step 206).

$$\tilde{S}_{bits} = u / (1 + P1_{PR} + P2_{PR})$$

Equation 50

$\tilde{S}_{bits}$ is the estimated number of systematic bits. $P1_{PR}$ is the puncturing ratio of the P1 sequence and $P2_{PR}$ is the puncturing ratio for the P2 sequence.

[00158] Four cases are assumed depending on the order of the bits (S, P1, P2 is forward and S, P2, P1 is reverse). S is the initial estimate for $\tilde{S}_{bits}$. The cases values are shown in Table 1.

Column	Forward	Reverse
--------	---------	---------

Top	S	P1	P2	S	P1	P2
S	S	S-1	S-1	S	S-1	S-1
	S	S	S-1	S	S-1	S
	S	S	S	S	S	S
	S+1	S	S	S+1	S	S
P1	S	S	S	S	S	S
	S	S+1	S	S	S+1	S
	S	S+1	S+1	S+1	S+1	S
	S+1	S+1	S+1	S+1	S+1	S+1
P2	S	S	S	S	S	S
	S	S	S+1	S	S	S+1
	S+1	S	S+1	S	S+1	S+1
	S+1	S+1	S+1	S+1	S+1	S+1

Table 1

[00159] Based on the type of bit being analyzed (column top), the appropriate four rows of Table 1 are selected. To illustrate for a P2 bit, the last four rows (for column top P2) are selected. If the bit is forward, the left most columns are used. If the bit is reverse, the right most columns are used. Using the appropriate four rows and the appropriate three columns of the row, an output index for each row is determined. To illustrate for a forward P2 bit, four cases are used (case 1 – S,S,S; case 2 – S,S,S+1; case 3 – S+1,S,S+1; and case 4 – S+1,S+1,S+1).

[00160] The four cases are used to calculate four candidates for the output position (step 208). The number of punctured bits is determined for each candidate shown in Table 2. Table 2 also shows the calculation for candidate output bit position.

$P1_{bits}$	$(e_1^{ini} - P1_{bits} * e_1^-) / e_1^+$
-------------	---

$P2_{bits}$	$(e_2^{ini} - P2_{bits} * e_2^-) / e_2^+$
Candidate Output Bit Position	$S_{bits} - 1 + P1_{bits} + P1_{Pbits} - P1_{Pbit\ sin\ i} + P2_{Pbits} - P2_{Pbit\ sin\ i}$

Table 2

$P1_{Pbits}$ is the number of punctured P1 bits. $P2_{Pbits}$ is the number of punctured P2 bits.

$P1_{Pbit\ sin\ i}$ is the number of initial P1 bits. $P2_{Pbit\ sin\ i}$ is the number of initial P2 bits.

[00161] The first candidate output bit position that matches the actual output bit position represents the number of S, P1 and P2 bits. Using this information, the input bit position, p, is determined, (step 210).

[00162] Although “pull” rate matching is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as in a UE, base station or Node-B used with a TDD/CDMA, FDD/CDMA and TDSCDMA system.

[00163] The next step in the process is reverse bit scrambling. The bit scrambling engine determines a bit scrambled address for the address output by the second interleaver.

[00164] The process of reverse bit scrambling is explained in conjunction with the flow chart of Figure 26. Using the position, k, of a bit in the CCTrCH, a corresponding bit in the scrambling code p_k is determined (step 400). The bit, h_k , is scrambled, such as by exclusive-oring the bit with p_k (step 402).

[00165] Although bit scrambling can be performed prior to reverse rate matching, it is preferably performed after reverse rate matching, as shown in Figure 27 and described with

the flow chart of Figure 28. This embodiment allows for all of the address mapping to be performed prior to any manipulation of the value of the bits. The address after reverse second interleaving (prior to reverse rate matching) is determined for a given bit after reverse rate matching (step 404). Using the address of the given bit after reverse second interleaving, the p_k to scramble the bit with is determined (step 406). The given bit is scrambled using the determined p_k , such as by exclusive-oring the bit with p_k (step 408).

[00166] Although “pull” bit scrambling is described in conjunction with a preferred TDD/CDMA communication system, it can be used in a variety of applications, such as in a UE, base station or Node-B of a TDD/CDMA system.

[00167] Another approach reduces the first interleaver buffering and is referred to as “reduced first interleaver buffering.” Figure 29 is a block diagram of “reduced first interleaver buffering”.

[00168] As shown in Figure 29, the output of the first interleaver 212 is not directly sent to a interleaver buffer. All the physical layer buffering is shown in Figure 29 as being performed by a single common memory 220. Transport channel data blocks are provided for one frame or multiple frames. This attribute is indicated by the TTI parameter. The TTI can be one of four possible values 10, 20, 40 and 80 ms. A TTI of 10 indicates that the data is for 1 frame, a TTI of 20 indicates 2 frames, a TTI of 40 indicates 4 frames and 80 indicates 8 frames. Data for the first frame of a TTI can be sent directly to the physical channel processor 218. Other frames of the TTI are buffered for later processing. As a result, the overall first interleaver buffering is reduced by one frame. To illustrate, if the TTI is 10 ms., that single frame is stored directly in the physical channel buffer and no first interleaver buffering is required. For a TTI of 80 ms., seven instead of eight frames of data are required to be stored.

[00169] The “reduced first interleaver buffering” preferably applies to the “push” approach for physical layer processing. As a result, as data is output from the first interleaver 212, it is written to the corresponding address of the physical channel mapping buffer, although other physical layer processing approaches may be utilized. If a physical layer processing approach is used where intermediate buffering, such as after rate matching and second interleaving, is used in the physical channel processing, reduced interleaver buffering can still be used. The first frame’s data is sent directly to physical layer processing and stored in the intermediate buffer.

[00170] As shown in Figure 23, all frames’ bits are input into a first MUX 214. The first MUX 214 sends the first frame’s bits to a second MUX 216 for physical channel processing, by the physical channel processing block 218. Other frames’ bits, if the TTI is greater than 10 ms., are sent to the memory 220 (first interleaver buffer) via the first MUX 214. After the first frame’s bits are sent to chip rate processing for transmission over the air interface. Subsequent frame’s bits are taken from the memory 230 via the second MUX 216 for physical channel processing. All of these operations are overseen by a physical channel controller 222.

[00171] Figures 30A and 30B illustrate “reduced first interleaver buffering” data flow for a transport channel data block of 10 ms TTI (one frame).. The transport channel data bits are sent directly to the physical channel processor 218 and then to the physical channel buffer for subsequent chip rate processing without the use of the first interleaver buffer. As shown in Figure 30A, Frame N is sent directly to the physical channel processor 218. As shown in Figure 30B, the next frame (Frame N+1) is also sent directly to the physical channel processor 218.

[00172] Figures 31A and 31B illustrate “reduced first interleaver buffering” data flow for a transport channel data block of 80 ms TTI. The transport channel data for the first frame (Frame

N) is sent to physical layer processing and stored in the physical channel buffer (memory 220). The other frames (Frames N+1 to N+7) are stored in the physical channel buffer bypassing the physical layer processing. In the next frame as shown in Figure 31B, (Frame N+1) is sent to physical layer processing and stored in the physical channel buffer. The other frames (Frames N+2 to N+7) are processed sequentially in the same manner during the next six frames. The chip rate processor is reading data bits from the physical channel buffer one frame behind the current frame. For example, if the physical layer processor is processing (Frame N+1) then the chip rate processor is reading Frame N. The processing approach for data with a TTI of 20 and 40 ms is the same as the 80 ms approach which was described above. The only difference is the number of frames that are buffered, prior to physical channel buffering.

*

CLAIMS

What is claimed is:

1. A method for physical layer processing for use in a wireless communication system, the method comprising:
 - providing a first interleaver buffer having bits stored at first interleaver addresses;
 - determining physical channel addresses for the bits corresponding to addresses of the bits after rate matching, bit scrambling, second interleaving and physical channel mapping using the first interleaver addresses;
 - directly reading the bits from the first interleaver buffer and writing the bits to a physical channel buffer using the determined physical channel addresses; and
 - transmitting the bits in the physical channel buffer over an air interface.
2. The method of claim 1 wherein the determining physical channel addresses comprises:
 - determining rate matching addresses for the bits corresponding to addresses of the bits after rate matching using the first interleaver addresses;
 - determining second interleaving addresses for the bits corresponding to addresses of the bits after second interleaving using the rate matching addresses; and
 - determining physical channel addresses for the bits corresponding to addresses of the bits after physical channel mapping.

3. A method for physical layer processing for use in a wireless communication system, the method comprising:

providing a physical channel buffer capable of storing bits at physical channel addresses;

determining first interleaver addresses for the bits corresponding to addresses of the bits after reverse physical channel mapping, reverse second interleaving, reverse bit scrambling and reverse rate matching using the physical channel addresses; and

for addresses of the physical channel buffer, directly reading bits from the first interleaver buffer at the determined first interleaver addresses and writing the bits to those addresses of the physical channel buffer.

4. The method of claim 3 wherein the determining first interleaving addresses comprises:

determining reverse physical channel mapping addresses corresponding to the addresses in the physical channel buffer;

determining reverse second interleaving addresses corresponding to the determined reverse physical channel mapping addresses; and

determining reverse rate matching addresses corresponding to the determined reverse second interleaving addresses.

5. A method for determining an address for bits after rate matching for use in a wireless communication system, the method comprising:

categorizing the bits as being turbo coded or non-turbo coded;

if the bits are categorized as turbo coded, treat the bits as a systematic, a parity 1 and a parity 2 string;

if the bits are categorized as non-turbo coded, treat the bits as a single string;

and

using a separate algorithm to determine the address for each type of string of the systematic, parity 1, parity 2 and single string.

6. The method of claim 5 wherein each separate algorithm uses the variable e-ini, e-plus and e-minus.

7. A user equipment for use in determining addresses for bits after rate matching, the user equipment comprising:

means for categorizing the bits as being turbo coded or non-turbo coded;

means if the bits are categorized as turbo coded, for treating the bits as a systematic, a parity 1 and a parity 2 string;

means if the bits are categorized as non-turbo coded, for treating the bits as a single string; and

means for using a separate algorithm to determine the address for each type of string of the systematic, parity 1, parity 2 and single string.

8. The user equipment of claim 7 wherein each separate algorithm uses the variable e-ini, e-plus and e-minus.

9. The user equipment of claim 7 wherein the rate matching is performed on the bits of received communications.

10. The user equipment of claim 7 wherein the rate matching is performed on the bits of to be transmitted communications.

11. A user equipment for use in determining addresses for bits after rate matching, the user equipment comprising:

a rate matching engine for categorizing the bits as being turbo coded or non-turbo coded; if the bits are categorized as turbo coded, for treating the bits as a systematic, a parity 1 and a parity 2 string; if the bits are categorized as non-turbo coded, for treating the bits as a single string; and for using a separate algorithm to determine the address for each type of string of the systematic, parity 1, parity 2 and single string.

12. The user equipment of claim 11 wherein each separate algorithm uses the variable e-ini, e-plus and e-minus.

13. The user equipment of claim 11 wherein the rate matching is performed on the bits of received communications.

14. The user equipment of claim 11 wherein the rate matching is performed on the bits of to be transmitted communications.

15. A base station for use in determining addresses for bits after rate matching, the base station comprising:

means for categorizing the bits as being turbo coded or non-turbo coded;

means if the bits are categorized as turbo coded, for treating the bits as a systematic, a parity 1 and a parity 2 string;

means if the bits are categorized as non-turbo coded, for treating the bits as a single string; and

means for using a separate algorithm to determine the address for each type of string of the systematic, parity 1, parity 2 and single string.

16. The base station of claim 15 wherein each separate algorithm uses the variable e-ini, e-plus and e-minus.

17. The base station of claim 15 wherein the rate matching is performed on the bits of received communications.

18. The base station of claim 15 wherein the rate matching is performed on the bits of to be transmitted communications.

19. A base station for use in determining addresses for bits after rate matching, the base station comprising:

a rate matching engine for categorizing the bits as being turbo coded or non-turbo coded; if the bits are categorized as turbo coded, for treating the bits as a systematic, a parity 1 and a parity 2 string; if the bits are categorized as non-turbo coded, for treating the bits as a single string; and for using a separate algorithm to determine the address for each type of string of the systematic, parity 1, parity 2 and single string.

20. The base station of claim 19 wherein each separate algorithm uses the variable e-ini, e-plus and e-minus.

21. The base station of claim 19 wherein the rate matching is performed on the bits of received communications.

22. A method for determining an address for a bit after second interleaving for use in a wireless communication system:

using an address of the bit prior to second interleaving, determine a column and row of the bit in a non-permuted array using a known number of columns in the permuted array;

determining a permuted column in a permuted array based on the determined column in the non-permuted array; and

using a known number of bits to be interleaved, the determined permuted column and the determined row, determine an address of the bit after second interleaving.

23. The method of claim 22 wherein the determined row is determined by dividing the address of the bit prior to interleaving by the known number of columns.

24. The method of claim 23 wherein the determined column is determined using a remainder of the dividing.

25. A user equipment for use in determining addresses for a bit after second interleaving, the user equipment comprising:

means for using an address of the bit prior to second interleaving, for determining a column and row of the bit in a non-permuted array using a known number of columns in the permuted array;

means for determining a permuted column in a permuted array based on the determined column in the non-permuted array; and

means for using a known number of bits to be interleaved, the determined permuted column and the determined row, for determining an address of the bit after second interleaving.

26. The user equipment of claim 25 wherein the determined row is determined by dividing the address of the bit prior to interleaving by the known number of columns.

27. The user equipment of claim 25 wherein the determined column is determined using a remainder of the dividing.

28. A user equipment for use in determining addresses for a bit after second interleaving, the user equipment comprising:

a second interleaver engine for using an address of the bit prior to second interleaving, for determining a column and row of the bit in a non-permuted array using a known number of columns in the permuted array; for determining a permuted column in a permuted array based on the determined column in the non-permuted array; and for using a known number of bits to be interleaved, the determined permuted column and the determined row, for determining an address of the bit after second interleaving.

29. The user equipment of claim 28 wherein the determined row is determined by dividing the address of the bit prior to interleaving by the known number of columns.

30. The user equipment of claim 28 wherein the determined column is determined using a remainder of the dividing.

31. A base station for use in determining addresses for a bit after second interleaving, the base station comprising:

means for using an address of the bit prior to second interleaving, for determining a column and row of the bit in a non-permuted array using a known number of columns in the permuted array;

means for determining a permuted column in a permuted array based on the determined column in the non-permuted array; and

means for using a known number of bits to be interleaved, the determined permuted column and the determined row, for determining an address of the bit after second interleaving.

32. The base station of claim 31 wherein the determined row is determined by dividing the address of the bit prior to interleaving by the known number of columns.

33. The base station of claim 31 wherein the determined column is determined using a remainder of the dividing.

34. A base station for use in determining addresses for a bit after second interleaving, the base station comprising:

a second interleaver engine for using an address of the bit prior to second interleaving, for determining a column and row of the bit in a non-permuted array using a known number of columns in the permuted array; for determining a permuted column in a permuted array based on the determined column in the non-permuted array; and for using a known number of bits to be interleaved, the determined permuted column and the determined row, for determining an address of the bit after second interleaving.

35. The base station of claim 34 wherein the determined row is determined by dividing the address of the bit prior to interleaving by the known number of columns.

36. The base station of claim 34 wherein the determined column is determined using a remainder of the dividing.

37. A method for determining an address for bits after physical channel mapping for use in a wireless communication system, the method comprising:

categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

for bits in the first case, determine the address after physical channel mapping using an address of those bit prior to physical channel mapping;

for bits in the second case, determining a switch point, classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and determining the address for those bits using the category classification;

for bits in the third case, determining a switch point, classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and determining the address for those bits using the category classification; and

for bits in the third case, determining a switch point, classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and determining the address for those bits using the category classification.

38. The method of claim 37 wherein the switch point for the second case is a length of a shortest resource unit multiplied by a number of resource units.

39. The method of claim 37 wherein the switch point for the third case is a length of the first resource unit multiplied by a modulo index, the modulo index is derived by the spreading factors of the first and second resource units.

40. The method of claim 37 wherein the switch point for the fourth case is a length of the first resource unit multiplied by a modulo index and divided by (the modulo index minus one), the modulo index is derived by the spreading factors of the first and second resource units.

41. A user equipment capable of determining an address for bits after physical channel mapping, the user equipment comprising:

means for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an

uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

means for bits in the first case, for determining the address after physical channel mapping using an address of those bits prior to physical channel mapping;

means for bits in the second case, for determining a switch point, for classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and for determining the address for those bits using the category classification;

means for bits in the third case, for determining a switch point, for classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and for determining the address for those bits using the category classification; and

means for bits in the third case, for determining a switch point, for classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and for determining the address for those bits using the category classification.

42. The user equipment of claim 41 wherein the switch point for the second case is a length of a shortest resource unit multiplied by a number of resource units.

43. The user equipment of claim 41 wherein the switch point for the third case is a length of the first resource unit multiplied by a modulo index, the modulo index is derived by the spreading factors of the first and second resource units.

44. A user equipment capable of determining an address for bits after physical channel mapping, the user equipment comprising:

a physical channel mapping engine comprising:

for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

for bits in the first case, determining the address after physical channel mapping using an address of those bits prior to physical channel mapping;

for bits in the second case, determining a switch point, classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and determining the address for those bits using the category classification;

for bits in the third case, determining a switch point, classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and determining the address for those bits using the category classification; and

for bits in the third case, determining a switch point, classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and determining the address for those bits using the category classification.

45. The user equipment of claim 44 wherein the switch point for the second case is a length of a shortest resource unit multiplied by a number of resource units.

46. The user equipment of claim 44 wherein the switch point for the third case is a length of the first resource unit multiplied by a modulo index, the modulo index is derived by the spreading factors of the first and second resource units.

47. The user equipment of claim 44 wherein the switch point for the fourth case is a length of the first resource unit multiplied by a modulo index and divided by (the modulo index minus one), the modulo index is derived by the spreading factors of the first and second resource units.

48. A base station capable of determining an address for bits after physical channel mapping, the base station comprising:

means for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

means for bits in the first case, for determining the address after physical channel mapping using an address of those bits prior to physical channel mapping;

means for bits in the second case, for determining a switch point, for classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and for determining the address for those bits using the category classification;

means for bits in the third case, for determining a switch point, for classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and for determining the address for those bits using the category classification; and

means for bits in the third case, for determining a switch point, for classifying those bits into one of three categories, the three categories including forward before the switch

point, reverse before the switch point and reverse after the switch point, and for determining the address for those bits using the category classification.

49. The base station of claim 48 wherein the switch point for the second case is a length of a shortest resource unit multiplied by a number of resource units.

50. The base station of claim 48 wherein the switch point for the third case is a length of the first resource unit multiplied by a modulo index, the modulo index is derived by the spreading factors of the first and second resource units.

51. A base station capable of determining an address for bits after physical channel mapping, the base station comprising:

a physical channel mapping engine:

for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

for bits in the first case, determining the address after physical channel mapping using an address of those bits prior to physical channel mapping;

for bits in the second case, determining a switch point, classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and determining the address for those bits using the category classification;

for bits in the third case, determining a switch point, classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and determining the address for those bits using the category classification; and

for bits in the third case, determining a switch point, classifying those bits into one of three categories, the three categories including forward before the switch point, reverse before the switch point and reverse after the switch point, and determining the address for those bits using the category classification.

52. The base station of claim 51 wherein the switch point for the second case is a length of a shortest resource unit multiplied by a number of resource units.

53. The base station of claim 51 wherein the switch point for the third case is a length of the first resource unit multiplied by a modulo index, the modulo index is derived by the spreading factors of the first and second resource units.

54. The base station of claim 51 wherein the switch point for the fourth case is a length of the first resource unit multiplied by a modulo index and divided by (the modulo index minus one), the modulo index is derived by the spreading factors of the first and second resource units.

55. A method for determining an address for bits prior to physical channel mapping using an address of the bits after physical channel mapping for use in a wireless communication system, the method comprising:

categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

for bits in the first case, determine the address prior to physical channel mapping using an address of the bits after physical channel mapping;

for bits in the second case, determining a switch point, classifying those bits into one of four categories, the four categories including forward before the switch point, reverse

before the switch point and forward after the switch point and reverse after the switch point, and determining the address for those bits using the category classification;

for bits in the third case, determining a reverse switch point, classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and determining the address for those bits using the category classification; and

for bits in the fourth case, determining a reverse switch point, classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and determining the address for those bits using the category classification.

56. The method of claim 55 wherein for bits in the second case, the switch point is a length of the shortest resource unit.

57. The method of claim 55 for bits in the third case, determining a forward switch point, the forward switch point is equal to a length of the first resource unit.

58. The method of claim 57 wherein for bits in the third case, the reverse switch point is equal to a length of the second resource unit minus ((a modulus index derived by the spreading factors of the first and second resource units minus 1) multiplied by the forward switch point).

59. The method of claim 57 wherein for bits in the fourth case, the reverse switch point is equal to a length of the second resource unit minus a length of the first resource unit divided by (a modulus index derived by the spreading factor of the first and second resource units minus one).

60. A user equipment for determining an address for bits prior to physical channel mapping using an address of the bits after physical channel mapping, the user equipment comprising:

means for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

means for bits in the first case, for determining the address prior to physical channel mapping using an address of the bits after physical channel mapping;

means for bits in the second case, for determining a switch point, for classifying those bits into one of four categories, the four categories including forward before the switch point,

reverse before the switch point and forward after the switch point and reverse after the switch point, and for determining the address for those bits using the category classification;

means for bits in the third case, for determining a reverse switch point, for classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and for determining the address for those bits using the category classification; and

means for bits in the fourth case, for determining a reverse switch point, for classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and for determining the address for those bits using the category classification.

61. The user equipment of claim 60 wherein for bits in the second case, the switch point is a length of the shortest resource unit.

62. The user equipment of claim 60 the means for bits in the third case, for determining a forward switch point, the forward switch point is equal to a length of the first resource unit.

63. The user equipment of claim 62 wherein for bits in the third case, the reverse switch point is equal to a length of the second resource unit minus ((a modulus index derived

by the spreading factors of the first and second resource units minus 1) multiplied by the forward switch point.

64. The user equipment of claim 62 wherein for bits in the fourth case, the reverse switch point is equal to a length of the second resource unit minus a length of the first resource unit divided by (a modulus index derived by the spreading factor of the first and second resource units minus one).

65. A user equipment for determining an address for bits prior to physical channel mapping using an address of the bits after physical channel mapping, the user equipment comprising:

a physical channel mapping engine:

for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

for bits in the first case, for determining the address prior to physical channel mapping using an address of the bits after physical channel mapping;

for bits in the second case, for determining a switch point, for classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and for determining the address for those bits using the category classification;

for bits in the third case, for determining a reverse switch point, for classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and for determining the address for those bits using the category classification; and

for bits in the fourth case, for determining a reverse switch point, for classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and for determining the address for those bits using the category classification.

66. The user equipment of claim 65 wherein for bits in the second case, the switch point is a length of the shortest resource unit.

67. The user equipment of claim 65 the means for bits in the third case, for determining a forward switch point, the forward switch point is equal to a length of the first resource unit.

68. The user equipment of claim 67 wherein for bits in the third case, the reverse switch point is equal to a length of the second resource unit minus ((a modulus index derived by the spreading factors of the first and second resource units minus 1) multiplied by the forward switch point.

69. The user equipment of claim 67 wherein for bits in the fourth case, the reverse switch point is equal to a length of the second resource unit minus a length of the first resource unit divided by (a modulus index derived by the spreading factor of the first and second resource units minus one).

70. A base station for determining an address for bits prior to physical channel mapping using an address of the bits after physical channel mapping, the base station comprising:

means for categorizing the bits into a first, second, third and fourth case, the first case is for bits transferred in an only resource unit in a time slot, the second case is for bits transferred in a downlink resource unit, the third case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is greater than or equal to a spreading factor of a second resource unit, the fourth case is for bits transferred in an uplink resource unit where a spreading factor of data in a first resource unit is less than a spreading factor of a second resource unit;

means for bits in the first case, for determining the address prior to physical channel mapping using an address of the bits after physical channel mapping;

means for bits in the second case, for determining a switch point, for classifying those bits into one of four categories, the four categories including forward before the switch point, reverse before the switch point and forward after the switch point and reverse after the switch point, and for determining the address for those bits using the category classification;

means for bits in the third case, for determining a reverse switch point, for classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and for determining the address for those bits using the category classification; and

means for bits in the fourth case, for determining a reverse switch point, for classifying those bits into one of three categories, the three categories including forward, reverse before the reverse switch point and reverse after the reverse switch point, and for determining the address for those bits using the category classification.

71. The base station of claim 70 wherein for bits in the second case, the switch point is a length of the shortest resource unit.

72. The base station of claim 70 the means for bits in the third case, for determining a forward switch point, the forward switch point is equal to a length of the first resource unit.

73. The base station of claim 72 wherein for bits in the third case, the reverse switch point is equal to a length of the second resource unit minus ((a modulus index derived by the spreading factors of the first and second resource units minus 1) multiplied by the forward switch point).

74. The base station of claim 72 wherein for bits in the fourth case, the reverse switch point is equal to a length of the second resource unit minus a length of the first resource unit divided by (a modulus index derived by the spreading factor of the first and second resource units minus one).

75. A method for determining an address for a bit prior to second interleaving for use in a wireless communication system, the method comprising:

using an address of the bit after second interleaving, a total number of interleaved bits and known column permutations, to determine a column and row of the bit in a permuted array;

using the known column permutations, to determine a non-permuted column in a non-permuted array based on the determined column in the permuted array; and

determining an address of the bit prior to second interleaving using the determined permuted array column and the determined row.

76. The method of claim 75 wherein the total number of interleaved bits and the known column permutations is used to determine a number of bits in columns prior to a the bit and the determined column and row is determined using the determined number of bits in the prior to columns.

77. A user equipment for determining an address for a bit prior to second interleaving, the user equipment comprising:

means for using an address of the bit after second interleaving, a total number of interleaved bits and known column permutations, to determine a column and row of the bit in a permuted array;

means for using the known column permutations, to determine a non-permuted column in a non-permuted array based on the determined column in the permuted array; and

means for determining an address of the bit prior to second interleaving using the determined permuted array column and the determined row.

78. The user equipment of claim 77 wherein the total number of interleaved bits and the known column permutations is used to determine a number of bits in columns prior to a the bit and the determined column and row is determined using the determined number of bits in the prior to columns.

79. A user equipment for determining an address for a bit prior to second interleaving, the user equipment comprising:

a second interleaving address engine for using an address of the bit after second interleaving, a total number of interleaved bits and known column permutations, to determine a column and row of the bit in a permuted array; for using the known column permutations, to determine a non-permuted column in a non-permuted array based on the determined column in the permuted array; and for determining an address of the bit prior to second interleaving using the determined permuted array column and the determined row.

80. The user equipment of claim 79 wherein the total number of interleaved bits and the known column permutations is used to determine a number of bits in columns prior to the bit and the determined column and row is determined using the determined number of bits in the prior to columns.

81. A base station for determining an address for a bit prior to second interleaving, the base station comprising:

means for using an address of the bit after second interleaving, a total number of interleaved bits and known column permutations, to determine a column and row of the bit in a permuted array;

means for using the known column permutations, to determine a non-permuted column in a non-permuted array based on the determined column in the permuted array; and

means for determining an address of the bit prior to second interleaving using the determined permuted array column and the determined row.

82. The base station of claim 81 wherein the total number of interleaved bits and the known column permutations is used to determine a number of bits in columns prior to a the bit and the determined column and row is determined using the determined number of bits in the prior to columns.

83. A base station for determining an address for a bit prior to second interleaving, the base station comprising:

a second interleaving address engine for using an address of the bit after second interleaving, a total number of interleaved bits and known column permutations, to determine a column and row of the bit in a permuted array; for using the known column permutations, to determine a non-permuted column in a non-permuted array based on the determined column in the permuted array; and for determining an address of the bit prior to second interleaving using the determined permuted array column and the determined row.

84. The base station of claim 83 wherein the total number of interleaved bits and the known column permutations is used to determine a number of bits in columns prior to a the bit and the determined column and row is determined using the determined number of bits in the prior to columns.

85. A method for determining an address for bits prior to rate matching for use in a wireless communication system, the method comprising:

categorizing the bits as being turbo coded or non-turbo coded;

if the bits are categorized as non-turbo coded, treat the bits as a string and determine an address of the bits; and

if the bits are categorized as turbo coded, treat the bits as a single string and using information of the systematic, parity 1 and parity 2 strings, determining the address of the bits.

86. The method of claim 85 wherein the step of determining the address of the bits categorized as turbo coded comprises:

approximating a number of punctures prior to one bit of the bits prior to an address of the one bit;

search a space around the approximated number; and

determine an address of the one bit with the search space using the known constraints and intermediate values.

87. The method of claim 85 wherein the step of determining the address of the bits categorized as turbo coded comprises:

for one bit of the bits, estimating a systematic ratio using a puncture ratio of the parity 1 and parity 2 sequences;

produce a plurality of the systematic ratio candidates using the estimated systematic ratio; and

determining at least one after rate matching address for each candidate;

determining a matching candidate out of the plurality of candidates, wherein the address of the matching candidate matches an address of the one bit after rate matching;

using the matching candidate to determine a number of systematic, parity 1 and parity 2 bits; and

determining the address of the one bit using the determined number of systematic, parity 1 and parity 2 bits.

88. The method of claim 87 wherein the number of candidates is three.

89. The method of claim 88 wherein a number of determined after rate matching addresses for each candidate is four.

90. A user equipment for determining an address for bits prior to rate matching, the user equipment comprising:

means for categorizing the bits as being turbo coded or non-turbo coded;

means if the bits are categorized as non-turbo coded, for treating the bits as a string and determine an address of the bits; and

means if the bits are categorized as turbo coded, for treating the bits as a single string and using information of the systematic, parity 1 and parity 2 strings, determining the address of the bits.

91. The user equipment of claim 90 wherein the means for determining the address of the bits categorized as turbo coded comprises:

means for approximating a number of punctures prior to one bit of the bits prior to an address of the one bit;

means for searching a space around the approximated number; and

means for determining an address of the one bit with the search space using the known constraints and intermediate values.

92. The user equipment of claim 90 wherein the means for determining the address of the bits categorized as turbo coded comprises:

means for one bit of the bits, for estimating a systematic ratio using a puncture ratio of the parity 1 and parity 2 sequences;

means for producing a plurality of the systematic ratio candidates using the estimated systematic ratio; and

means for determining at least one after rate matching address for each candidate;

means for determining a matching candidate out of the plurality of candidates, wherein the address of the matching candidate matches an address of the one bit after rate matching;

means for using the matching candidate to determine a number of systematic, parity 1 and parity 2 bits; and

means for determining the address of the one bit using the determined number of systematic, parity 1 and parity 2 bits.

93. The user equipment of claim 92 wherein the number of candidates is three.

94. The user equipment of claim 93 wherein a number of determined after rate matching addresses for each candidate is four.

95. A user equipment for determining an address for bits prior to rate matching, the user equipment comprising:

a rate matching engine for categorizing the bits as being turbo coded or non-turbo coded; if the bits are categorized as non-turbo coded, for treating the bits as a string and determine an address of the bits; and if the bits are categorized as turbo coded, for treating

the bits as a single string; and using information of the systematic, parity 1 and parity 2 strings, for determining the address of the bits.

96. The user equipment of claim 95 wherein the determining the address of the bits categorized as turbo coded comprises:

approximating a number of punctures prior to one bit of the bits prior to an address of the one bit;

searching a space around the approximated number; and

determining an address of the one bit with the search space using the known constraints and intermediate values.

97. The user equipment of claim 95 wherein the determining the address of the bits categorized as turbo coded comprises:

for one bit of the bits, estimating a systematic ratio using a puncture ratio of the parity 1 and parity 2 sequences;

for producing a plurality of the systematic ratio candidates using the estimated systematic ratio; and

for determining at least one after rate matching address for each candidate;

for determining a matching candidate out of the plurality of candidates, wherein the address of the matching candidate matches an address of the one bit after rate matching;

for using the matching candidate to determine a number of systematic, parity 1 and parity 2 bits; and

for determining the address of the one bit using the determined number of systematic, parity 1 and parity 2 bits.

98. The user equipment of claim 97 wherein the number of candidates is three.

99. The user equipment of claim 98 wherein a number of determined after rate matching addresses for each candidate is four.

100. A base station for determining an address for bits prior to rate matching, the base station comprising:

means for categorizing the bits as being turbo coded or non-turbo coded;

means if the bits are categorized as non-turbo coded, for treating the bits as a string and determine an address of the bits; and

means if the bits are categorized as turbo coded, for treating the bits as a single string and using information of the systematic, parity 1 and parity 2 strings, determining the address of the bits.

101. The base station of claim 100 wherein the means for determining the address of the bits categorized as turbo coded comprises:

means for approximating a number of punctures prior to one bit of the bits prior to an address of the one bit;

means for searching a space around the approximated number; and

means for determining an address of the one bit with the search space using the known constraints and intermediate values.

102. The base station of claim 100 wherein the means for determining the address of the bits categorized as turbo coded comprises:

means for one bit of the bits, for estimating a systematic ratio using a puncture ratio of the parity 1 and parity 2 sequences;

means for producing a plurality of the systematic ratio candidates using the estimated systematic ratio; and

means for determining at least one after rate matching address for each candidate;

means for determining a matching candidate out of the plurality of candidates, wherein the address of the matching candidate matches an address of the one bit after rate matching;

means for using the matching candidate to determine a number of systematic, parity 1 and parity 2 bits; and

means for determining the address of the one bit using the determined number of systematic, parity 1 and parity 2 bits.

103. The base station of claim 102 wherein the number of candidates is three.

104. The base station of claim 103 wherein a number of determined after rate matching addresses for each candidate is four.

105. A base station for determining an address for bits prior to rate matching, the base station comprising:

a rate matching engine for categorizing the bits as being turbo coded or non-turbo coded; if the bits are categorized as non-turbo coded, for treating the bits as a string and determine an address of the bits; and if the bits are categorized as turbo coded, for treating the bits as a single string; and using information of the systematic, parity 1 and parity 2 strings, for determining the address of the bits.

106. The base station of claim 105 wherein the determining the address of the bits categorized as turbo coded comprises:

approximating a number of punctures prior to one bit of the bits prior to an address of the one bit;

searching a space around the approximated number; and

determining an address of the one bit with the search space using the known constraints and intermediate values.

107. The base station of claim 105 wherein the determining the address of the bits categorized as turbo coded comprises:

for one bit of the bits, estimating a systematic ratio using a puncture ratio of the parity 1 and parity 2 sequences;

for producing a plurality of the systematic ratio candidates using the estimated systematic ratio; and

for determining at least one after rate matching address for each candidate;

for determining a matching candidate out of the plurality of candidates, wherein the address of the matching candidate matches an address of the one bit after rate matching;

for using the matching candidate to determine a number of systematic, parity 1 and parity 2 bits; and

for determining the address of the one bit using the determined number of systematic, parity 1 and parity 2 bits.

108. The base station of claim 107 wherein the number of candidates is three.

109. The base station of claim 108 wherein a number of determined after rate matching addresses for each candidate is four.

110. A method for physical layer processing for use in a wireless communication system, the method comprising:

first interleaving bits received in a time transmission interval, the time transmission interval having bits for at least one frame; and

for the first interleaved bits of a first frame of the at least one frame, performing physical channel processing prior to buffering the first frame first interleaved bits, the physical channel processing comprising rate matching.

111. The method of claim 110 wherein if the time transmission interval having bits for a plurality of frames, the method comprising buffering frames other than the first frame after first interleaving and prior to physical channel processing.

112. The method of claim 110 wherein the performing physical channel processing further comprises bit scrambling, second interleaving and physical channel mapping.

113. The method of claim 110 wherein no buffering is performed during physical channel processing.

114. The method of claim 112 wherein no buffering is performed during physical channel processing.

115. A user equipment for physical layer processing, the user equipment comprising:
means for first interleaving bits received in a time transmission interval, the time transmission interval having bits for at least one frame; and
means for the first interleaved bits of a first frame of the at least one frame, for performing physical channel processing prior to buffering the first frame first interleaved bits, the physical channel processing comprising rate matching.

116. The user equipment of claim 115 wherein if the time transmission interval having bits for a plurality of frames, the user equipment comprising means for buffering frames other than the first frame after first interleaving and prior to physical channel processing.

117. The user equipment of claim 115 wherein the means for performing physical channel processing further comprises bit scrambling, second interleaving and physical channel mapping.

118. The user equipment of claim 115 wherein no buffering is performed during physical channel processing.

119. The user equipment of claim 117 wherein no buffering is performed during physical channel processing.

120. A user equipment comprising:

- a first interleaver for first interleaving bits received in a time transmission interval, the time transmission interval having bits for at least one frame;
- a first multiplexer for directing the first interleaved bits of a first frame to a second multiplexer and the first interleaved bits of frames other than the first frame to a memory;
- a second multiplexer for outputting bits selected between the first frame bits and the other frames' bits stored in the memory for physical channel processing; and
- a physical channel processing block for performing physical channel processing of the outputted selected bits.

121. The user equipment of claim 120 wherein the physical channel processing block performs rate matching, bit scrambling, second interleaving and physical channel mapping.

122. The user equipment of claim 120 wherein an output of the physical channel processing block is stored in memory.

123. A base station for physical layer processing, the base station comprising:

means for first interleaving bits received in a time transmission interval, the time transmission interval having bits for at least one frame; and

means for the first interleaved bits of a first frame of the at least one frame, for performing physical channel processing prior to buffering the first frame first interleaved bits, the physical channel processing comprising rate matching.

124. The base station of claim 123 wherein if the time transmission interval having bits for a plurality of frames, the base station comprising means for buffering frames other than the first frame after first interleaving and prior to physical channel processing.

125. The base station of claim 123 wherein the means for performing physical channel processing further comprises bit scrambling, second interleaving and physical channel mapping.

126. The base station of claim 123 wherein no buffering is performed during physical channel processing.

127. The base station of claim 125 wherein no buffering is performed during physical channel processing.

128. A base station comprising:

a first interleaver for first interleaving bits received in a time transmission interval, the time transmission interval having bits for at least one frame;

a first multiplexer for directing the first interleaved bits of a first frame to a second multiplexer and the first interleaved bits of frames other than the first frame to a memory;

a second multiplexer for outputting bits selected between the first frame bits and the other frames' bits stored in the memory for physical channel processing; and

a physical channel processing block for performing physical channel processing of the outputted selected bits.

129. The base station of claim 128 wherein the physical channel processing block performs rate matching, bit scrambling, second interleaving and physical channel mapping.

130. The base station of claim 128 wherein an output of the physical channel processing block is stored in memory.

131. A method for determining a value of a given bit after bit scrambling for use in a wireless communication system:

using an address of the given bit prior to bit scrambling, determine a scrambling bit in the scrambling code corresponding to the given bit; and

scrambling the bit using the given bit.

132. The method of claim 131 wherein the scrambling is performed by exclusive-oring the given bit with the scrambling bit.

133. A user equipment comprising:
means for using an address of the given bit prior to bit scrambling, for determining a scrambling bit in the scrambling code corresponding to the given bit; and
means for scrambling the bit using the given bit.

134. The user equipment of claim 131 wherein the scrambling is performed by exclusive-oring the given bit with the scrambling bit.

135. A user equipment comprising:
a bit scrambling engine using an address of the given bit prior to bit scrambling, for determining a scrambling bit in the scrambling code corresponding to the given bit; and for scrambling the bit using the given bit.

136. The user equipment of claim 135 wherein the scrambling is performed by exclusive-oring the given bit with the scrambling bit.

137. A base station comprising:

means for using an address of the given bit prior to bit scrambling, for determining a scrambling bit in the scrambling code corresponding to the given bit; and

means for scrambling the bit using the given bit.

138. The base station of claim 137 wherein the scrambling is performed by exclusive-oring the given bit with the scrambling bit.

139. A base station comprising:

a bit scrambling engine using an address of the given bit prior to bit scrambling, for determining a scrambling bit in the scrambling code corresponding to the given bit; and for scrambling the bit using the given bit.

140. The base station of claim 139 wherein the scrambling is performed by exclusive-oring the given bit with the scrambling bit.
