(54) Title: NOVEL METHOD OF TREATING MACULAR DEGENERATION

**FIG. 3**

(57) **Abstract:** Formulations and methods of treatment are disclosed for prevention and/or treatment of visual loss from age-related macular degeneration. The disclosed formulations include botulinum neurotoxin (e.g., botulinum neurotoxin or a fragment thereof, either in pure form or with one or more peptide fragments and/or neurotoxin associated proteins). In some embodiments, the disclosed formulations also include one or more anti-VEGF agents. The disclosed formulations may be applied to an intraocular or extraocular region of a patient. If applied to an extraocular region of a patient, the botulinum-based pharmaceutical formulation may be transported to the intra-ocular region of the patient via axoplasmic transport, thereby allowing the active ingredient(s) to penetrate into the choroid, neuro-retina, and/or retinal pigment epithelium without direct injection into the eye, allowing for improved therapeutic safety by eliminating risk of retinal detachment, retinal break, retinal hemorrhage, and blindness associated with direct injection into the eye.

NOVEL METHOD OF TREATING MACULAR DEGENERATION

CROSS REFERENCE TO RELATED APPLICATIONS

5

This application claims priority from U.S. Provisional Application Serial No. 62/431,512, filed December 8, 2016, U.S. Provisional Application Serial No. 62/449,914, filed January 24, 2017, and U.S. Provisional Application Serial No. 62/533,961, filed July 18, 2017, the contents of which are each incorporated by reference herein.

10

BACKGROUND

Macular degeneration is a major cause of human blindness, generally occurring in the population over 50 years in age. The condition is genetic with offspring having about a 50 % chance of inheriting a clinically significant condition from a parent who became legally blind from the affliction. Macular degeneration accounts for up to 70% of the irreversible blindness in the United States and is one of the most common problems encountered by Ophthalmologists. Worldwide, the projected number of people with age-related macular degeneration in 2020 will be 196 million and is predicted to increase 288 million in 2040.

15

SUMMARY

Novel formulations and methods of treating and possibly preventing visual loss from macular degeneration by administering botulinum toxin-based pharmaceuticals are disclosed herein. Administration of the disclosed formulations can be intra-ocular or extra ocular, and, in some embodiments, may include subcutaneous, sub-muscular, intraneural, topical, intraosseous, and/or interfacial injection. As used herein, the term “intra-ocular” refers to the application of formulation directly to the globe of the eye and the term “extra ocular” refers to the application of formulation to regions other than the globe of the eye (e.g., to the eyelid or to the orbital). In cases where extra ocular injections are employed, complications of intra-ocular injections can be avoided. In some embodiments, repeated injections may be employed to keep biologic effect current and operational. Improvements in vision can be subjectively reported after treatment according to the disclosed methods and, in some cases, SD-OCT, fundoscopy, or other imaging techniques may be used to observe physical changes in the physical structure of the eye.

20

25

30

In some embodiments, an injection may penetrate the orbit and macular via pathways which do not cause a weakening of the extra ocular muscles, thereby avoiding diplopia, apoptosis, and other neuromuscular effects which can create complications. As explained below in detail, the disclosed formulations and methods may be designed to target one or more of the following tissues:

5 choroid, neuro retina, retinal pigment epithelium (RPE), peripheral nerves entering the eye, and/or other associated tissues. The disclosed formulations and methods may, in some embodiments, be used to treat both exudative forms of macular degeneration (i.e., with intra retinal fluid, blood, or sub-retinal fluid or blood and non-exudative forms, which can lead to geographic atrophy).

Prior to administering the disclosed formulations to a patient, a clinical assessment may be

10 made by a qualified medical practitioner to evaluate whether treatment according to the disclosed methods is appropriate. Clinical assessment may be made based on one or more of the following: family history, fundus inspection using photography, SD OCT, with careful evaluation of the status of the retinal pigment epithelium for defective signs, including but not limited to presence of pigment in fundoscopy, pigment migration anteriorly into the neuro-retina (intra-retinal hyper

15 pigment), presence and volume of drusen, focal intra retinal hyper reflection, sub drusenoid deposits, sub-drusenoid hyperreflectivity, dynamic reduction in drusen volume, second eye staging for severity, hypo reflectivity, choroidal neovascularization, hypo pigmentation, discontinuity and disappearance of OCT reflectivity lines (e.g., IS-OS, external nuclear layer, RPE layer), retinal and choroidal thickness or associated components, dynamic changes in any measurements, thickening

20 of reflectivity lines, cyst formation, and any configuration of fluid formations. In some cases, activation of the RPE may be a risk factor for macular degeneration progression and an assessment may be made for progression risk based on one or more of: anatomic pathologic findings, history, and tempo of disease progression and status of the second eye.

As explained in detail below, the disclosed formulations and treatment methods may delay

25 degeneration of the RPE, preserve photoreceptors, treat or prevent high risk leakage, treat and prevent neovascularization, prevent cell apoptosis, treat and prevent RPE activation, treat and prevent RPE migration, treat and prevent sheet distortion in the RPE, prevent geographic atrophy, prevent retinal atrophy, prevent loss of rods and cones, convert wet stage to dry stage, preserve vision and/or restore vision.

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1A-1C are illustrations of the macula of an eye. In particular, FIG. 1A illustrates a healthy macula, FIG. 1B illustrates a macula suffering from dry macular degeneration, and FIG. 1C

illustrates a macula suffering from wet macular degeneration. Wet macular degeneration is often associated with rapid loss of vision and dry macular degeneration is associated with slow progression loss of vision. Forms of dry macular degeneration can also indicate risk for conversion to a wet (exudative state) and should be followed by the clinician over time.

5 FIG. 1D is an image obtained using optic coherent tomography (OCT), showing breakage in continuity of the retinal pigment epithelium (RPE), as would occur in early-stage age-related macular degeneration.

10 FIG. 2 is an OCT image illustrating a dense disciform fibrotic scar in end stage macular degeneration. Portions of the scar illustrated in FIG. 2 demonstrate geographic atrophy (GA), with attendant loss of photoreceptors.

FIG. 3 is an OCT image illustrating leakage of fluid through the RPE under the neuro retina in a case of wet macular degeneration.

FIGS. 4A-4C illustrate the hexagonal structure of the RPE.

15 FIGS. 5A-5F illustrate disruption of membranes, sub membrane condensation, alteration of hexagonal shapes of the structure, RPE autolysis, stress fiber formation from actin associated with macular degeneration.

FIG. 6 illustrates a top view of a human dissection orbit with penetration of nerves and vessels into the posterior pole under the macula.

20 FIG. 7 illustrates extra-ocular administration followed by nerve penetration and transcytosis with eye penetration.

FIG. 8 shows a schematic drawing of the glomerular barrier.

FIGS. 9A-9F illustrate OCT images obtained from patients treated with the disclosed therapeutic formulations, according to the disclosed methods. Enhancement effects of anti-VEGF agents are also visible in FIGS. 9A-9F.

25 FIGS. 10A-10B illustrate OCT images obtained from a patient treated with the disclosed therapeutic formulations, according to the disclosed methods.

FIGS. 11A-11D illustrate OCT images obtained from a patient treated with the disclosed therapeutic formulations, according to the disclosed methods.

30 FIGS. 12A-12C illustrate OCT images obtained from a patient treated with the disclosed therapeutic formulations, according to the disclosed methods.

FIGS. 13A and 13B illustrate OCT images obtained from a patient treated with the disclosed therapeutic formulations, according to the disclosed methods.

FIGS. 14A-14D illustrate stress fibers in RPE cells.

DETAILED DESCRIPTION

Macular degeneration generally destroys central vision in an afflicted individual, causing inability to read, drive and conduct an independent and productive life. The rapid decline of vision is generally associated with the exudative “or wet” form of the disease in which there is a leakage of fluid from newly formed pathologic choroidal vessels through the biologic barrier established by the retinal pigment epithelium. The leak through the retinal pigment epithelium leads to the destruction of photoreceptors with alteration in the structure of the retinal pigment epithelium into a fibrotic scar or an atrophic state with associated photoreceptor destruction.

Current treatments for macular degeneration involve intra-ocular injections of protein-based antibodies (monoclonal antibodies) to vascular endothelial growth factors (VEGF and related targets) resulting in diminished leakage from neovascularization and recession of the new vessel growth with restoration of the vital interface between the neuro retinal photoreceptors and the retinal pigment epithelium. These current therapies require intra-ocular injections due to the short half-life and molecular size of the existing agents. Intra-ocular injections practiced in the field of Ophthalmology carry many risks, including damage to intra-ocular contents (lens, retina, choroid and potential for intra-ocular infections).

In contrast to previous therapeutic approaches for macular degeneration treatment, a novel method of treating, preventing, mitigating, and/or reversing macular degeneration is disclosed. In the disclosed methods, botulinum toxin (in any known form, for example, botulinum neurotoxin or a fragment thereof) or one or more of its peptide fragments or neurotoxin associated proteins (accessory proteins) are injected into intra ocular regions (i.e., the globe of the eye) and/or extra ocular regions (i.e., outside the globe of the eye, for example, the eyelid) of the patient. Application of the disclosed compounds to one or more extra ocular regions of the patient can treat or, in some cases, prevent visual loss from macular degeneration or any of its associated conditions. As described herein in detail, botulinum toxin and fragments thereof may undergo axoplasmic transport. Accordingly, providing botulinum toxin and related compounds to a patient’s per-ocular region or extra orbital region(s) can allow for penetration into intra-ocular regions and penetration into choroid, neuro-retina, and/or retinal pigment epithelium, without direct injection into the eye. In the disclosed remote administration format, botulinum toxin and related compounds may produce barrier-enhancing effects and regression of pathologic processes associated with macular degeneration, all without potential complications associated with intra-ocular injection.

As used herein, the term “botulinum toxin” refers to any known form of botulinum toxin, including but not necessarily limited to: pure botulinum neurotoxin, a fragment thereof, and/or neurotoxin associated proteins. For example, the botulinum toxin may be produced by the bacterium *Clostridium botulinum* (for example, by fermentation) or by recombinant techniques,

including engineered variants and fusion proteins. In some particular example embodiments, the botulinum toxin is produced using recombinant or synthetic chemical techniques (for example, a recombinant peptide, a fusion protein, and/or a hybrid neurotoxin prepared from subunits of different botulinum toxin serotypes). The botulinum toxin may be of serotype A-H and, in some
5 embodiments, the botulinum toxin is present as an isolated botulinum neurotoxin molecule (e.g., botulinum toxin type A neurotoxin having a molecular formula of $C_{6760}H_{10447}N_{1743}O_{2010}S_{32}$ and an atomic mass of 150 kDa). The formulation Xeomin® (incobotulinumtoxinA), is an example of a pure botulinum neurotoxin (devoid of associated accessory proteins). In embodiments with an isolated botulinum neurotoxin molecule, one or more exogenous stabilizers (e.g., albumin) may
10 also be included in the formulation. In embodiments with botulinum toxin in a complexed form (i.e., with hemagglutinin and associated proteins present), one or more exogeneous stabilizers may also be present. In some particular example embodiments, the botulinum toxin used in the disclosed formulations and methods includes one or more associated proteins that are devoid of pure neurotoxin. Some example associated proteins that are devoid of pure neurotoxin include but
15 are not limited to hemagglutinin derived from the fermentation processes which create the raw materials for botulinum toxin based pharmaceuticals (e.g., Hall strain fermentation for botulinum toxin type A) and non-hemagglutinin, non-neurotoxin from the fermentation of the same process. Additionally, hemagglutinin and fragments thereof which carry specific activity on cell to cell adhesion proteins (e.g., cadherin or other associated proteins) can be separated or genetically
20 expressed in suitable carriers which subsequent purification. Fermentation processes prototypes have been described (e.g., Borodic GE, Pearce LB, Johnson E, Schantz E: *Clinical and Scientific Aspects of Therapeutic Botulinum Toxin Administrations*, Ophthalmology Clinics of N America, September, Vol. 4, No. 3, 1991). In some embodiments, purification of end products of fermentation may create the raw materials for the associated proteins. Proteins can be recombinant
25 process expressed from whole or portions of identified genes corresponding to associated proteins.

In some embodiments, the disclosed formulations may include a botulinum toxin (in pure neurotoxin form or with neurotoxin associated proteins present), hemagglutinin (in any known and suitable form), and/or one or more anti-VEGF agents. In some embodiments, the botulinum toxin may be fused to the anti-VEGF agent(s) present, while, in other embodiments, the botulinum toxin
30 may be separate and distinct from (i.e., not fused to) the anti-VEGF agent(s).

Fusion proteins are produced using genetic material corresponding to a protein or protein fragment, wherein the genes from one protein are ligated (via suitable ligases) to one or more separated genes corresponding to other proteins created a protein hybrid with preservation of the desired biologic activity of each protein to create a useful agent or drug. The fused genetic material

may be amplified by PCR in the process, often with addition of connecting materials and elimination of termination codons. In some embodiments, target domains of botulinum toxin can involve selective nerve uptake (near carboxy terminus of the botulinum heavy chain, fragment of botulinum molecule, or accessory molecules), which express proteins involved in forming or
5 regulating expression of structural proteins connecting cells or regulating cytoskeleton, or involved in proteins governing RPE function, or rod con function. Further, proteins with anti-VEGF activity can be fused with botulinum toxin or its fragments or accessory proteins or fragments. Further monoclonal antibodies targeting inflammatory mediators such as complement or other inflammatory autacoids can be added to a fusion protein, which contains a botulinum fragment.
10 Rho and/or ROCK modulators may also be added to the fusion protein, in some embodiments. One or more fragments of VEGF receptors, entire receptors, fragments of nerve growth proteins, VEGF subtypes or fragments which impede angiogenesis, and/or immunoglobulin fractions which improve protein stability and decrease immunogenicity may also be added, in some embodiments.

A unique aspect of fusion proteins relates to fluorescent tags, which can be used to study
15 transport in animal models (and possibly clinically) to further understand axoplasmic flow dynamics to target specific retinal and choroidal tissues from injection outside the globe and penetrating through various structures such as peripheral nerves. In this disclosure, fusion proteins may be formed with botulinum toxin-based carriers, which affect binding and transport through peripheral nerves. The fusion protein may contain both the carrier portions of a botulinum subtype,
20 a fragment of a botulinum type, and a fluorescent marker, in some embodiments. Other additions with biologic effects can be added to the fusion protein. Such compositions can be used to study the pharmacodynamic effect of botulinum toxin-based pharmaceuticals *in vivo* using standard photography used in ophthalmic practice (e.g., fluorescein angiography). In some such embodiments, the tag can also confirm that adequate drug has been delivered to the lesions on the
25 retina or choroid targeted for treatment. Differential penetration to targeted lesions by the therapeutic agent may also provide important individualized dosing, general dosing, effectiveness of carrier proteins, formulations, and pre-clinical data necessary for qualifying a fusion protein for clinical use. The disclosed methods may also involve direct visualization of retinal tissue *in vivo* or *in vitro* for penetration and localization in the retina and choroid.

30 In these and other embodiments, the disclosed formulations may also include a stabilizing excipient, such as albumin. In embodiments where one or more accessory proteins (i.e., complexing proteins, such as hemagglutinin) are present, the concentration and/or activity of the accessory proteins may be increased from naturally-occurring levels. Numerous configurations and

variations will be apparent to those skilled in the art upon consideration of the subject disclosure and teachings provided herein.

Current Macular Degeneration Treatment Methods

Currently, effective therapy for age-related macular degeneration (AMD) is limited to the wet form treated with anti-vascular endothelial growth factors (“anti-VEGF”) agents and related fusion proteins with both antibody and receptor. The primary treatment for “wet AMD” is intravitreal injection with VEGF inhibitors. Currently, ranibizumab (Lucentis®) has FDA approval, whereas bevacizumab (Avastin) is used on an off-label basis. Eylea® (aflibercept) has been recently approved for macular degeneration with a slightly improved duration of action. Each of these drugs are given by intra-ocular injection. Eylea®, the newest FDA approved agents, achieves a commercial sale of almost 1 billion dollars per quarter.

Macular degeneration occurs in stages, typically starting with visible alterations of the retinal pigment epithelium on direct observation using photographs made through the human pupil and disruption of the cellular organization of the retinal pigment epithelium on optic coherent tomography (OCT). FIGS. 1A-1C provide illustrations of the various stages of macular degeneration, with FIG. 1A illustrating a normal macula, FIG. 1B illustrating dry macular degeneration, and FIG. 1C illustrating wet macular degeneration.

FIG. 1D is an image obtained using OCT, illustrating breakage in continuity of the retinal pigment epithelium, as would occur in early-stage AMD (age related macular degeneration). Disconnection and disruption of the retinal pigment epithelial cells can lead to tectonic barrier defects within the retinal pigment epithelial sheets and basement membrane (Bruch’s membrane) and growth of new blood vessels from the choroid layer of the posterior human eye. During AMD, retinal pigment epithelial cells are often seen breaking away from contiguous and adjacent cells adapting a migration into the neuro-retina (as shown in FIG. 1D). Discontinuity of the integrity of the retinal pigment epithelium is an important component in the pathogenesis of the disease. In stage 1 of the disease, atrophy, migration, autolysis, and disorganization occur in cells and associated pigment, leading to an abnormal appearance of the macular with irregularity of the pigment characterized by disruption in the usual pigment densities surrounding the fovea and irregular cell shapes, often with breakage of retinal epithelial barriers as the disease progresses. Alterations of the retinal pigment epithelium (RPE) leads to the formation of drusens (and drusenoid) pseudo drusens, pigment clumping, speckling, vitelliform regions, and hypopigmentation. In some cases, these symptoms may appear before more devastating changes occur (for example, geographic atrophy, choroidal neovascularization, and sub-retinal hemorrhaging).

As the disruption in cell to cell adhesion and cell to basement membrane adhesion advances, the growth of new vessels from the choroecapillaris through the pigment epithelial defects leads to further, more dramatic, vascular and choroidal leakage, disruption of the neural-retinal and retinal pigment epithelium apposition, ultimately resulting in devastating destruction of the photoreceptors (rods and cons) with loss of vision characterized by a central blind spot and loss of a person's ability to read.

FIG. 2 illustrates a dense disciform fibrotic scar with geographic atrophy (GA) in end stage macular degeneration. The eye shown in FIG. 2 is beyond legally blind. The disciform fibrotic scar shown in FIG. 2 is likely formed by collagen and related polarization of filamentous protein from other cellular elements. The retinal pigment epithelium (RPE) shown in FIG. 2 has undergone metaplasia to fibrous scarring (a process involving epithelial to mesenchymal transformation) and flat cellular atrophy and degeneration. This is an irreversible (end-stage) form of macular degeneration and difficult to treat.

FIG. 3 is an image obtained using OCT techniques and illustrates leakage of fluid through the RPE under the neuro retina in a case of wet macular degeneration. The type of leakage illustrated in FIG. 3 is generally associated with rapid vision deterioration and requires immediate medical intervention. Wet macular degeneration (as shown in FIG. 3) can be treated using drugs such as Avastin®, Lucentis®, EYLEA®, and abicipar (Allergan). These current drugs include different antibodies to various isoforms of vascular endothelial growth factors (VEGF), which cause recession of the developing neovascularization and/or leakage, resulting in return or stabilization of vision with partial restoration of the structural derangement in the retina with reduction in sub-retinal fluid.

Treatment with these drugs (anti-VEGF agents) usually require multiple injections and carry the risk of intra-ocular hemorrhage, infections (e.g., eye threatening endophthalmitis), PVR (post-operative proliferative vitreoretinopathy), lens dislocation, cataract, glaucoma, and/or retinal break and detachments. These injections can also be painful. The more injections that are given to a patient, the higher the chance of an administration-related complication. Injections into the eye are more painful than soft tissues surrounding the eye (e.g., lid, orbit, periocular and/or orbital muscles). Experts in the field of monoclonal antibodies and genetically engineered proteins have tried to prolong the duration of anti-VEGF agent action using a fusion protein between an anti-VEGF antibody, fractions of VEGF receptor 1 and 2, and Fc portion of immunoglobulin.

Overview of Presently Disclosed Treatment Approach

Without wishing to be bound by theory, enhancing the duration and potency of anti-VEGF therapy using an agent with a very long duration of action such as botulinum toxins, may add to

both safety and to improvement in the targeted relief of leakage, neo vascularization or tectonic instability of the continuity of the retinal pigment epithelium. Extra-ocular botulinum toxin can be used repeatedly, with well-defined, superior safety results. Extra ocular botulinum injections may, in some cases, eliminate the risk of intra-ocular hemorrhage, infections (endophthalmitis), lens
5 dislocation, cataract, and/or retinal break and detachments which can occur with existing therapeutic standard.

Fewer injections over longer intervals would be an improvement over existing therapeutic approaches. Many complications of the currently known treatments for macular degeneration are related to the anti-VEGF intra-ocular injection procedure rather than a medicinal side effect of the
10 agent. Botulinum toxins work for a longer period than known agents currently used for this condition. Further, diminished injection frequency would provide safer and more convenient treatment methods for patients.

In some embodiments, botulinum toxin can be used in conjunction with VEGF antibodies to further enhance potency of the injectable. For example, in some cases, treatment of macular
15 degeneration can be accomplished with one or more applications. Additionally, the disclosed botulinum toxin-based compounds may reduce or eliminate the need for frequent intra-ocular injections. Furthermore, botulinum toxin can be used with other agents that promote actin polymerization, such as nerve growth factor. Botulinum toxin may, in some cases, influence and bind to cadherin proteins, catenin polymers and on the Rac 1 system of acting on intracellular and
20 extracellular actin with enhancement of barrier functions along an epithelial or endothelial surface. Botulinum toxin also can be transported by axoplasmic flow, a unique property that allows transport into the eye without causing paralytic neuromuscular effects on extra-ocular muscles. As direct diffusion of botulinum toxin-based compounds may cause paralysis of extra-ocular muscles, the axoplasmic route of entry provides a novel delivery method for intra-ocular disease and may be
25 used for any of the disclosed compounds. In embodiments where an axoplasmic route of delivery is employed, medication may be delivered through nerves entering the back of the eye (posterior delivery) rather than the front of the eye (intravitreal, drop-topical, or intra-cameral delivery).

Fragments of botulinum toxin also can, in some embodiments, be fused with anti-VEGF agents to provide an intra-ocular administration via axoplasmic flow, thereby avoiding the need for
30 intra-ocular injections even for these agents which must currently be used by riskier intra-ocular injections. Botulinum toxin may interact with mast cell leading to alterations in maintenance neurotransmitters, neuropeptides, trophic agents, nerve growth factors, important to maintain a healthy retinal pigment epithelium. Other mechanisms of action are also possible and contemplated.

Anatomy of the RPE and Its Impact on Macular Degeneration

The RPE is a neuro-derived structure in utero which forms a cellular sheet with cell structure taking the configuration of a regular (equal sided hexagon) in RPE-RPE cell to cell contact. The apical surface is in the form of a microvilli which maximizes the physical contact with photoreceptors (rods, cones), allowing the physiologic phagocytosis of the photoreceptor membranes while the base of the RPE is attached tightly to its basement membranes (Bruch's membrane). This anatomic arrangement has been geometrically proven to maximize the compactness of the cells minimizing the connection of the cell surfaces. This assessment is also the same arrangement for a honey bee hive, and subject to a proposition made over 2,00 years ago (36 BC) by Roman scholar Marus Terentius Varro (the Honey bee conjecture). Geometric proof followed by Thomas Hales in 1999 (University of Michigan). This conjecture proposed that the regular hexagon sheet minimized connection material while maximizing sheet area. This anatomic allows bees to economize on producing beeswax in constructing the hive. This arrangement indicated the functional barrier is important for RPE cells and the biology of maintaining this barrier effect is a vital target for use of botulinum toxin to treat macular disease.

FIGS. 4A-4C illustrate the hexagonal structure of the RPE. In particular, FIG. 4A illustrates healthy a RPE and FIG. 4B illustrates interlocking hexagon structures. In the RPE, the structure allows for an economy for actin production, one of the major intracellular protein governing the attachments of the cell to cell adhesion, and the structural protein forming the sub-membrane support for the hexagon. Further, the microvilli of the RPE surface also is supported in structure by the projection and maintenance of intracellular actin, as well as the RPE attachment of the basement membranes. Actin also attaches to other cell to cell protein such as cadherins which functions as the grout-glue of the RPE sheet and support its functioning barrier effect. Derangement in actin formation, formation of altered forms and arrangement of actin and associated proteins, and regression of microvilli have been described as early changes in stage 1 age related macular degeneration and related diseases. FIG. 4C illustrates an RPE suffering from macular degeneration. As illustrated in FIG. 4C, the actin and microvilli of the diseased cells are misshapen and no longer arranged as orderly hexagons.

Without wishing to be bound by theory, botulinum toxin type A may act as a stimulator of actin on neural tissue. In other words, botulinum toxin may have an effect on neurally-derived RPE, providing a unique opportunity to alter RPE cells in certain disease states, such as age-related macular degeneration. In some cases, cell-to-cell barrier function, enhancement of microvilli surface area, and perhaps other associate structural proteins may provide a method to maintain RPE structure and function. In some embodiments, botulinum toxin may retard the progression of the

various stages of macular degeneration and related retinal diseases. The genomics expression toward actin may function to keep RPE cells in the differentiated state, allow adhesion, and prevent separation from surrounding cells and attachment to its basement membrane. It is conceivable that the genomic effects also keep the RPE cell producing other adhesion proteins (and functionally-related proteins) expressed. Repression mRNA expression of proteins of the RPE cell, which govern motility, cell death, cell atrophy, or metaplasia to a fibrocyte may also be possible and could be used to treat various stages of macular degeneration. This effect can be operational, in part with other mechanisms, but structural changes are critical to RPE, a neuro embryological neutrally-derived cell layer. The neural elements of the RPE may allow this useful interaction with botulinum neurotoxin(s) that allow and/or promote a therapeutic response.

Overview of Therapeutic Compounds and Related Methods

In some embodiments of the subject disclosure, a therapeutic formulation is provided. For example, in some embodiments, the therapeutic formulation comprises botulinum toxin (e.g., botulinum toxin types A-G, specifically, C2, C3 and/or various subtypes of A (for example, A1-A5)). The botulinum toxin included in the disclosed therapeutic formulation may be prepared with standardization of biologic activity via dose using LD 50, enzyme cleavage of SNAP-25, time to death assays, neuronal cell based assays, or any other method of measuring biologic activity to produce suitable dosings. Any fusion protein added to a fragment or a native structure of the botulinum toxin which enhances potency can also be used in the disclosed formulations. The disclosed formulations may also include permeation adjuvant peptides or other molecules which can enhance diffusion through membranes or potency duration, such as poly-lysine polymers or albumin, in some embodiments. Suitable adjuvants may include but are not limited to: polycationic or poly ionic peptides, hyaluronidase, and/or derivatives of local anesthetics (e.g., lidocaine, Marcaine).

In some embodiments, an injection can be administered through the pars plana so as to avoid retinal tissues, ciliary body or lens. In some such embodiments, the injected formulation may flow from the injection site into the vitreous body. The formulation may then diffuse into the neuro retina and subsequently diffuse into the retinal pigment epithelium. The toxin may then be taken up by the retinal pigment epithelium, neo vascular membranes, or diffuse through defects in Bruch's membrane, blood retinal barrier, and/or into the choroid. Any suitable level of activity may be utilized in some such methods. The retinal pigment epithelium has an extremely active in membrane vesicular cellular uptake interacting with the rods and cones of the neurologic retina and could, in some cases, easily incorporate the molecular botulinum toxin into its cytoplasm.

Alternatively, the botulinum toxin may be given in upstream neural structures (for example, the peripheral nervous system) which eventually penetrate the inner eyeball via axoplasmic flow.

In cases where the disclosed formulations are injected, one or more of the following results may be achieved: (1) leakage from new vessel formation with fluid egression under the neuro-
5 retina or retinal pigment epithelium may be decreased; (2) regression of new blood vessel growth may occur; (3) the retinal pigment epithelium degeneration may regress, resulting in intracellular morphologic changes, including reduction of retinal pigment epithelium activation; (4) cellular element polarity of the retinal pigment epithelium may be preserved, with enhancement of its barrier function and metabolic activity with enhancing density, length, and expression of
10 microvilli; and (5) enhancement of the tight junctions within the retinal pigment epithelium and enhancement of pigment epithelial attachment to its basement membrane may occur.

In some cases, injection results may be measured using one or more of the following: (1) visual acuity and/or validating methods of measuring acuity; (2) contrast sensitivity; (3) fundus photography; (4) fluorescein angiography (including OCT angiography); (5) OCT (for example,
15 examining sub retinal fluid, neovascularization under and through the retinal pigment epithelium, of any physical type); (6) changes in the RPE (drusen/drusenoid heights and volumes, density, distance from basement membrane, migration, loss of photoreceptors, loss of IS-OS and outer nuclear lines, fluid accumulations in retina and subretina, pseudo drusen density, pigment clumping and tears, choroidal thickness, neuro-retinal thickness, RPE atrophy, formation and leakage pattern
20 of choroidal neovascularization, extent of geographic atrophy, hemorrhage, and shape and regularity of lines of retina defined by OCT (for example, ONL, IS-OS, RPE alignment; (7) Amsler grid; (8) auto florescence from RPE lipofusen; (9) focal ERG (electro -retinogram); (10) polarity, thickness and shape changes in the retinal pigment epithelium using OCT; (11) visual fields; (12) any subjective instrument which assesses patient satisfaction that has been validated against
25 objective measurements; and (13) use of conventional clinical study methods using controls and repeated injections. In some cases, serial follow-ups may be made with the patient and assessments of the need for repeated injections may also be utilized, as needed. In these and other embodiments, fundus photography and OCT may be used for monitoring treatment effect.

Effects of Botulinum Toxin on Intra Cellular Cytoskeleton

30 Botulinum toxin may have important biologic effects on endothelium and RPE, which plays an important role in the pathogenesis of degenerative and exudative forms of human retinal disease. The RPE has been studied using electron microscopy during early stages and later stages of age related macular degeneration. Studies have revealed condensations of intracellular cytoskeleton near the basement membrane (base) of the cells causing disruption of the cell membrane, with cell

shape irregularity, loss of polarity, disruption in cell to cell adhesion, accumulation of leaked protein with membrane instability, and derangements of the apical-apical orientation of the RPE cells with the rods and cone cellular structure. A distortion of the REP can result in one or more of the following: (1) inability of the RPE to sustain its supportive functional and metabolic interplay with macular rods and cones, maintain the tight barrier between the choroid and neuro-retina allowing for emission of reactive macromolecules from the neuro-retina into the choroid. Such exposure excites release of vascular growth factors as well as mediators from choroidal endothelial cells, nerves, mast cells leading to fluid accumulation under the neuro retina (RPE and neurosensory detachment, hall mark of both “wet” and “dry” macular degeneration); (2) leakage from the neo-vascular endothelial tight junctions which occurs because of a deranged cytoskeleton associated with endothelial vasculature; (3) exposure of the antigenic structure of the neuro retina through the blood retinal barrier, causing reactivity of immune cells in the choroid with a limited response from blood containing cellular elements which circulate through the choroid. The immune response can include complement activation, which further damages RPE structure; (4) interruption of the rates of nutrient delivery into the neuro retina leading to toxicity of the rod and cones and RPE; (5) loss of RPE micro-villi, critical for maintaining rod and cone function by removal of photoreceptor breakdown products; (6) destruction of rods and cones; and (7) formation of a geographic atrophic state of RPE.

FIGS. 5A-5F show images of RPE obtained using microscopy techniques. In particular, FIGS. 5A-5F illustrate disruption of membranes, sub membrane condensation, alteration of hexagonal shapes of the structure, RPE autolysis, stress fiber formation from actin (shown in FIG. 5A), barrier function disruption, and migration of the RPE away from the barrier sheet. It should be noted that structure and function relationship of the neuro-retina is one of isolation from blood elements with most of the exposure being to vitreous body, a chamber containing hyaluronidate with no transient perfusion. Defects in the retinal vasculature are fairly consistent in creating retinal pathology. The blood retinal barrier in the retinal and choroidal vascular is important to the health of the neuro retina. The choroid is one of the most densely perfused tissues in the human body and the RPE and photoreceptors are highly metabolically dependent on a close structural relationship with the choroid. Separation of the blood compartment with both retinal and choroidal vascular is important in maintaining neuro-retinal health and functional integrity of photoreceptors. Further, certain antigenic stimuli get exposed with barrier breakdown which excites genetically individuals to react with immune responses at varying levels including but not limited to complement activation, neurogenic reactivity, alteration in regulatory autocoids, alterations in cell

functions independent of inflammation, fluid accumulations within neuro-retina, barrier incompetence in choroidal and retino vascular endothelium, and dysfunction of the RPE photoreceptor functions.

The disruptions of the cytoskeletons of endothelium and RPE by cytoskeleton structure in
5 endothelium and RPE are important to the pathogenesis of macular degenerations with respect to leakage of blood containing fluid and membrane altering mediators and function of the choroid of the eye. Generally, increased in generation of pathologic arrangements of actin, microtubule proteins, accumulated as a first step in macular degeneration associated with distortion of RPE and endothelial membranes, which may cause: (1) toxic leakage of sub retinal fluid (wet macular
10 degeneration); (2) loss of cell to cell adhesion and cell to basement membrane adhesion disruption of barrier function (drusen and drusenoid formation, RPE migration); (3) loss of polarity orientation of RPE, which can be important to its role supporting the structure and function of the rod and cones (progressive dry degeneration) and may ultimately result in loss and retraction of RPE microvilli; (4) loss of RPE ability to remove photoreceptor breakdown products (lipofuscin) at a
15 sufficient rate to avoid photoreceptor toxicity (auto florescence increase); (5) pathologic condensation of RPE intra-cellular fiber elements ultimately reflected by metaplasia of the RPE into a white “fibrocystic” cell type which appears on fundus photography as a “Disciform scar”(see FIG. 2) and formation of geographic RPE atrophy and neurosensory retinal atrophy; (6) disciform scars and geographic atrophy are often seen in patients blinded with macular degeneration
20 reflecting evidence of the nature of the degenerative and deranged process by which the macular is destroyed by alteration in accumulation orientation of intracellular pathologic actin and related fiber accumulation, which fundamentally alters the RPE and causes RPE/photoreceptor death. The ensuing result is retinal pigment epithelial to mesenchymal type differentiation to a fibrocyte, migrated cell, and/or atrophic cell. The ensuing events involves a substantial change in mRNA
25 expression by the RPE to reorganized cell attachments, basement membrane attachment, pigment epithelial motility and migration into the neuro-retina. This process denotes the early changes in macular degeneration with vascular response with growth of vessels into the RPE and choroid denoting the later stages (FIG. 1, stages of macular degeneration). Following barrier function disruption, immune process may ensure, which results in complement activation, mast cell
30 activation, neuropeptides release, which further aggravates disrupted barriers and fluid accumulation; and/or (7) genomic changes resulting in altered RPE morphology, retinal layer tissue dysfunction and loss of photoreceptors.

It should be noted that botulinum toxin can get into cells either via specialized receptors as exists on nerves cells or by facilitation with adjuvant proteins either in vivo or in drug formulation. Vital concentrations may, in some cases, be inherently low with this molecule's ability to effect enormous changes in cytoplasmic physiology or genomic responses and exquisitely low molecular concentrations.

Botulinum and Cytoskeleton Interactions

The disclosed formulations and methods, in some embodiment, involve injections or topical application of a botulinum toxin formulation for the treatment of macular degeneration and other relational degeneration. Botulinum toxin A may have a critical effect on cytoskeleton structures.

The C3 version has been noted to interact of the Rho actin polymerization system in cellular biologic experimental observations. While the C2 and C3 toxins may not cause neuromuscular weakness, these agents are cyto toxins able to cause cell death by different mechanisms than type A subtypes, B, C1, D, E, F, and G. Further, as described in detail below, animal injection of type A botulinum into muscle cells may cause a shrinkage of cells associated with diameter morphometric out of proportion to the effect created by nerve cutting (neurogenic atrophy). This rapid rate observation (which was not previously reported) indicates that the A toxin has a fundamental direct effect on the cytoskeleton of muscle cells independent of neuromuscular blockage associated with blocked acetyl choline release on myoneural junctions. This effect may cause a dissolution and re-organization of cytoskeleton actin and related intracellular micro tubules to an extent that the effect can interfere with a degenerative process leading to cell death, critical dysfunction, and block a critical disease degenerating process so as to preserve cell function. Caspase and apoptotic intracytoplasmic enzymes can be depressed, in some cases. The effect would be to maintain polarity of vital cell structures such as the RPE, delay or halt the accumulation of pathological cytoskeleton proteins, with preservation of cell structure polarity and associated cell interacting functionally with the target cell group.

In some embodiments, endothelial cell health can be preserved as well as integrity of any cell undergoing a degenerative process by increases in the intracellular generation of cytoskeleton protein which disfigure the shape or critical cell configuration destroying critical junctions and associated barriers, movement of metabolites, neuro-retinal antigenic exposure, or cell to cell relations. Such changes can be elicited by alterations in expression of cellular adhesion proteins, interactions with vital surface and internal receptors governing cell metaplasia, apoptosis, epithelial mesenchymal transformations, epithelial sheet loosening and adhesiveness to basement membranes,

alterations in the quantity of various isoforms of adhesion proteins such as cadherin isoforms and related proteins so as to alter barrier functions of epithelium and endothelium to inflammatory cytokines (such as VEGF) and related proteins. Important barrier functions in macular degeneration include endothelial governing leakage, epithelial cell to cell adhesion governing RPE barrier, choroidal neo-vascular barrier functions along the neo vascular endothelium. Additionally, botulinum toxin can suppress inflammatory autacoids, such as mast cell function.

In the case of the RPE, the tight junctions at the level of the RPE can become incompetent from abnormal cytoskeletal protein accumulation, causing barrier fractures along tight junctions with ensuing antigenic exposures of the neuro retina to choroid, with opportunity for various immunologic and inflammatory proteins to egress, choroidal fluid, and subsequent photoreceptor death based on immunologic reactivity. Such as process involves histamine release inferentially present in platelets and mast cells both present in choroid. Vasoactive intestinal peptide and CGRP may also play a role. Mast cells are capable of interplay with autonomic nerves present in choroid and still another target for botulinum modulating or blocking effect. Barrier function seems to be implicit and tissue organization of the retina and choroid and disruption of this function may be viewed as upstream derangement, occurring in macular degeneration. It is noted that retrograde movement (toward the central nervous system) and ante grade movement (away from the central nervous system) of botulinum toxin via peripheral nerves or veins occurs during use of the disclosed compositions and methods. Further, direct penetration of the disclosed formulations into the eye may encounter natural barriers of scleral and cornea. Prior to the filing of the subject application, botulinum toxin has not been advocated for intraocular diseases. This is due, at least in part, to the fact that the eye barrier was previously believed to block the neurotoxin from entering the eye.

Interaction of the RPE and Photoreceptors

The phagocytic interaction of the RPE on the rods and cones is critical for photoreceptors health. Damage to this interplay will result in photoreceptor damage and eventual death with vision loss. Driving this relationship at the sub cellular level is the microtubules within the retinal pigment epithelium which allows for phagocytic interactions at a rapid cellular rate, with active actin and related tubule polymerizations allowing for photoreceptor maintenance. Defects in cytoskeleton assembly maintenance and disassembly can result in photoreceptor damage. Such defects can be reflected in the disorganization of the polarity of the RPE cells as well as alterations in cell shape actin and tight junction integrity and cellular relationships on the basement membrane

(Bruch's membrane). Early macular degeneration changes are associated with alterations in RPE morphology and accumulation of dense accumulation of subcellular fibers indicating microfiber dysfunction (Drusen body accumulation). Auto fluorescence is a sign of RPE dysfunction, indicating a compromised RPE with accumulation of Rhodopsin due to defective catabolism and accumulation of lipofuscin pigment seen with blue light filters on retinal cameras. Lipofuscin is an indication of functional RPE dysfunction and often occurs in both wet macular degeneration and in progressive dry macular degeneration with geographic atrophy.

Botulinum Toxin and Microtubule Derangements and Microfiber Accumulation

Botulinum toxin has the ability to alter the accumulation formation of subcellular actin and microfibers so as to suppress the pathologic accumulation polymerization of critical cytoskeleton components to provide one or more of the following:

1. Maintain barriers within the RPE essential for maintaining integrity of the neuro-retina and rods and cones maintained by tight junctions.
2. Maintain polarization and cytoskeleton to assure continued function.
3. Maintain integrity of endothelium and suppress neovascularization from the choroid
4. Block or modulate mast cell activity and modulate release of neuropeptides or other mediators in the choroid which can damage or sustain photoreceptors.
5. Microvilli enlargement and enhancements.
6. Barrier function within the basement membrane attachments of the RPE and cell to cell adhesions of the RPE.
7. Block exudative vascular leakage from choroid.

Botulinum Interplay with Microvilli of the Retinal Pigment Epithelium

The retinal pigment epithelium contains microvilli, a critical structure maintaining the physiologic health of the rod and cones of the neuro-retina. The neuro-retina structures convert images and light into transmittable signal into brain via optic nerve projections allowing for visual decoding within the central nervous system. The effect of age is to dwindle the extent, size and integrity of the microvilli causing a dysfunctional microanatomy between the rods and the cone ultimately leading to the early stages of macular degeneration. The effect of botulinum toxin causes a shift in this deterioration, expression of enhance actin and associated protein polymerization, with rejuvenation and reversal of vital structures of the apex of the retinal pigment epithelium causing cessation of the degeneration and deterioration of the maintenance role of the choroid and retinal pigment epithelium on the neuro-retina.

Botulinum toxin species effects this change act on Rho kinase and ROCK intracellular systems achieving the shift in expression of mRNA toward vital protein expression causing a robust microvilli and reversing or impeding atrophic shift and apoptosis of RPE cells involved in macular degeneration. In genomic studies using neural ganglion with assessment using robust cDNA fragments on gene chips, botulinum toxin has elicited a mRNA response which regulates production of proteins important to actin expression, cell to cell adhesion molecules and anabolic proteins governing enhance cell structures. Photoreceptor proteins have been shown to shift expression after botulinum toxin infusions into cell cultures.

Duration of Action

The disclosed formulations and methods may provide a biologic effect which enhances duration of action over existing therapies, with possible effects lasting between 4-50 weeks and possibly longer upon repeated injections. The increased duration may allow for fewer invasive procedures needed to administer the drug when intra-ocular injections are used. Botulinum toxins have varying durations in clinical practice dependent on the target tissue. The autonomic nerve effects can last longer than the effect on heavily myelinated motor nerves. Most of the nerves within the choroid have minimal myelination and many represent autonomic nerves from ganglionic structure outside the orbit and accessible to injection with a botulinum formulation described herein.

The duration of action of anti-VEGF agents (both FDA approved and in development) have targeted longer duration of action as the need for intra-ocular injection is associated with many complications. Fewer injections or a period of time is more comfortable for a patient and reduces administration risks. The half-life of the aflibercept EYLEA® in rabbit is about 7 days. In contrast, .5 mg of ranibizumab (Lucentis®) is about 2.88 days and 1.25 mg of bevacizumab (Avastin®) is 4.3 days.

Given botulinum toxin based pharmaceuticals have intrinsically long duration of action, fewer injections may be needed as compared to known anti-VEGF agents. For neuromuscular effect, duration of action is generally between 10-14 weeks. With some preparations, duration as long as 20 weeks between treatments may be possible. Further, for autonomic effects, durations for up to 24 weeks have been recorded. As botulinum technology offers superior duration over the currently used and anticipated with anti-VEGF pharmaceuticals, the convenience for patient treatment, with marked risk reduction and the possibility of additive effects are clear advantages. Further anti-VEGF agents have been associated with vaso-occlusive disease (e.g., stroke and

arterial occlusions). Despite complications with anti-VEGF agents, assessments with botulinum toxin have not resulted in any serious reported complications at conventional dosing levels (as defined by FDA-approved dosings). Botulinum toxin-based pharmaceuticals as described herein can act similar to anti-VEGF agents and, in some embodiments, can increase potency and duration of ant-VEGF agents (see Example 1).

Dosing

The disclosed therapeutic formulations may, in some embodiments, include botulinum toxin or a fragment thereof. Any suitable form of botulinum toxin may be used in the disclosed formulations, for example, the disclosed formulations may include botulinum toxin A1-A5, B, C1-3, D, E, F, G and H. Additionally, fermentation yields with higher LD 50 units per cc of fluid may be used as a source of botulinum toxin, with or without complexing proteins.

The disclosed formulations can be prepared with an appropriate dose of botulinum toxin. For example, in some embodiments, the disclosed formulations may be administered to a patient according to one or more of the following dosings:

.01 to .5 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

.5 to 5 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

5-10 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

10-20 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

20-40 LD 50 units, administered via intra-ocular, extra ocular, periorbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

40-80 LD 50 units, administered via intra-ocular, extra ocular, periorbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

80-160 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

160-320 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

320-640 LD 50 units, administered via intra-ocular, extra ocular, peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

5 640-1280 LD 50 units, administered via intra-ocular, extra ocular, subconjunctival peribulbar injection peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

10 0.5-25,000 LD 50 units, administered via intra-ocular, extra ocular, subconjunctival peribulbar injection peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

0.01 to 3,000 LD 50 units, administered via intra-ocular, extra ocular, subconjunctival peribulbar injection peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

15 1280-6,000 LD 50 units, administered via intra-ocular, subconjunctival peribulbar injection peri orbital, subconjunctival peribulbar injection, epibulbar injection, or topically.

In some example methods, conventional dosing of botulinum toxin may be used. As used herein, the term “conventional dosing” refers to any FDA-approved dosing of botulinum toxin for an indication of the head or neck. In select embodiments, 300 LD 50 units or less of botulinum toxin may be administered to a patient. For botulinum toxins with lower LD 50 potency, conversion assessment and table subject to existing dose conversions may be used. These example doses are given for a conventional form of botulinum toxin marketed using the trademark BOTOX®.

Topical and Subconjunctival Administration

As described herein, clinical efficacy can be derived from topical application of botulinum toxin based pharmaceuticals. Dosing can range from 1-2500 Units using the botulinum toxin with complex. In order to reduce unwanted toxicity, the botulinum toxin protein molecule can be modified so as to reduce or eliminate the neuro-muscle effect so when applied to a mucous membrane surface like the skin, conjunctiva, or mucosal surfaces in the sinus nose, or mouth paralytic or weakening side effect do not occur. Further adjuvant protein can be removed so as to limit toxicity from gastro-intestinal absorption by eliminating botulinum toxin derived

hemagglutinin protein represent as the botulinum toxin complex (e.g., BOTOX®). As dosing is determined by LD 50 in Swiss Webster mouse, units generally are accepted but may be converted into alternate forms such as derived from alternate assay or quantitative method.

5 Importantly, permeators such as lidocaine, albumin, polylysine, or mechanical devices such as contact lens, intra-ocular implants, subconjunctival implants, can be used to provide a delivery system appropriate for intra-ocular administration. Transconjunctival administration through lid or bulbar conjunctiva can be used. Drying techniques of the ocular surface can also be used to enhance penetration. Use of goggles which enhance permeation of the ocular surface can be employed to provide a positive pressure atmosphere or hyperbaric state such as used in hyperbaric oxygen
10 chambers. Micro punctures of corneal and conjunctival epithelial followed by botulinum toxin based protein with or without contact lenses can increase corneal and ocular penetration. Varying concentration allowing for more effective uptake of the internal eye can be employed based on the specific stage of macular degeneration and based on specific pathologic findings clinically or SD-OCT.

15 Intra cameral (aqueous humor) injections are known to be safer than intravitreal injections and can provide a superior method of increasing intra-ocular botulinum concentrations, with less chance of damage to intra-ocular contents.

Drugs in Trials for Dry Non-Exudative and Wet Exudative Stages of Macular Degeneration

20 Tables 1 and 2 outline various agents in trials or being contemplated for trials for the treatment of dry macular degeneration.

Table 1 - Summary of Clinical Trials Targeting Macular Degeneration

Drug/Therapy	Mechanism of Action	Route of Administration	Study Group/Sponsor	Clinical Trial Number
<i>Photoreceptor and RPE preservation</i>				
Trimetazidine	Anti-ischemic agent with cytoprotective effects	Oral	Institut de Recherches Internationales Servier	
Alprostadil (prostaglandin E1)	Increase choroidal blood flow	Intravenous	UCB Pharma	NCT00619229
Moxaverine	Nonselective phosphodiesterase inhibitor	Oral	Medical University of Vienna	NCT00709449 NCT01629680 NCT00709423
Sildenafil	Phosphodiesterase type-5 inhibitor	Oral	Duke University	NCT01830790
MC-1101	Increase choroidal blood flow	Topical	MacuCLEAR, Inc.	NCT01601483
Ozonated autohemotherapy	Increase oxygenation	Autohemotherapy		

Fenretinide	Visual cycle modulator	Oral	Sirion Therapeutics	
ACU-4429		Oral	Acucela Inc.	NCT1802866
Tandospirone	Neuroprotection	Topical	Alcon Research	NCT00890097
CNTF (NT-501)		Intravitreal implant	Neurotech Pharmaceuticals	NCT0044954
Brimonidine		Intravitreal implant	Allergan	NCT00658619
RN6G	Anti-amyloid antibodies	Intravenous	Pfizer	NCT01577381
GSK933776	Anti-amyloid B antibodies	Intravenous	GlaxoSmithKline	NCT01342926
Doxycycline (Oracea)	Promotes photoreceptor survival	Oral	Paul Yates, MD, PhD., University of Virginia	NCT01782989
<i>Prevent oxidative stress injury</i>				
AREDS formulation	Antioxidant	Oral	National Eye Institute	NCT00345176

Crocetin	Reduces apoptosis, increases oxygen diffusion through plasma, reduces lipid peroxidation, upregulates trophic factors	Oral		
Curcumin	Reduces lipid peroxidation and formation of reactive oxygen species, modulating the expression of many oxidative stress-regulating genes, such as PDGF, VEGF, HO1, and others	Oral		
Vitamins B9, 12, 6	Decrease serum homocysteine levels	Oral		
Resveratrol	Modulates cell proliferation, apoptosis, and angiogenesis	Oral		
<i>Inflammatory Suppressors</i>				
Eculizumab (SOLIRIS)	Humanized monoclonal antibody targeting complement 5	Intravenous	Philip J. Rosenfeld, MD, Ph.D., University of Miami	NCT00935883

ARC-1905	Peylated RNA aptamer targeting complement 5	Intravitreal injection	Ophthotech Corporation	NCT00950638
FCFD4514S (lampalizumab)	Humanized monoclonal antibody antigen-binding fragment targeting complement FD	Intravitreal injection	Genentech, Inc.	NCT01602120
LFG316	Humanized monoclonal antibody targeting complement 5	Intravitreal	Novartis Pharmaceuticals	NCT01527500
Glatiramer acetate (copaxone)	T cells and inflammatory suppressor	Subcutaneous	The New York Eye and Ear Infirmary	NCT00541333 NCT00466076
Flucinolone acetoneide (iluvien)	Corticosteroid	Intravitreal implant	Alimera Sciences	NCT00695318
Sirolimus (rapamycin)	mTOR inhibitor	Subconjunctival	National Eye Institute	NCT01445548
<i>Lipid metabolism</i>				
Statins	Lowering lipid accumulation in Bruch's membrane	Oral		

Heparin-induced extracorporeal lipoprotein precipitation	Reduces serum LDL, fibrinogen, lipoprotein	Extracorporeal circulation	B. Braun Avitum AG	NCT01840683
<i>RPE: Retinal pigment epithelium, LDL: Low-density lipoprotein, CNTF: Ciliary neurotrophic factor, AREDS: Age-Related Eye Disease Study, PDGF: platelet-derived growth factor, VEGF: Vascular endothelial growth factor, HO1: Heme-oxygenase-1, FD: Complement factor D</i>				

Table 2 - Summary of Clinical Trials Targeting Geographic Atrophy

Target	Treatment	Clinical trial number	Company	Status of clinical trials
Anti-inflammatory	Eculizumab	<u>NCT00935883</u>	Alexion Pharmaceuticals (Cheshire, CT)	Completed phase II
	Sirolimus	<u>NCT00766649</u>	National Eye Institute (Bethesda, MD)	Completed phase I/II
	<i>Lampalizumab</i>	<u>NCT02247479</u>	Hoffmann-LaRoche (Basel, Switzerland) Roche (Basel, Switzerland)	Phase III currently recruiting

Target	Treatment	Clinical trial number	Company	Status of clinical trials
	<i>ARC-1905</i>	<u>NCT00950638</u>	Ophthotech (Princeton, NJ)	Completed phase I
	<i>Glatiramer Acetate</i>	<u>NCT00541333</u>	The New York Eye & Ear Infirmary (New York, NY)	Phase I suspended participant recruitment
Antioxidants	AREDS2	<u>NCT00345176</u>	National Eye Institute (Bethesda, MD)	Phase III completed
	OT-551	<u>NCT00306488</u>	National Eye Institute (Bethesda, MD) Othera Pharmaceuticals (Exton, PA)	Phase II completed
Visual cycle inhibitors	Fenretinide	<u>NCT00429936</u>	ReVision Therapeutics, Inc. (San Diego, CA)	Phase II completed
	Emixustat Hydrochloride (ACU-4429)	<u>NCT01802866</u>	Acucela Inc. (Seattle, WA)	Phase II/III ongoing

Target	Treatment	Clinical trial number	Company	Status of clinical trials
	ALK-001	<u>NCT02230228</u>	Alkeus Pharmaceuticals, Inc. (Boston, MA)	Phase I completed
Amyloid beta	MRZ-99030	<u>NCT01714960</u>	Merz Pharmaceuticals GmbH (Dessau-Roßlau, Germany)	Phase I completed
	<i>RN6G</i>	<u>NCT01003691</u>	Pfizer (New York, NY)	Phase I completed
	<i>GSK933776</i>	<u>NCT01342926</u>	GlaxoSmithKline (Brentford, UK)	Phase II ongoing
Choroidal perfusion	MC-1101	<u>NCT02127463</u>	MacuCLEAR, Inc. (Plano, TX)	Phase II/III currently recruiting
Stem cell therapy	MA09-hRPE	<u>NCT01344993</u>	Ocata Therapeutics (Marlborough, MA)	Phase I/II currently recruiting

Target	Treatment	Clinical trial number	Company	Status of clinical trials
	MA09-hRPE	<u>NCT01674829</u>	CHABiotech CO., Ltd (Seoul, South Korea)	Phase I/IIa currently recruiting
	HuCNS-SC	<u>NCT01632527</u>	StemCells, Inc. (Newark, CA)	Phase I/II ongoing

It is of note that there are no clear agents that consistently work for repressing or stopping dry macular degeneration. Also of note is the fact that no contemplated treatment agents contemplate a botulinum toxin-based pharmaceutical for the treatment of dry or wet degeneration.

5 The mechanisms of action are also listed in Tables 1 and 2. Note that anti-VEFF, choroidal flow enhancers, anti-amyloid antibodies, visual cycle modulators, antioxidants, apoptosis modulators, a number of anti-complement directed antibodies, neuroprotectors, nerve growth factor, phosphodiesterase inhibitors, stem cells, and anti-inflammatory agents are being tried. However, no review or study either contemplated or provided rationale or reduction to practice of a botulinum
10 toxin-based pharmaceutical. Most recently, Lampalizumab (Genetech, Inc.) has been reported to fail at the 2017 American Academy of Ophthalmology in New Orleans. Recently, studies involving inserting intra-ocular implants complexed with corticosteroids for slow release have been added to Anti-VEGF agents (e.g., EYLEA®) for wet macular degeneration treatment. Further, newer agents, such as angiopoietin, are being tried with anti-VEGF agents to increase potency and
15 duration of action of intravitreal drugs.

At a 2017 Retina meeting, a review of eye delivery mechanisms was conducted which failed to cite trans neural delivery mechanism for the treatment of choroidal or retinal diseases, including AMD. The void gives credence to this novel component to formulations and treatment methods described herein (e.g., trans neural delivery of botulinum or its components to the choroid and
20 choroidal ganglion, with favorable effects on RPE and neuroretina).

Pharmacodynamic Delivery System for the Treatment of Human Macular Diseases (Axoplasmic flow from extra-ocular injections)

Described herein is not only a unique agent but a unique delivery system for the treatment of human macular diseases. Botulinum toxin has the ability to diffuse from the injection sites affecting a regional biologic effect that is directly and volumetrically related to dose. Biologic effects on structures can be accomplished additionally by retro-grade and ante grade axoplasmic flow through autonomic, sensory and motor nerves causing a change by genetic upregulation of proteins governing cell to cell adhesions such as actin, various cadherins, and having a direct action to upregulate structural proteins governing membrane barrier functions, cells adhesion to basement membranes and differentiation of the polarity of epithelial cytoplasm relating to the function of the epithelial barriers. The unique feature is very useful in that intravitreal injections may not be necessary, in some embodiments. Elimination of this step in the treatment of macular degeneration may reduce or eliminate the risk of vitreous hemorrhage, endophthalmitis, retinal detachment, traumatic cataract formation, glaucoma, retinal breaks, and pain associated with a direct injection into the eye. These complications can be devastating and may result in blindness.

A pharmacologic effect from injection of soft tissues around the eye is not associated with the more serious, potentially blinding, complications which can occur with direct injections into the eye. These injection locations may be less painful as well. Dosing of the disclosed formulations can vary between 1-3000 units, preferably 1-300 units and more preferably 1-200 units (BOTOX®). Higher dosing can be used with less potent formulations (Dysport, Xeomen, Myobloc or other preparations). The injections are generally given over the regions involving motor and sensory nerves which enter the eye, especially the trigeminal nerve, oculomotor nerve, and most particularly autonomic nerves such as the pterygopalatine ganglion under temporalis muscle. Transport via venous system is also possible as periocular tissue in the forehead, lids and immediate surrounding anatomic regions drain directly into the orbit with collateral flow into the eye. Autonomic nerves also supply the human eye (pupillary fibers) and transport via collateral autonomic nerves can act as a conduit for a biologic intra-ocular effect delivery from nerves penetrating the poster eye pole overlying the macular (see figure of orbital dissection). This conduit offers a passage for low concentration delivery of botulinum or its fragments to the choroid and retinal pigment epithelium, possibly in concentrated forms. Sensory nerves can further this conduit to the target retinal pigment epithelium. Transcytosis is possible with penetration of botulinum material by retinal pigment epithelial and neuro retinal structures affecting both blood vessel responsiveness to vascular endothelial growth factors, vascular permeability, barrier integrity

of the retinal pigment epithelium, and potential for leakage and new blood vessels growth from immunologic cytokines emitted from loss of integrity of the RPE barriers. This process allows botulinum toxin to enhance cell to cell adhesion via possibly modulating action on Rho kinase, ROCK, and other proteins critical in maintaining the RPE actin cytoskeleton, cell to cell adhesion molecules, cell to basement membrane adhesion molecules, and endothelial adhesion molecules rendering the biologic RPE barrier function more robust and inert as well as improve physiologic functions such as processing, catabolizing and removing rhodopsin protein. Further, the effect of the botulinum toxin may prevent vascular leakage and/or diminish and stabilized vascular endothelial growth. Such an effect can also involve the retino-vascular blood retinal barriers as occurs in macular edema from inflammation and diabetes. Additionally, autonomic nerves have been shown to integrate with choroidal autonomic ganglion cells under the macular.

Prior to the filing of the subject application, the intra-ocular effects of botulinum toxin on RPE-retina were unknown. Moreover, it was not known that injections of botulinum into skin of lids, face, forehead, facial bones, facial and jaw muscles, scalp sinus mucosa, nasal mucosa, neck, mouth or palate and in autonomic parasympathetic and sympathetic ganglion which project axons into the eye had any effect whatsoever on the RPE/choroid. This information alone is novel and, in combination with the disclosed formulations and methods can provide safer administration paradigm than intra-ocular injections.

Penetration of the Internal Eye by Peri Orbital and Peri-Ocular Injections

Another unique aspect of the disclosed therapeutic formulations and methods is that an effect on the internal eye in the macular region can be achieved by a peri-ocular or peri-orbital injection. Not to be limited to the high dose effects gained by pars plantar injection (discussed with respect to other embodiments), the opportunity to gain entrance into the eye by per-orbital lid, or peri-ocular and neck injections using axoplasmic transport is an operational improvement which avoids serious complications of other methods. Extraocular injections via pars plana would easily be possible and much easier for patients. Extra-ocular injections targeting upstream nerves remote from the eye which eventually enter the eye allows for selective effect on intra-ocular contents without subjecting muscle tissue to the effects of the toxin causing extra-ocular muscle weakness with diplopia and ptosis. Positioning the injection needle deep into the orbit with resulting botulinum toxin-induced paralysis of the extra-ocular muscles may be undesirable. The risk of repeated intra-ocular injections which can cause intra-ocular hemorrhage, eye destroying endophthalmitis, retinal detachment or retinal breaks, lens dislocations, or increases in intra-ocular

pressure. The toxin can reach the targeted choroid, retinae by unique mechanisms such as axoplasmic flow, venous retrograde diffusion, and/or direct diffusion from peri-ocular and paraorbital injections. These indirect mechanisms for the treatment of AMD and associated conditions afford a selective entry into the eye, novel in itself, via nerve transport to avoid
5 undesirable side effects from muscle weakness.

Notably, the choroid nerve fiber structure has proven to be positive for a number of neuropeptide and related neurotransmitters. With age, there has been noted to be a recession of nerves in the choroid in close approximation to the retinal pigment epithelium. Such denervation can render a trophic effect on structure and function of the retinal pigment epithelium to cause RPE
10 dysfunction, loss of cell to cell adhesion and loss of vital RPE barrier function, as well as other structure and functional degenerative changes. Certain neurotransmitters, nerve peptides, present in the choroid can be vital to epithelial health and function. Recession and depletion of such chemicals can result in atrophy, mesenchymal and migratory changes in the RPE, loss of RPE- photoreceptor interplay and ultimately photoreceptor damage with loss of retinal function and vision.

15 In the ocular surface case presented in the examples (filamentary keratitis), loss of barrier function with cell to cell adhesion and epithelial cell adhesion to basement membrane strands of corneal epithelium break off form filaments exposing corneal sensory nerves resulting in pain and pathologic reactive changes (neovascularization). Filamentary keratitis is a common problem with corneal denervation and a condition called neurotrophic keratitis. Neurotrophic keratitis results
20 from damage to sensory nerves from trauma, recurrent infection with neurotrophic viruses (e.g., herpes simplex, herpes zoster), chronic infections, dry eyes, with mucous and tear deficiencies. The epithelium is often degenerated prior to loss of corneal epithelium and neovascularization, a in a manner similar to macular degeneration. In the case described herein, topical botulinum toxin resulted in repair and mitigation of the filaments in a time course consistent with known botulinum
25 pharmacokinetics and with repeated efficacy. Botulinum here is causing increased cell adhesion to surrounding cells and basement membranes and stimulating nerve structures in a fashion favorable to corneal epithelial function and elimination of filaments breaking off the continuous corneal epithelial sheet. Botulinum stimulates nerve/epithelial structures to produce actin and related adhesion molecules to that epithelium barrier function and structure is facilitated and sensory
30 nerves function is at least partially restored over the pathologic state.

The epithelial discontinuity in such cornea cases proceeds to growth of new vessels. In the case of macular degeneration, the stage 1 dry form of macular degeneration precedes the growth of

new vessels which destroys the RPE- photoreceptor interface leading to blindness. Avoiding the discontinuity by enhancing nerve fiber effect from choroidal axons and ganglion cells is a mechanism described herein which is useful for the treatment of macular degeneration. The botulinum enhanced choroidal nerve fiber effect on the RPE provides function stability to the RPE allowing for enhancement of barrier function, maintenance and prevention of degeneration of the retinal pigment epithelium with time. Defects in the choroidal innervation results in loss of important chemical derived from peripheral nerves vital to RPE health. Loss of certain neuropeptides such as vaso-active intestinal peptide (VIP), have been known to be depleted in cases of macular degeneration. Leaching of the toxin through the RPE or nerves surrounding arteries entering the eye can also have an effect to seal leakage from retinal arterioles, leading to the treatment of retino-vascular leakage.

Botulinum toxin by stimulation of peripheral sensory nerves to sustain and stimulate vital intra cytoplasmic structures, such as formative actin molecules, and associated proteins, adhesion molecules, and neurotransmitters and RPE can be vital to maintaining RPE and delaying the effects of macular degeneration. Botulinum toxin has a potent effect to stimulating actin-actin associated proteins formation on peripheral motor nerves and such effects can carry over to the peripheral nerves penetrating the human eye.

Safety

Utilizing peri-ocular botulinum toxins is also safe. For cosmetic, facial movements diseases (hemifacial spasm, blepharospasm, Meiges syndromes, dystonia, bruxism, migraine, tension headache), crows feet, forehead lines, glabellar lines, induced ptosis, facial inflammatory states, well-established dosing parameters have been designed to provide an exquisitely high safety record. As the material is known to be very safe after repeated injections, the unique opportunity is present to provide patients with retina and macular diseases a superb opportunity to understand the risks benefits over existing FDA approved drugs (Eylea®, Lucentis®, and Avastin®). Most of the studies done over the last 3 decades have had safety eye exams and no serious irreversible eye complication has been identified. This opportunity is truly unique for clinical studies and will serve as an impetus to proceed using various endpoints such as acuity (such as defined in ETDRS-early treatment diabetic retinopathy study) and other endpoints mentioned herein.

Trans-neural delivery to the Maculae

In some embodiments disclosed herein, the peripheral nerves are utilized as a conduit to deliver botulinum toxin-based pharmaceutical into the eye, retina and/or macula without using a direct intra-ocular injection (which inherently increases the risk of complications). The smooth muscle of the vessel walls of the choroid, like those of skeletal and cardiac muscle blood vessels are innervated by both divisions of the autonomic nervous system, which form dense plexuses of fibers around the vessels ("perivascular plexus"). Axon terminals are also found throughout the stroma, terminating on non-vascular smooth muscle, intrinsic choroidal neurons (ICNs), and possibly other cell types. There are also primary afferent sensory fibers that project to the trigeminal ganglion via the ophthalmic nerve; some of these give rise to peptide-positive collaterals that terminate on and around the vessels and intrinsic choroidal neurons.

FIG. 6 illustrated a human dissection orbit from above. In FIG. 6, the thin dark arrow represents a needle placement next to orbit. Note proximity and presence of vessels and nerves in this region giving botulinum toxin formulations access to the posterior surface of sclera with nerve vessel penetration into macular and choroid-pigment epithelium. Injections target autonomic nerves and/or sensory nerves in the pterygopalatine fossa.

FIG. 7 illustrates extra-ocular administration followed by nerve penetration and transcytosis with eye penetration. Transport along axons in each direction and transcytosis to achieve penetration into the eye (choroid, retinal pigment epithelium and neuroretina). Dendrite-axon penetration, cells transcytosis to new axon and dendrite (retrograde penetration and transport) may also be utilized in some embodiments.

The main parasympathetic input to the choroid originates from the pterygopalatine ganglion located within the pterygopalatine fossa (FIG. 6). These fibers are predominantly cholinergic and are rich in the vasodilators vasoactive intestinal polypeptide (VIP) and nitric oxide (NO). These nerves are targets for botulinum toxin penetration and transport into the eye when injections are given into the region of the pterygopalatine fossa (outside the eye and orbit). The sympathetic innervation of the choroid comes from the superior cervical ganglion. These noradrenergic neurons terminate on the blood vessels and mediate vasoconstriction. This anatomic arrangement allows for neck injections penetrate the eye by axoplasmic flow.

The choroid has been shown to use peptides such as substance-P and calcitonin gene-related peptide in a pre-central reflex arc, or axon reflex, a non-synaptic response in which a local stimulus (chemical or mechanical) depolarizes a sensory terminal which travels to the nearest collateral (branch), releasing the peptide onto the effector tissue. Evidence for this reflex has been found in

the primary sensory afferents from the trigeminal ganglion in the uvea and choroid, which use both peptides; the reflex may mediate changes in blood flow or a variety of other functions. For instance, in both mammals and birds, sensory fibers projecting to the trigeminal ganglion from the choroid via the ophthalmic branch of the trigeminal nerve elicit vasodilation. These terminals are positive for substance-P and calcitonin-gene-related peptide.

Botulinum toxin may be transported via any peripheral neural path capable of collateral axoplasmic flow and, in some cases, can penetrate into the choroid and into retinal pigment epithelial structures via transcytosis to achieve a biologic effect on target tissues in the macula (see FIG. 7).

Venous delivery is not mutually exclusive of axoplasmic delivery to the eye. Diffusion into the cavernous sinus (venous sinus with carotid artery passing through the center) brings toxin molecules in proximity to the carotid syphon which contains sympathetic nerves throughout its surface (sympathetic plexus). Binding of botulinum to autonomic neurons surround the carotid artery surface in the cavernous sinus results in axoplasmic flow along the ophthalmic artery into the orbit and eventually into the posterior eye and maculae with an effect on neuromuscular junctions.

Veins drain from the periocular region nasal region and via inferior orbital fissure in proximity to the orbital veins in proximity to the vortex veins draining the internal eye. Venous anastomosis allows another conduit for delivery into the choroid and retina.

Axoplasmic Flow (unique conduit for entry into the choroid and retina)

Early experiments with radiolabeled full length BoNT/A showed that the toxin is transferred to the ventral roots and adjacent spinal cord segments upon intramuscular injection in the cat gastrocnemius. Similarly, radiolabeled BoNT/A has been shown within the axoplasm of myelinated axons after its peripheral injection in mice. A dose-dependent retrograde transport of BoNT/A in brainstem motor neurons was also shown by electrophysiological and ultrastructural experiments in cats. Further segments of botulinum toxin have also been noted to undergo axoplasmic flow (HcA segment). Both full length botulinum toxin and binding segmental forms can undergo long range transport via axoplasm. This phenomenon is exploited in one delivery mechanism demonstrated in the invention and case examples. In compartmentalized cultures of rat sympathetic neurons, BoNT/A moves retrograde into cell bodies when applied at high concentrations into the distal compartments. However, retrograde trafficking of BoNTs has been inferred mainly indirectly, i.e. by observing the appearance of radioactivity or BoNT-cleaved substrates away from the site of administration. Thus, the kinetics and intracellular pathways used

by BoNTs for their long-range transport remains unclear but more recently tracking SNAP 25 lysis activity along the neurons axon and cell body over time has been helpful in substantiating initial observations. Transcytosis has been demonstrated and is operational in various embodiment of the invention.

5 In addition to axoplasmic transport and effects on choroid and retinal structures, botulinum toxin A or its segments and associated proteins can be used in unison or as part of a fusion protein complex involving anti-VEGF proteins to achieve higher and more sustained biologic effects to enhance barrier function, stop leakage and regress neovascularization and its pathologic effects, and/or alter intracellular RPE structural protein expression. A combined molecular approach
10 provides for an alternate method for bringing an anti-VEGF drug to the choroid without and intra-ocular injection and using a carrier protein which further targets a cellular mechanism involving retinal pigment epithelial integrity. Such a formulation may involve use of one or more of the following: botulinum toxin (for instance, a subtype of type A) or fragment (for instance HcA, binding domain), a fusion addition of an anti-VEGF agent (for instance, a non-fused addition of an
15 anti-VEGF agent, Avastin® or another fusion protein with anti VGF properties), and a stabilizing excipient known to facilitate stability and nerve cell axonal uptake.

 The anti-VEGF agent can be delivered by botulinum or its fragments which participates by axoplasmic flow and undergoes transcytosis with the anti-VEGF agent causing a multifaceted mode of action causing reversal of leakage from new vessel growth, regression of new vessels,
20 enhancement and promotion of a robust retinal pigment epithelium intercellular attachments to basement membranes and contiguous cells and a reversal of intracellular structural proteins which foster RPE degeneration. This formulation may also react with retino-vascular circulation to limit leakage from the retino-vascular capillaries and post capillary small veins.

 The disclosed formulations may be used with conventional para plana injection, intra-ocular
25 injection, or other types of extraocular injection. Additionally, in some embodiments, one or more fusion proteins and axoplasmic transport may be used to produce unique formulations. The disclosed formulations can be used with the conventional para plana injection (intra ocular) of anti-VEGF agents to produce a potency enhancement with respect to using a single anti VEGF alone (see example), in some embodiments. Further, one or more anti-VEGF agents can be included with
30 a botulinum toxin formulation described herein and applied via an extra-ocular delivery method (as described herein) to produce enhanced potency.

Para-Orbital Injection of Botulinum Toxin for AMD

As previously described, extra orbital injections of botulinum toxin can result in delivery of botulinum toxin to the macular via axoplasmic flow. An anatomic arrangement conducive to macular delivery involves placing the needle over the zygomatic arch aiming the bevel toward the pterygopalatine fossa and in proximity of the external portion of the inferior orbital fissure. The inferior orbital fissure extends very anteriorly (unlike the superior orbital fissure), allowing a 2 cm needle to very closely approach the fissure. Projection of the pterygopalatine ganglion, which projects through this fissure, supplies the globe and allow botulinum toxin close proximity to autonomic synapses as well as veins which drain toward the cavernous sinus. Penetration of botulinum toxin into the globe from this injection point may be facilitated by this anatomic arrangement. Toxin in cavernous sinus veins can infiltrate the sympathetic autonomic nerves on rout the retina via ophthalmic, retinal arteries and ciliary arteries (countercurrent movement of botulinum toxin nerve vs vein). The ganglion noted in the human choroid most likely picks up its innervation by the pterygopalatine ganglion. These ganglions are often seen in close proximity to the posterior pole of the globe. This unique injection location is devoid of major vessels and critical structures, resulting in a very low risk procedure. Sensory (V2) and autonomic nerves are closely abutting the fissure and the fissure may allow some orbital and globe penetration. In these and other embodiments, other para orbital areas may also be used as injection points.

Rho Kinase

A unique aspect of the invention described herein is that type A botulinum toxin has Rho kinase modulating action and can affect expression of actin and cadherin important in preventing apoptotic changes in cell structure (programed cell death cycles). Botulinum type C3 has been long known to have highly significant Rho kinase activity. Herein the effect from immunotype A of botulinum toxin is achieving such effects similar and identical at regional dosing levels below necessary to cause muscle weakness with attendant dysfunction such as diplopia lid malposition's and eyelid weakness is an operational component of the invention. Rho Kinase can effectively interact with the actin cytoskeleton causing anabolic gene expression, enhancing rapid turnover and expression of actin in such as fashion as to alter and enhance cell, tissue and organ function. Effects on other ocular tissue pertinent to Retinal Pigment Epithelial Interaction (Filamentary keratitis) are discussed relative to Example 3.

The effect on epithelial barriers has been demonstrated in another ocular condition known as filamentary keratitis, which can serve as a surface model for the understanding effect on the RPE. This is a condition often associated with dry eye syndromes, and inflammatory syndromes

characterized by epithelial strains separating from attachment to the epithelial sheet and underlying basement membranes. The process in a predisposed patient can be chronic and be associated with visual loss, pain, photophobia, and involuntary eyelid closure. Botulinum toxin has been used to close eyelids to treat various forms of corneal ulcers in the past to mimic a surgical tarsorrhaphy, an operation used to close the space between eyelids (palpebral fissure) and protect the ocular surface. In these descriptions, no mention has been made about the intrinsic effect on botulinum toxin on the epithelium, cellular structure of the epithelium, intrinsic effect of botulinum on cell to cell adhesion, cell to basement membrane adhesion from a direct effect of botulinum on adhesion molecules, or an effect on actin-cadherin proteins or any intra or extracellular proteins causing an increased cohesion of corneal epithelium

Herein describes an intrinsic effect on corneal epithelium in which increases the cohesive integrity of corneal epithelial cells which improve symptoms of filamentary keratitis, with reduction and disappearance of filamentous. This condition has been treated by concepts describes herein with topical botulinum drops which gain access to the epithelial cells on the eye surface via topical application defects created by the disease. Botulinum toxin causes expression of actin, enhancement the expression and intra-cellular organization of actin, cadherin and associated proteins, which enhance epithelial cohesion and integrity causing diminished filament formation and disease improvement. A similar effect in achieve in macular degeneration which the retinal pigment epithelium achieves an increased integrity from promotion of cell to cell, cell to basement membrane and enhance specialization of intracellular-extracellular function created by the botulinum toxin based agent. With topical (eye drops) use of botulinum toxin, beneficial effects on epithelial structures can be achieved.

For filamentary keratitis, botulinum toxin is directly observed to:

1. Enhance epithelial sheet adhesion on the ocular surface using a slit lamp bi- microscope on the human eye
2. Decreased exposure of underlying nerves
3. Decrease corneal neovascularization in chronic conditions
4. Decrease pain from covering exposed nerve endings
5. Enhanced and rejuvenated microvilli on micro anatomic structure of the epithelial surface causing a vital enhancement of corneal integration with the tear film (needs for oxygen transportation). Such microvilli improvement can be useful in administering botulinum

toxin for dry eye syndromes and inflammatory conditions of the ocular surface such as recurrent erosions.

6. Decreased incidence of recurrence

Similar effects can be used to treat other forms of keratitis involving basement membrane such as recurrent corneal erosion, basement membrane dystrophy (map dot fingerprint dystrophy), trophic corneal ulcers, herpes simplex keratitis, thyroid related eye surface disorders, corneal melt syndromes, chemical burns, ocular cicatricial pemphigoid, chronic dry eye syndrome, rosacea keratitis, Stevens Johnson syndrome, and exposure keratitis. Topical formulations can be devised as many of the aforementioned conditions occur on or near the ocular surface.

Topical formulations containing larger concentration of botulinum toxin can enter the eye and provide a superior method of administration over pars plana intra-ocular injections.

Botulinum Toxin Formulations

Example botulinum toxin formulations include type A1-5, B, C1-C3, D, E, F, and/or G botulinum toxin. Fragments of botulinum toxin may be used to elicit specialized cellular effects including isolated genomic expression of cellular constituents involved in enhancing barrier effects, actions on VEGF related pathways, interactions with presently available anti-VEGF drugs, structural proteins, regulators of structural proteins, and inflammatory regulating proteins. The disclosed formulations may, in some embodiments, include stabilizing proteins, poly cationic proteins or permeators (albumin or polycationic proteins), use of lidocaine within preparation or given prior to injections, protein derivative from botulinum with SNAP-25 interactive portions chemically removed, formulations with enhanced hemagglutinin protein typically found in the botulinum complex, enhancement with cadherin binding proteins or agents known to act on Rho kinase, upstream and down-stream metabolite and (ROCK). Modulation of ROCK by botulinum toxin compositions described herein (e.g., type A toxin) contributes to therapeutic effects for many disease conditions described herein.

ROCK1 is a protein serine/threonine kinase also known as rho-associated, coiled-coil-containing protein kinase 1. Other common names are ROK β and P160ROCK. ROCK1 is a major downstream effector of the small GTPase RhoA and is a regulator of the actomyosin cytoskeleton which promotes contractile force generation. ROCK1 plays a role in cancer and in particular cell motility, metastasis, cells adhesion, and angiogenesis. ROCK1 has a diverse range of functions in the body. It is a key regulator of actin-myosin contraction, stability, and cell polarity. These contribute to many progresses such as regulation of morphology, gene transcription, proliferation,

differentiation, apoptosis and oncogenic transformation. Other functions involve smooth muscle contraction, actin cytoskeleton organization, stress fiber and focal adhesion formation, neurite retraction, cell adhesion and motility. Modulation and/ or inhibition of ROCK1 influences reduction of stress fiber formation in RPE cells. Stress fibers formed by actin condensation in the RPE cytoplasm often occurs in age related macular degeneration causing RPE barrier function disruption and downstream reactions including neo vascularization, impaired RPE fluid pumping activity, immune exposure of the neuro-retina, influx of neuropeptides, cytokines, and complement. Stress fibers in RPE cells are depicted in FIGS. 14A-14D, as well as in FIGS. 4C, 5A, and 5C. Furthermore, botulinum toxin formulations described herein can be considered to promote retinal neuronal regeneration by changing Rho activity. These formulations can include, in some cases, botulinum complex typically known as BOTOX® (type A botulinum toxin complex).

Formulations are preferably given by injection but may be delivered with an eye drop. Eye drop deliverer may vary between 10-10,000 units but preferable under 3,000 units. Alteration in dosing with different formulations can be derived from the literature.

Preferably, Type A (or subtypes) or type B would be used as the safety of dosing forms are well established for the existing preparations but other subtype and non-neuromuscular subtypes or chemically altered types of botulinum type A are anticipated to be useful.

A botulinum toxin formulation comprising only hemagglutinin proteins devoid of neurotoxin can also be used to isolate and enhance the effects of hemagglutinin on adhesion proteins such as cadherin isoforms and associated intracellular proteins so as to allow for greater biologic effects not limited by the weakening and paralytic effects of the neurotoxin. Further, in a unique embodiment, a formulation with neurotoxin with cleaved portion removing the SNAP-25 and neuromuscular weakening effect but preserving the effects on actin and cell adhesion function can be used for treatment. Such formulations have been cited and studied in past but have not been suggested for use in medical indications such as macular degeneration or use on membrane barrier functions beneficial for the treatment of disease described herein.

Formulation consisting of toxin derivatives with cleaved SNAP 25 activity can also be used as carrier molecules for anti-VEGF agents as well as in conjunction with accessory proteins.

A botulinum toxin formulation comprising enhanced quantities of botulinum related hemagglutinin proteins with neurotoxin can be used to isolate and enhance the effects on cadherin and related adhesion proteins and associated intracellular proteins so as to allow for greater biologic effects not limited by the weakening and paralytic effects of the neurotoxin.

Epithelial to Mesenchymal Cell Transformations and Botulinum Toxin Effect

Generally, most forms of macular degeneration involve a metaplasia of the retinal pigment epithelium. This process has been described as a conversion of the RPE cells to a fibrocystic cell capable of migrating into the neuro-retina or vitreous of the eye. The process importantly involves
5 break away of the transformed RPE cell from its continuous sheet with reduced cell to cell adhesion allowing for membrane disruption (see FIG. 1B and FIGS. 5D-5F) and possible antigenic recognition of inflammatory cells in the choroid to initiated leakage and growth of new blood vessels. Further growth of new vessels from the choroid most often leak causing an accumulation of cytokines and toxic discharges into the neuro-retina.

10 Botulinum toxin formulations described herein essentially have the effect to retard or even reverse this process by causing expression and /or modulation of actin, maintaining cell differentiation and structure towards maintaining barrier function, halting the epithelial to mesenchymal transformation of the retinal pigment epithelium and effectively arresting both major forms of macular degeneration (wet and dry).

15 Because of the impaired conversion to mesenchymal forms from the retinal pigment epithelium by botulinum toxin formulations, it is possible to treat or provide prophylaxis against proliferative vitreoretinopathy following various forms of retinal detachments, a leading and often blinding complication of corrective retinal detachment surgery.

Targets for Therapy in the Clinical Setting

20 The disclosed formulations and methods may, in some cases, improve and/or maintain vision in patient afflicted with macular degeneration. Further, the botulinum toxin can be used to reduce anatomic changes in populations at risk for macular degeneration.

Functional measurements can involve various forms of visual acuity testing, contrast sensitivity testing, visual fields, anatomic outcome measurement using coherence retinal
25 tomography or fluorescein angiograms, color vision, OCT, light dark adaptation measurements, or any other measurement of visual function.

The disclosed formulations may be used for one or more of the following:

1. Prophylactic in high risk populations as determined by genetic testing or strong family history
- 30 2. Arrest progression of dry degeneration to neo vascular stage with attendant leakage

3. In wet stage to both enhance drying and decrease choroidal leakage from recession of choroidal neovascularization.

An approach to treating dry macular degeneration involves maintaining the barrier between the neurosensory retina and choroid the source of neovascularization. As such an application involves making injections with barrier enhancing agents at the level of the retinal pigment epithelium, such injections would need to be extra-ocular to achieve a risk benefit ratio suitable repeated dosing in a patient with stage 1 or earlier stages of macular degeneration with leakage. Botulinum toxin via extra –ocular injections would be ideal as the safety factor are well known to be favorable for peri-orbital and facial injections at dosing levels described herein. Such repetition can provide a prophylactic for early macular degeneration cases progressing to stage 2 (wet variety) which is associated with a rapid deterioration in visual acuity and reading potential.

Botulinum Toxin Hemagglutinin in the Complex, Free from muscle weakening Neurotoxin, and Role in the Macular Application (VEGF action)

For the first decades of botulinum use in humans, the toxin has been administered as a complex of neurotoxin associated with non-covalently bound proteins. The type A molecule is composed of neurotoxin, hemagglutinin proteins, and non-hemagglutinin, non-neurotoxin proteins. Most publications to date have indicated the latter two proteins have no role in clinical application of injectable botulinum toxins for various disease states and cosmetic applications.

The non-hemagglutinin may stabilize the formation to shelf life and the hemagglutinin has been shown to be important in to trans epithelial penetration and toxicity to orally ingested botulinum toxin and influence oral ingested toxicity. The hemagglutinin makes the complex more toxic by promoting gastric absorption. Collectively, these proteins may enhance in part or when used in combination the effects on the human retinae causing benefit to macular degeneration.

Contrary to the above, the macular and other epithelial applications to botulinum toxin are influenced by adjuvant proteins within the formulation. In fact, such proteins can be used enhancers, independent pharmaceutical agents to enhance botulinum potency on epithelial structures involving eye applications, and can have substantial directed biologic effects even when used in the absence of neurotoxin.

The examples given herein used BOTOX®, which is a complex with hemagglutinin adjuvant proteins. Botulinum toxin derived hemagglutinins have a direct action on cleaving cadherin E, a critical protein maintaining tight junction between gastric epithelial cells allowing for increase uptake of the botulinum neurotoxin increasing its toxicity. Further and even more

remarkable relative to the retinal and eye applications, this effect (contrary to publications) can have an effect on various cadherin types causing a critical interaction with important receptors involved with endothelial cell growth (neovascularization.) Example 1 showed evidence of improvement in leakage and recession of a sub epithelial neo vascular membrane which is associated with improved prognosis for macular degeneration progression. Further, the effect of BOTOX® impedes differentiation of the RPE cells into mesenchymal fibrocytes which attendant death of neuro-retinal photoreceptors.

Cadherin cell connector proteins have been implicated in a number of retinal diseases including juvenile macular dystrophy, butterfly dystrophy, Ushers syndrome, autosomal recessive rod-cone dystrophy. A number of typed polymorphisms to cadherin genes have been linked to these macular and retinal conditions, which effect appearance and degeneration of the RPE. The unexpected result is that cadherin activity via botulinum complex or hemagglutinin known to act on cadherin lysis can in fact cause re-expression of cadherin cell connecting protein which enhance barrier activity.

Cadherin VE is known to be an important protein contained within vascular endothelium important to vascular integrity and growth of new blood vessels. Cadherin VE not only mediated adhesions between endothelial cells but is required for endothelial cell survival and maintenance. Vascular endothelial growth factor (VEGF) requires forms of cadherin to bind to its receptor tyrosine kinase to maintain and actuate endothelial growth. To this extent the hemagglutinin with the complex with or without the neurotoxin can act as an anti VEGF capable of enhancing the effects of Avastin®, EYLEA®, or other forms of anti-VEGF drugs. The use of botulinum toxin with hemagglutinin can provide an action on VEGF function so as to inhibit activity and growth of vessels. This effect augments applications of retinal pigment epithelial barriers function, attachment to basement membrane, cell polarity, microvilli projections, desmosome integrity, and function of the retinal pigment epithelium also produced by the botulinum toxin based formulation.

The serendipity of these observations and applications is that quantities of hemagglutinin have been present in Botox-Occulium® for years and safety factors of these quantities have been tested in numerous clinical studies, which have demonstrated a very high degree of safety. The complex has been demonstrated to disassociate quickly from the neurotoxin component once injected into a subject indicating free complexing protein are well tolerated not producing complications and substantial adverse events. Further isolates of the hemagglutinin protein via ion exchange or other forms of protein separations allow for the development of possibly more directed

pharmaceuticals formulated being a specific anti-VEGF for the treatment of macular degeneration. Not to be limited by mechanism, the case reports presented herein proved the substrate to formulate theory and practice both from observation, unexpected pharmacodynamics (eye penetration) and important medicinal effects consistent with the novel applications described herein.

- 5 Hemagglutinin derived from botulinum toxin can be recombinantly produced and purified by removing the neurotoxin from the formulation. For type A botulinum and its various subtypes, the final product may be tested for weakening capacity using regional and mouse LD 50 assays to assure no residual neurotoxin is left in the formulation. The formulation may be administered in a periorbital or intravitreal form in dose quantities that have no effect on red cell
- 10 agglutination but in a dosing format capable of suppressing neovascularization and retinal pigment epithelial cell leakage and vascular growth under the retinal pigment epithelium.

Botulinum Toxin Complexing Proteins

- All naturally occurring serotypes of botulinum toxin (types A–G), have noncovalently associated, complexing proteins and thus form toxin complexes. Complexing proteins are
- 15 encoded in two gene clusters located close to each other on the *C. botulinum* chromosome. The first cluster encodes botulinum toxin itself plus a nontoxic, nonhemagglutinin (NTNHA) protein, while the second encodes three hemagglutinin (HA) proteins (HA1, HA2, and HA3), with HA3 being cleaved in serotype A post-translationally into two smaller components (HA3a and 3b). In botulinum toxin serotypes A–D and G, these components form two different toxin complexes (i.e.,
- 20 a medium toxin complex comprising botulinum toxin and NTNHA (300 kDa) and a large toxin complex that also includes the three HA molecules (500–600 kDa)). In contrast, serotypes E and F produce only the medium toxin complex. Serotype A also forms a third complex with a higher molecular weight (900 kDa). The detailed molecular structure of botulinum toxin type D large toxin complex has been visualized and comprises a 14-subunit complex of neurotoxin, NTNHA,
- 25 three HA3 molecules (a 70 kDa molecule, also known as HA-70), three HA2 (also known as HA-17), and six HA1 (also known as HA-33). A denaturing capillary electrophoresis method can determine the subunits forming the very large/or higher molecular weight toxin complex of botulinum toxin type A, concluding that it contains single copies of the 150 kDa neurotoxin and NTNHA subunits, as well as 5–6 HA-17, 4–5 HA-23, 3–4 HA-48, and 8–9 HA-34 subunits, with a
- 30 total mass of 880–1000 kDa.

Any component of botulinum toxin hemagglutinin would be a candidate for assessment of Biologic Activity as an Anti-VEGF agent, cell to cell, cell to basement membrane or cytoskeletal

stabilizing agent or an agent useful in application toward eye diseases described herein. The formulation may include neurotoxin with the complex proteins, any one or more of the complex proteins or component of the complexing proteins.

Enhancing the quantity of hemagglutinin in existing formulations is anticipated and can be useful for the treatment of spasticity conditions (post stroke and cerebral palsy), blepharospasm, hemifacial spasm, torticollis, prostate hypertrophy, plantar fasciitis, bruxism, arthritic conditions, myofascial pain, migraine headache, tension headache, major depression (MDD), anxiety, and wound healing. The inventor has observed inflammation as a sensitizer for worsening of many of the aforementioned conditions which can be addressed by higher quantities or enhanced quantities of botulinum toxin derived hemagglutinin to existing formulations to achieve a more potent effect.

Dose of HA and Dosing at Higher Concentrations than previously used Anticipated

As botulinum as Botox® has been used for decades quantities of HA derived from botulinum toxin type A complex (see Schantz Therapy with Botulinum Toxin) are anticipated to be at levels commonly used varying between the quantity associated between 5 U-8000 U (1 U = LD 50 for a white mouse). Most preferred is the quantity of hemagglutinin associated between 5-4000 U.

Topical Formulations of Isolated Botulinum Toxin Derived Hemagglutinin. Injectable Formulations Applications

Higher dosing with botulinum toxin associated hemagglutinin (doses associated with excess of 800 U of botulinum complex) are possible as the lethal component of the complex (neuro-toxin) is not present so systemic weakness is not limited by doses. Inherently this concept allows for unique dosing forms free of paralyzing toxin.

Topical formulations of hemagglutinin derived from botulinum toxin is a viable composition at dose described herein for limiting new vessels formation and scarring on the human cornea from various infections (herpes virus, rosacea, ocular cicatricial pemphigoid, traumatic injury, exposure keratitis, corneal graft rejection, alkaline burns, socket inflammation, or other infections degenerations or dystrophies to the human cornea. Aerosols botulinum derived hemagglutinin are possible to prevent, vascular leakage and treat scarring in lungs, upper respiratory systems, esophagus, pharynx, intestinal tracts, nasal mucosa, rectal region. Infusions via intraperitoneal can be used to prevent scarring in the peritoneum and surface of the large and small intestine. Intravenous infusion can be used to mitigating new vessel growth into malignant tumors,

which promote neovascularization such as metastatic tumor to the liver, spleen, lungs, brain, and other organs. Use in allergy is anticipated as well as autoimmune disease, such as Graves disease and auto-immune thyroid disease. Use in various forms of uveitis, to prevent exudation and leakage is anticipated by per-ocular, intravitreal, or intravenous injection. Treatment of leaking blood vessel associated with diabetic retinopathy and blinding diabetic neovascularization can be targeted by the “anti-VEGF” component action of botulinum toxin hemagglutinin activity. Chronic asthma with vascular leakage and scarring can also be targeted, in some embodiments. Eczema and inflammatory skin diseases can be targeted. Various forms of sinusitis can be targeted for treatment. Use in IGE mediated edema can also be targeted. Other inflammatory conditions can be anticipated for an anti-VEGF action.

The novel use of isolated hemagglutinin for macular degeneration circumvents issues related to induced paralysis from the neurotoxin component of the molecule allowing larger dosing of the hemagglutinin than possible when the hemagglutinin is used with a complex with muscle paralyzing neurotoxin.

15 Extension of Invention to other Forms of Disease involving the Retinal Pigment Epithelium

Other forms of disease of the retina can be targets for botulinum toxin given by extra orbital and/or per-orbital method, including:

1. Retinitis pigmentosa (RP), recessive, x linked and dominant forms
2. Best disease
- 20 3. Stargardts disease
4. Pattern retinal and macular dystrophy
5. Chloroquine retinopathy
6. Lattice dystrophy (with and without retinal breaks)
7. Angioid streaks
- 25 8. Birdshot retinopathy
9. Central serous retinopathy
10. Ocular histoplasmosis syndrome
11. Irvine Gass syndrome
12. White dot syndromes
- 30 13. Trauma to retinal pigment epithelium
14. Ocular Toxoplasmosis syndrome
15. Ocular conditions associated with pseudo exfoliation syndrome

16. PVR (post-operative proliferative vitreoretinopathy)
17. RPE damage associated with choroiditis
18. Macular hole (partial and complete)
19. Early and late stages of Retinal Detachment (both rhegmatogenous-break related and non-
- 5 rhegmatogenous, non-break related).
20. Diabetic macular edema
21. Diabetic retinopathy (any stage) (both retino-vascular barrier effect enhancement by
- botulinum toxin, and RPE enhancements in barrier and fluid leak functions)

10 In each of the above diseases disruptions of the retinal pigment epithelium can occur causing damage to photoreceptors by leakage of choroidal fluid containing cytokines, leukocytes, antibodies and various immune reacting agents destructive to photoreceptors leading to visual loss and blindness.

15 Agents that augment the epithelial barrier elicit an increased integrity of the pigment epithelial barrier enhancing the protection of the photoreceptors and visual function, even in conditions not associated with age related macular degeneration. Further botulinum toxin can have an effect on neuropeptide and other agents of neurogenic inflammation which when transported to choroid acts to suppress barrier damage and subsequent visual loss associated with macular degeneration as well as other forms of degenerative and inflammatory diseases. Further, even if effects do not address genetic causes or other processes, the enhancement of the RPE photoreceptor

20 system can be neuroprotective for photoreceptors by mechanisms of enhancement of RPE function supporting the phagocytosis, transport of apical rod cone structures.

25 In the case of retinal degeneration such as retinitis pigmentosa, the defect may involve primarily the photoreceptors with retinal pigment epithelial changes being secondary to excessive degenerative rod and cones material undergoing phagocytosis with toxic accumulation in retinal pigment epithelial cells followed by RPE degeneration and dysfunction. An agent which may augment the RPE tolerance for toxic protein accumulation will retard visual deterioration based on RPE loss. Other mechanism at the level of the photoreceptors can play a role. Stabilization of barrier membranes with endothelial cells may further be operational in preventing or migrating against progression of photoreceptor damage and protection. The cause of macular edema in RP is

30 possibly related to inflammatory autacoids and antibodies entering the neuroretina and elicited a breach in the blood retinal barrier at the retinal circulation. The edema suggests that RPE leakage from vascularized choroid may be important in the progression of RP. Further intrinsic functions of the RPE such as preservation of microvilli, increased efficiency of phagocytosis based on actin

stimulation in submembrane regions, increased metabolic turnover of accumulated dysfunctional rhodopsin protein in the photoreceptors can play a role in reducing the visual loss over time in the various forms of retinitis pigmentosa.

Genetic defects have been associated with retinitis pigmentosa, a hereditary condition
5 associated with night blindness and degeneration of rods and cones in the neuroretina leading to progressive and often relentless loss of vision.

Proliferative Vitreal Retinopathy (PVR) and Epithelial Mesenchymal Transformation (EMT)

PVR is one of the most devastating complications occurring after retinal detachment surgery. The reaction of the RPE here is to undergo EMT with proliferation of cell into the vitreous
10 with conversion to fibrocytes leading to traction membranes causing recurrent retinal detachments which are poorly treated with existing measures. The application of botulinum toxin by extra ocular or intra-ocular administration stabilizes the retinal pigment epithelial from fibrous and migratory conversions leading mitigation of the fibrotic conversion surrounding retinal detachment surgery. Application as a prophylactic before, during and after the surgery proves useful measure to
15 decrease incidence and progression of this complication.

Pseudo-Exfoliation Syndrome is still another condition associated with abnormality in cell to cell adhesion. Here migration of pigment epithelial cell from uvea can often causes glaucoma by cell accumulation in the trabecular meshwork. Use of botulinum toxin by intra ocular or extraocular injections can result in tightening of the adhesions between pigment cells leading to less
20 pigment dispersion, allowing a novel method to treat this disease. Further, this condition can be associated with higher cataract surgery complication rate from lens and zonule dislocation. This agent can be used for stimulating a tighter connection between pigment epithelium and zonules.

In some embodiments, formulations comprising botulinum toxin may be injected or topically applied to a patient for the treatment of surface epithelial ulcers and stabilization of
25 biologic tissue barriers. Botulinum toxin has conventionally been used to treat spasmodic muscle contractions, relax muscles causing effects on muscles tone, blocking autonomic function causing secretions, causing diminished sensation of pain such as headaches of various causes, and smoothing muscle generated skin wrinkle. Application to non-muscular portions and regions of skin can cause epithelial tightening by the mechanisms described herein.

30 Another novel application of botulinum toxin which when used topically or by injection causes a rapid healing of an epithelial ulcers or stabilize biologic tissue barriers disrupted by

various disease processes other than macular degeneration. The effect centers around a novel biologic observation that actin and related cyto-structure subcellular elements are stimulated by botulinum toxin causing upregulation of cyto architectural protein after injections, causing preservation of cellular structures through enhancement of the cytoskeleton, preservation of cell
5 internal structures, and enhancements of adhesions between cells, enhancement of actin production and microtubules cross connections between cells which support and enhance biologic barriers.

Targeted ulcers occur in the colon, skin along extremities and lower legs, decubitus ulcers, pressure ulcers, corneal ulcers, mouth and tongue ulcerations, esophageal ulcers, stomach ulcers, poorly healing surgical and cutaneous wounds, burn induced wounds, ulcers induced by vasculitis,
10 infections by bacteria and fungus, around surgically induced ostea, per rectal ulceration, radiation induced ulcerations, mouth and gingival ulcers, gingival retraction, conjunctival ulcers, and post infectious ulcers. Injectable and topical methods of delivery are operational for these injections.

Critical epithelial/endothelial barriers include not only the retinal pigment epithelial barriers, but corneal epithelial integrity, urologic epithelial barriers in urethra and bladder, blood
15 brain barriers, endothelial barriers in blood vessels and corneal endothelium, repair of endothelial microvilli with the GI tract and enhancement of dental gingival barriers important in generation of tooth decay and periodontal disease. The biologic barriers are enhanced by augmentation of the actin and related protein cyto skeleton causing enhancement of barrier integrity necessary for the health maintenance of the target organ and related tissues.

Botulinum toxin has been conventionally used to treat spastic muscles, temporally
20 denervate glands (eccrine and sebaceous glands, salivary glands, prostate gland, lacrimal gland, mucous secretions from nasal mucosa, acid secretion in stomach. Muscular targets have been to induce myoneural blockage causing neurogenic muscular atrophy by blocking acetyl choline release by blockage of vascular release of acetyl choline. The targets involve binding of the heavy
25 chain to the presynaptic membrane via the c- terminus of the botulinum toxin heavy chain to the membrane receptor with penetration of the light chain into the cytoplasm causing cleavage of SNAP-25, a mechano-fusion protein essential in exocytosis. The blockage of myoneural junctions occurs on a dose-dependent area surrounding injections in a fashion that the effects are targeted to involved area and that undesirable diffusion causing complications does not occur. Beyond these
30 applications, botulinum toxin is used herein to produce increased integrity of an epithelial surface to enhance to cell to cell integrity of the surface, enhance the barrier function of the surface and

function to sustain the surface from degenerative changes occurring in senescence or in disease processes.

The cellular effect which enhances the applications of botulinum toxin to novel indications which are difficult and often impossible to effectively and definitively treat. The invention stems from a formerly described “epi phenomena” associated with neuro- muscular injection blockade. Injections of botulinum toxin causes blockage of exocytosis of acetyl choline from pre synaptic vesicles, flaccid muscular paralysis, with subsequent atrophy of the muscle cells. The epi phenomena involves sprouting of the nerve around the myoneural block with growth of the sprouts away from the neuromuscular junction. Prior observers have interpreted this cellular response was secondary just to the myoneural block, however this explanation ignores the observation that this effect is a direct effect of botulinum toxin to enhance actin and related cyto architectural protein stimulated directly by the toxin and associated proteins causing increased protein synthesis and expression of the actin and related cyto architecture which causes the sprouting. This observation is operational to the inventions and clinical applications described herein and define a subcellular process by which the toxin produced benefit to targeted tissues.

Actin and related adhesion and associated protein cyto architecture is critical for many cell and cellular tissue functions, longevity, and barrier integrity. Programed cell death can occur by spontaneous cellular destruction of the cyto skeleton protein and such proteins are critical to cellular polarity, specialization, and cell adhesion. Upregulation of actin and related proteins in disrupted cell and tissue cause by inflammation, degeneration, infections, metabolic derangements, trauma, or burns helps cells and tissues to resist death and destruction. This essential effect of botulinum toxins is critical to the practice of use of botulinum toxin to assist in the healing process, enhancing wound healing, enhancing epithelial healing and the velocity of healing. Cyto skeleton enhancing drugs can be enormously helpful to be used to preserve cells from destruction based on various causes.

Botulinum Toxin Types (Topical Application and Injection) to achieve cytoskeletal changes similar to C2, C3)

Botulinum toxin exists as types A(1-5), B ,C,C2,C3, D,E,F ,G. The toxin type C2,3 cause a cytotoxic effect causing cell death by influencing the lysis of actin, increased tissue and cell permeability and integrity causing a cytotoxic effect. The other neurotoxins cause organism death by flaccid paralysis, asphyxiation from respiratory paralysis. The essential component to this invention involves using various forms of non type C2,C3 toxin to achieve intra cellular and

intercellular enhancing effect on actin and related protein production as a cyto-protective effect of the botulinum use by application at lower doses (e.g., various forms of type A toxin). In effect, various forms and doses (concentrations) of botulinum toxin can have opposite effects on the cyto skeleton proteins depending on tissue type and cell cycles. This observation and derivative
5 application is essential to understanding the practice of the invention. Type A botulinum toxin by enhancement and preservation of the cyto skeleton can be protective and not toxic at given dosing and application methods described herein. This concept is counter intuitive to the know effects of certain isoforms of botulinum toxin such as type A.

Epithelial Surfaces

10 Epithelial surfaces tend to have cellular and tissue integrity requirements important to the health and resilience to various forms of diseases and injuries.

The skin and mucous membranes are the apparent epithelial surfaces in the human body. The skin functions to maintain moisture content in the body and protect against life threatening dehydration with humidity, temperature, convection changes. The skin involves tightly compacted
15 squamous epithelial cells important to the function of the biologic barriers. These cells arise from germinal cells attached tightly to a basement membrane and to each other on a plane that is normal to the epithelial surfaces. Actin and related microtubule structure are strongly expressed in the cytoplasm of these cells and respond to various insults such as burns, viral diseases, trauma, autoimmune diseases, degenerative conditions, and hereditary defects. The subcellular elements
20 important to the contribution of the skin as a functioning barrier include actin and microtubule organization of the skin cell allowing for a high number of adhesions including transcellular tubular organization, desmosomes and hemi-desmosomes, and cell membrane integrity. Diseases and genetic experimental models involving actin and related protein derangements causes a disruption of the barrier leading to structural changes, dehydration, protein loss and damage and structural
25 skin disfigurement.

Herein, an approach is described which alters the actin and related microtubule elements of the skin cells so that:

1. The integrity of the skin barrier is maintained by topical or injectable botulinum toxin so that evaporation, protein leak, release of proteases enzymes, immuoglobulins, and
30 leukocytes potentially harmful to the epithelial barrier.
2. Enhance epithelial cell integrity and proliferation so that ulceration and other forms of skin discontinuity can heal more effectively.

3. Function as a preventative therapy to keep wound ulcers from forming such as cutaneous pressure ulcers, ocular exposure ulcers from facial paralysis or exophthalmos, esophageal ulcers with the esophageal mucosa due to reflux, bladder ulceration from irritates such as radiation or chemo therapy, peptic ulceration in in patient with active or past duodenal ulcers, genival retraction from breakdown of gingival epithelium from bacteria or genetic predisposition.

Mucous membrane surfaces are also subject to ulcerations, and dysfunctions related to loss of barrier integrity. Such loss of integrity can lead to leakage of enzymes, immunoglobulins and rr4lated cellular elements such as polymorphonuclear leukocytes capable of further damage to barrier functions and other cellular functions of the mucous membrane surfaces. Botulinum toxin when applied by injection or topically can function to enhance the integrity of the mucous membrane epithelial barrier by causing a microtubule alteration in the mucous membrane cellular structure allowing for increased barrier function of the epithelial cells.

Herein, an approach is described which alters the actin and related microtubule elements of the mucous membranes and intercellular binding proteins (cadherins) cells so that: (1) the integrity of the skin barrier is maintained by topical or injectable botulinum toxin so that evaporation, protein leak, release of proteases enzymes, immuoglobulins, and leukocytes potentially harmful to the epithelial barrier and/or (2) epithelial cell integrity and proliferation are enhanced so that ulceration and other forms of skin discontinuity can heal more effectively.

Examples of mucous membrane surfaces applicable include but are not limited to: Conjunctival, Vaginal, Rectal, Alveolar, Glomerular and renal tubules, Intestinal, Gastric, Esophageal, Nasal Mucosa, Oral mucosa, Dental- Gingival mucosa (periodontal disease), Bronchiolar and tracheal mucosa, Bladder mucosa, Urethral mucosa, Ureter Mucosa, and/or Gall Bladder and biliary duct mucosa.

Conventionally, botulinum toxin is used to removed dynamic lines and wrinkles based on a neuromuscular weakening effect. This approach has been employed for decades and is the source of billion-dollar revenue market. This approach also has been the target for United States FDA approval pathways for these indications using forced frown lines as an endpoint. Muscle injections are described as the target for injection to produce the favorable aesthetic results.

The disclosed formulations and therapeutic methods may, in some cases, tighten the cell to cell adhesions in epithelial surfaces provide more insight and utility to aesthetic application. Application of botulinum toxin by injection to non-muscular regions at multiple puncture sites on

surfaces away from muscle tissue can prove beneficial to skin texture and be effective in removing non-dynamic wrinkles (wrinkles not generated by resting muscle tone or contractions of muscles). The disclosed formulations may be delivered along multiple punctures sites far lower than necessary to produce a muscle weakening effect.

5 Botulinum Toxin Action on the Rho Protein Family

Certain immune-types of botulinum toxin are known to act as cytotoxins causing cell damage and poisoning by non-neuromuscular mechanisms. These are the botulinum C2,C3 types which are distinctive both in chemistry and cellular effect. These toxins are known to enhance actin dissolution by actin and disruption of tight junctions with vascular leakage, hemodynamic
10 instability and death. This toxin act as ADP ribosylating toxin which interfere with actin formation and integrity. Recently, botulinum toxin type A has been shown to interfere which fibroblast migration and function and reduce cutaneous scars. The observations indicate by observers that other botulinum toxins have an effect on actin cytoskeleton elements in a way that impairs actin formation and cellular functions associated with actin such as cell motility, and tissue functional
15 integrity. These biologic effects are negative when toxin is given at high doses to cause impairment of cellular function.

Cell motility requires actin cell polymerization and dissolution occurring rapidly to accomplish this function from member of the Rho protein family (Cdc2, Rac, Rho). These proteins are also involved in the maintenance of cell polarity, motility, important to many tissue barrier
20 functions.

Contrary to the above, the invention described herein involves a positive effect on barrier cells to enhance and strengthen cell to cell contact and cell to basement membrane contacts for non-motile epithelial cells constituting a biologic barrier as well as enhancing (not depressing) cell migration when a defect is present or enhancing biologic barriers important to disease processes
25 when there is a defect in epithelial adhesion and transformation. Improvement in barrier dysfunction results from the cyto architectural effect from the toxin. The type A botulinum toxin has been associated with reorganization of actin fibers in neural derived cell cultures indicating a contrary effect to related type C2,C3 and type D toxin. Rather than disrupt cell to cell contacts, type A toxin is able to cause actin and related proteins to reorganize the cytoskeleton in a
30 configuration that tightens cell to cell contact, increase integrity of biologic barriers, enhance function of epithelial barriers and promote epithelial and endothelial growth ton seal defects in endothelial and epithelial cell barriers. The mechanism can relate to interacting to similar enzymes

in the Rho family adjusting relative rates of actin and related protein reorganization to that the tight junctions are enhanced and biologic interactions of actin with its attachment protein cadherin and specialized cell intermediate filaments enhance cell function and barrier functions.

The above appears contrary to published reports but just as the neuromuscular effects are controlled by dose. These cytological effects are also subject to doses conventionally used to treat medical conditions described herein. Such doses can modulate the actin skeleton in a way to enhance the barriers and cellular adhesive quality increasing the function within the epithelial barrier to mitigate a disease process based on a subliminal effect on the cytoskeleton with enhancements of adhesion from actin, cadherin interactions.

10 Complex vs Pure Neurotoxin

Current efforts in pharmaceutical design have sought to remove the accessory protein from botulinum toxin preparations. These proteins include hemagglutinin and non-hemagglutinin non-neurotoxin proteins. Recently, botulinum-associated protein hemagglutinin has been associated with interaction and weakening of cadherin proteins in tissue types. Cadherin interactions can be important in maintaining the integrity of the neural synapse. This disruption is tight to further disrupt the actin cell element of the presynaptic neuron and provide for an enhance of botulinum toxin uptake at the presynaptic structure causing a more effective penetration of botulinum toxin uptake enhancing the potency and effectiveness of the injectable or topically applied botulinum formulation. The interaction with cadherin protein can trigger genomic response causing enhanced cadherin and associated proteins for cell and tissue repair.

The effectiveness of some formulations of botulinum toxin have been observed by clinicians not to be equivalent to botulinum complex (BOTOX® vs XEOMEN). Any membrane interactive substance which can increase permeability of botulinum toxin into the neuron may be useful to enhance potency. Recently, two studies on rhytids and adult onset spasmodic torticollis which reported increased potency based on an adjuvant poly-lysine (poly-cation) which was designed to increase penetration to the motor neuron axon tip. Alternate methods are described herein of increasing the concentration of the hemagglutinin to enhance effect of the formulation on muscle to axon nerve tip intercellular attachment protein in such a way to increase permeation of the neuron to the axon tip and enhance potency.

30 Prophylactic Therapy in Stage 1 Macular degeneration

The therapies disclosed herein, in some embodiments, include benign placement alternatives to intra-vitreous injections which represents the current placement method in using anti-VEGF pharmaceuticals such as Eylea®, Lucentis®, and Avastin®. In some embodiments, the disclosed methods provide an opportunity for a novel treatment approach of providing a prophylactic therapy for high risk patients, patients diagnosed with stage 1 AMD, and/or patients with high risk features to progress to geographic atrophy or stage 2 (exudative) AMD.

In current practice, macular degeneration is often diagnosed as stage 1 before the disease progresses to the rapid vision-destroying stage 2 degeneration involving intra-retinal and sub-retinal leakage from new vessels growth and new vessel growth under or over the retinal pigment epithelium. In some embodiments, a method of preventing any stage of macular degeneration is provided that involves: identifying a patient with high risk for AMD based on genomic testing for high risk polymorphisms genes structures noted to be associated with macular degeneration. In these and other embodiments, the method continues with providing an extra-ocular injection in the orbit, Para orbital, peri orbital region (sinuses or temporal), and/or pterygopalatine fossa lateral orbital region, in a manner that allow botulinum effect on the posterior eye, macular or intra-ocular structures. The method may continue with monitoring the patient and eventually decreasing the incidence of macular degeneration on the targeted eye or eyes using the methods as described herein for macular degeneration assessment.

There are risk factors for the development and progression of AMD that may be used in connection with the disclosed methods. For example, possible risk factors that may be considered include but are not limited to: number and volume of drusen and drusenoid lesions, extent and position of geographic atrophy in target or contralateral eye, number and position of hyper-reflective foci into the neuroretina (either position over drusen-drusenoids), loss and disorganization of continuity of IS-OS line or outer nuclear layer, hyper or hypo pigmentation, hyper-reflectivity and deposits within the drusens, dynamic changes in number and size of drusens, soft drusen, hyperreflective foci, IS-OS lines ONL, and presence and number of pseudo-drusen. Additionally, genetic testing may be employed in connection with the disclosed methods to assess polymorphisms associated with severe macular degeneration as well as complement factors and other genes associated with severe disease.

Macular Edema

There are many known causes of macular edema. For example, macular edema is frequently associated with diabetes, where damaged blood vessels in the retina begin to leak fluids,

including small amounts of blood, into the retina. This is the most common cause of visual loss associated with diabetes. Sometimes deposits of fats may also leak inside the retina. This leakage causes the macula to swell. In this situation, the biologic barrier is defined by the retino-vascular endothelium and supporting pericytes in the retinal circulation.

5 Eye surgery, including cataract surgery, can increase your risk of developing macular edema due to blood vessels becoming irritated and leaking fluids. Macular edema that develops after cataract surgery is called cystoid macular edema (CME). Some of the other macular edema causes include: type 1 and type 2 diabetes, age-related macular degeneration (AMD), uveitis, retinal vein occlusion (branch and central retinal vein occlusion- Example 8), blockage in the small
10 veins of the retina, due to radiation, macular telangiectasias, side effects of certain medications, and certain genetic disorders, such as retinoschisis or retinitis pigmentosa, incontinentia pigmenti. The disclosed formulations are methods may be used to treat, prevent, or cure macular edema caused by one or more of these conditions.

 By mechanisms described herein, the barrier occurring around the retinal vessels
15 (endothelium and peri-cytes) can be augmented causing less leak, less macular edema, and/or preservation of vision. For these indications, injections can be given via pars plana (intra-ocular injections) or through soft tissue injections surrounding the eye in a similar manner described for macular degeneration. Topical applications with higher doses used to achieve greater penetration can also be used. Such higher doses are within the ranges from 1-5,000 units.

20 Renal Function (Barrier Function) and Nephrotic Syndrome

 Nephrotic-range proteinuria is the loss of 3 grams or more per day of protein into the urine or on a single spot urine or on a single spot urine collection, the presence of 2 g of protein per gram of urine creatinine. Nephrotic syndrome is the combination of nephrotic-range proteinuria with a low serum albumin level and edema. Nephrotic syndrome has many causes, including primary
25 kidney diseases such as minimal-change nephropathy, focal glomerulosclerosis, and membranous nephropathy. Nephrotic syndrome can also result from systemic diseases that affect other organs in addition to the kidneys, such as diabetes, amyloidosis, and lupus erythematosus. Nephrotic syndrome may affect adults and children of both sexes and of any race. It may occur in typical form, or in association with nephritic syndrome. The latter connotes glomerular inflammation, with
30 hematuria and impaired kidney function.

Nephrotic syndrome can be primary, being a disease specific to the kidneys, or it can be secondary, being a renal manifestation of a systemic general illness. In many cases, injury to glomeruli is an essential feature. Kidney diseases that affect tubules and interstitium, such as interstitial nephritis, will not cause nephrotic syndrome.

5 Primary causes of nephrotic syndrome include the following, in approximate order of frequency: Minimal-change nephropathy, Focal glomerulosclerosis, Membranous nephropathy, and Hereditary nephropathies. Secondary causes include the following, in order of approximate frequency: Diabetes mellitus, Lupus erythematosus, Viral infections (e.g., hepatitis B, hepatitis C, human immunodeficiency virus [HIV]), Amyloidosis and paraproteinemias, Preeclampsia, and
10 Allo-antibodies from enzyme replacement therapy.

Nephrotic-range proteinuria may occur in other kidney diseases, such as IgA nephropathy. In that common glomerular disease, one third of patients may have nephrotic-range proteinuria. Nephrotic syndrome may occur in persons with sickle cell disease and evolve to renal failure. Membranous nephropathy may complicate bone marrow transplantation, in association with graft
15 versus host disease. From a therapeutic perspective, nephrotic syndrome may be classified as steroid sensitive, steroid resistant, steroid dependent, or frequently relapsing.

In a healthy individual, less than 0.1% of plasma albumin may traverse the glomerular filtration barrier. Controversy exists regarding the sieving of albumin across the glomerular permeability barrier. On the basis of studies in experimental animals, it has been proposed
20 that ongoing albumin passage into the urine occurs in many grams per day, with equivalent substantial tubular uptake of albumin, the result being that the urine contains 80 mg or less of albumin per day.

However, studies of humans with tubular transport defects suggest that the glomerular urinary space albumin concentration is approximately 3.5 mg/L. At this concentration, and a
25 normal daily glomerular filtration rate (GFR) of 150 liters, one would expect at most 525 mg per day of albumin in the final urine. In health, urine albumin is less than 50 mg/day, because most of the filtered albumin is re-absorbed by the tubules. Amounts above 500 mg/day typically point to glomerular disease.

The glomerular capillaries are lined by a fenestrated endothelium that sits on the glomerular
30 basement membrane, which in turn is covered by glomerular epithelium, or podocytes, which envelops the capillaries with cellular extensions called foot processes. In between the foot processes are the filtration slits. These three structures—the fenestrated endothelium, glomerular basement membrane, and glomerular epithelium—are the glomerular filtration barrier. A schematic drawing of the glomerular barrier is provided in FIG. 8.

FIG. 8 shows a schematic drawing of the glomerular barrier. In FIG. 8, the abbreviation “GBM” refers to the glomerular basement membrane and “ESL” refers to the endothelial cell surface layer (often referred to as the glycocalyx). Primary urine is formed through the filtration of plasma fluid across the glomerular barrier (arrows); in humans, the glomerular filtration rate (GFR) is 125 mL/min. The plasma flow rate (Q_p) is close to 700 mL/min, with the filtration fraction being 20%. The concentration of albumin in serum is generally 40 g/L, while the estimated concentration of albumin in primary urine is 4 mg/L, or 0.1% of its concentration in plasma.

Filtration of plasma water and solutes is extracellular and occurs through the endothelial fenestrae and filtration slits. The importance of the podocytes and the filtration slits is shown by genetic diseases. In congenital nephrotic syndrome of the Finnish type, the gene for nephrin, a protein of the filtration slit, is mutated, leading to nephrotic syndrome in infancy. Similarly, podocin, a protein of the podocytes, may be abnormal in a number of children with steroid-resistant focal glomerulosclerosis.

The glomerular structural changes that may cause proteinuria are damage to the endothelial surface, the glomerular basement membrane, or the podocytes. One or more of these mechanisms may be seen in any one type of nephrotic syndrome. Albuminuria alone may occur or, with greater injury, leakage of all plasma proteins (ie, proteinuria) may take place.

Proteinuria that is more than 85% albumin is selective proteinuria. Albumin has a net negative charge, and it is proposed that loss of glomerular membrane negative charges could be important in causing albuminuria. Nonselective proteinuria, being a glomerular leakage of all plasma proteins, would not involve changes in glomerular net charge but rather a generalized defect in permeability. This construct does not permit clear-cut separation of causes of proteinuria, except in minimal-change nephropathy, in which proteinuria is selective.

The renal tubules are also governed by barrier function in the cell to cell adhesion and attachments to basement membranes. Targeting the kidney or nerves entering the kidney can be useful to treat renal diseases in which barrier function are essential.

As botulinum toxin is capable of stimulating proteins which are essential to cells to cell adhesion and attachments to basement membranes, the enhancement of the adhesion complexes at the glomerular barrier and tubules can be useful to treat kidney disease. The kidney lies in the retro-peritoneum close to the mid to lower back making this organ assessable to injections through back muscles, and organ via innervation with axoplasmic transport. Needle can access the kidney from back injections and diffusion through dosing nomograms. In some cases, the treatment objective may be to slow progression on diabetic need for dialysis or to treat or prophylactically treat

glomerular disease with high risk patients (for example, advanced stage diabetics, system lupus patients, para-proteinemias, patients with systemic amyloidosis, or primary nephrotic syndromes).

Periodontal Disease Tooth Loss

Teeth are attached to the surrounding and supporting alveolar bone by periodontal ligament (PDL) fibers. PDL fibers run from the bone into the cementum that naturally exists on the entire root surface of teeth. They are also attached to the gingival (gum) tissue that covers the alveolar bone by an attachment apparatus. Because this attachment exists superficial to the crest, or height, of the alveolar bone, it is termed the supracrestal attachment apparatus. This apparatus is subject to deterioration in Periodontal disease.

The supracrestal attachment apparatus is composed of two layers: the coronal junctional epithelium and the more apical gingival connective tissue fibers. The two layers together form the thickness of the gingival tissue and this dimension is termed the biologic width. Plaque-induced periodontal diseases are generally classified destructive or non-destructive. Clinical attachment loss is a sign of destructive (physiologically irreversible) periodontal disease. The quality of the epithelial layers define the extent and progression of periodontal disease.

The barrier function of the epithelial layers helps prevent and retard periodontal disease. Repeated use of botulinum toxin by topical application, regional injection can cause a tighter seal from augmentation of cell to cell adhesion protecting the quality of bone loss and PDL integrity. In gingivitis, inflammation localized to the supracrestal region of the periodontium leads to ulceration of the junctional epithelium. Although this is technically a loss of clinical attachment, the term clinical attachment loss is used almost exclusively to refer to connective tissue attachment loss. Use of repeated botulinum injections can result in prevention and therapy of ulceration, epithelial erosion, with subsequent loss of PDL integrity, connective tissue attachment and loss of bone.

Example 1 - Exudative (Wet) Macular Degeneration Not Responsive to Conventional Therapy

A 71 year old man was diagnosed with progressive macular degeneration with substantial sub retinal and sub foveal fluid, which was unresponsive to repeated Avastin® intra-vitreous injections and Eylea Intra vitreal injections (10 injections)(FIG. 9A-9E). Patient was treated with 100 units of per-ocular botulinum toxin type A (BOTOX®) in forehead, orbicularis and deep temporal fossa which resulted in a substantially augmented response to an anti-VEGF agent on subsequent injection with substantial resolution of sub foveal fluid (see FIG. 9A-9E).

The patient noted his vision was augmented after the combination of anti-VEGF and botulinum formula than the prior unsuccessful Anti-VEGF therapy. The interpretation was that the

botulinum toxin given before the next anti-VEGF enhanced the response and converted this patient wet macular degeneration to a dry state (due to the antecedent botulinum toxin injections).

Anatomic improvement in this patient included flattening of the retina as documented with ocular coherence tomography, decrease in sub-retinal and intra retinal fluid, decreased choroidal
5 neovascular membrane, and thickening of the RPE (FIG. 9F). These anatomic findings are typical for positive response to exudative (WET) age related macular degeneration.

Example 2 – Non-Exudative Macular Degeneration (dry macular degeneration)

The results of this example are shown in FIGS. 10A and 10B. Elderly female with well-
documented non-exudative macular degeneration in each eye and about 20/40 vision in each right
10 and left eye receives botulinum injection comprising about a total of 100 unit to head, per-orbital region and an area into the pterygopalatine fossa targeting the autonomic and sensory ganglionic structures in this region. The patient notices slow improvement in contrast sensitivity and clarity of vision, which lasted about three months. She desired another injection with the type A botulinum toxin (BOTOX-A®, Allergan) in order to maintain vision. On ophthalmologic exam no other
15 reasons for the subjective improvement in vision could be established on pre-injection and post injection examinations.

Optical coherence tomography indicates flattening and regression of drusen bodies as well as increased surface regularity of the retinal pigment epithelium (FIG. 10). Findings were concomitant with subjective visual improvement.

20 Without wishing to be bound by theory it is believed that the injections in peri orbital nervous structures allowed for axoplasmic transport into the eye improving functioning of the retinal pigment epithelium function and possibly structure allowing improved vision.

Example 3 - Filamentary Keratitis (improvement of corneal epithelial integrity and adhesion based on direct surface examination of an epithelial sheet)

25 A 71-year-old man was treated for blepharospasm for 10 years. He noted improvement after injections ranging from 40-80 units. Concomitantly, he was diagnosed to have filamentary keratitis. After botulinum administration by drop form (20 units) and by injection into lids, the filaments disappeared or were markedly improved associated with decreased light sensitivity, decreased pain, improved vision, and increased regularity of the epithelium, as demonstrated by
30 computerized reflective corneal topography. The increased adhesiveness of the epithelium resulted

in improvement in his corneal surface with improved vision, reduced surface distortion and lessened pain with concomitant resolution of detached filaments.

Example 4

An 82-year-old woman with long standing stage 1 macular degeneration had been followed for stage 1 macular degeneration for about 4 years. She noted some decrease in vision in the left eye over one year. OCT (Zeiss) showed accumulation of intra-retinal fluid over degenerated retinal pigment epithelium as a change from a previous scan (see FIGS. 11A-11D). Previous scan showed dry degeneration with irregularity in sheet configuration of the RPE with evidence of RPE discontinuity and breakup with neural retinal RPE migration (focal hyper reflective lesions moving into neuroretina) (FIG. 11A).

Injection of botulinum toxin after advice to patient of side effects was made using 70 units under the temporal muscle in several locations and in peri-orbital region (multiple dose injection). Region of the pterygopalatine fossa was also targeted for diffusion effect. FIG. 11B shows peri-foveal leakage with conversion of the macular degeneration to wet variety.

The plan for treatment with Avastin® or Eylea® was made within 2 weeks. Sub muscular injection toward the pterygopalatine fossa was made with 70 IU of botulinum toxin type A. Repeat OCT scan after 10 days showed no resolution of fluid (FIG. 11C). After 14 days there was complete resolution of the fluid (see FIG. 11D).

This case demonstrated the tempo of effect required about 14 days consistent with a delay expected with axoplasmic flow. This case demonstrated converting stage 2 macular degeneration (wet variety) to stage 1. No intra ocular injection with Eylea® or Avastin® was necessary and intra-ocular injections were aborted. The patient was referred for continued monitoring.

Example 5

An 87-year-old woman with 20 years of hem-facial spasm. She developed dry macular degeneration 4 years prior. About 2 years after she converted to wet degeneration with leaks into the sub retinal space and neuro-retina, several injections of Avastin® resulted in drying of the neuroretina with improvement in vision. She remained stable for about two years when a routine OCT exam revealed re-accumulation of fluid in the peri foveal region. A botulinum toxin injection was given for her hemi facial spasm in doses routine for this condition. Additionally, a deep injection of 20-30 unit was directed toward the pterygopalatine fossa directed at nerve ganglion. Her pre-injection photo is shown in FIG. 12A.

After two weeks improvement in perifoveal fluid was noted to occur (FIG. 12B). Vision improved in the left eye from 20/40 to 20/25. Note the fluid accumulation on both sides of the fovea is substantial mitigated after two weeks. Further, increase structural regularity (surface smoothness of RPE is enhanced, black and white, and external limiting membrane and IS-OS interface are more defined). At 10 weeks, know duration end for botulinum toxin and fluid accumulation begins to recur. Repeat injections after re accumulation of fluid in 10 weeks resulted in a second cycle response with complete resolution of intra-retinal edema. Dosing injections were increased to 100 units.

Example 6 – Macular Edema

A 90-year-old man with a 35-year history of type 2 diabetes presents with macular edema 5 years after cataract surgery. Micro aneurysms/leakage are documented in the macular by inspection and angiography. Macular edema is documented by OCT. 40 U of botulinum type A toxin is injected in region of pterygo palatine fossa outside the eye and eye socket. After 3 weeks there is complete resolution of macular edema. The experimental results of this example are provided in FIGS. 13A and 13B. In particular, FIG. 13A illustrates the macular edema prior to injection and FIG. 13B illustrates the macular edema symptom reduction visible 3 weeks after temporal injection toward the pterygo-palatine fossa (with spatial computer registration). Repeat injections are planned.

Example 7- Retrospective Review

After initial observation (Example 1), a retrospective review of several hundred records of general eye patients treated for types blepharospasm and cervical dystonia (treated with botulinum toxin), diseases in older age groups, was conducted for progressive age related macular degeneration. No patient had a macular degeneration progression while under repeated botulinum injections. The absence of this common problem in patients over the age of 60 was unusual and suggests cause effect with concomitant botulinum treatment. Dosing ranges for these patients was typically between 10 and 600 units.

Example 8 – Central Vein Occlusion

An 84-year-old woman with central vein occlusion OD who, for other medical reasons, could not receive anti VEGF therapy for a period of 5 months, presented with extreme macular edema and hand motions vision. 50 Units of botulinum toxin was injected on the involved side. After 2 weeks the macular edema was reduced by 60-70 % on SD OCT with some visual improvement (CF 3 ft) in the involved eye. Repeat dosing of 100 units was given to the patient.

Selected Example Embodiments

In some embodiments, a method of preventing and slowing the development of macular degeneration is provided. In some such embodiments, the method comprises administering a formulation comprising botulinum neurotoxin, a fragment thereof, and/or a neurotoxin associated protein to a human or mammalian patient suffering from or at risk for losing vision from macular degeneration. In these and other embodiments, the botulinum neurotoxin, fragment thereof, and/or neurotoxin associated protein is selected from the group consisting of: botulinum toxin A1-A5, B, C1-3, D, E, F, G and H.

In another example embodiment, a method of enhancing activity of anti-VEGF injectable agents is provided. In some such embodiments, the method comprises administering a formulation comprising a botulinum neurotoxin, a fragment thereof, and/or a neurotoxin associated protein to a patient suffering from exudative forms of macular degeneration, wherein the formulation is administered to the patient via intra-ocular injection or extra ocular injection and administering an anti-VEGF agent to the patient. In select embodiments, the formulation comprises a fusion protein containing botulinum neurotoxin or a fragment thereof and the anti-VEGF agent. In these and other embodiments, the formulation is administered to the patient separately from the anti-VEGF agent. In certain cases, the anti-VEGF agent is selected from the group consisting of: a ranibizumab, a bevacizumab, and an aflibercept.

In other embodiments, a method of diminishing progressive visual loss from retinitis pigmentosa is provided. The method may comprise, in some cases, administering a formulation comprising a botulinum toxin or a fragment thereof to a patient suffering from retinitis pigmentosa, wherein the formulation is administered to the patient via intra-ocular injection or extra ocular injection.

In other embodiments, a method of diminishing visual loss from diabetic macular edema from diabetes, central or branch vein occlusion, degenerative retinal disease, retinitis pigmentosa (RP) retinal disease, or uveitis is disclosed. The method may include, in some cases, administering a formulation comprising a botulinum toxin or a fragment thereof to a patient suffering from macular edema from diabetes, branch vein occlusion or uveitis, wherein the formulation is administered to the patient via intra-ocular injection or extra ocular injection.

In select embodiments, a method of preventing age-related macular degeneration in a patient is described. The method may include administering a formulation comprising a botulinum toxin or a fragment thereof to the patient, wherein the formulation is administered to the patient via

intra-ocular injection or extra ocular injection. In these and other embodiments, the patient may be at risk for macular degeneration as determined by medical history or genetic evaluation.

A method of treating periodontal disease and tooth loss in a patient is also described herein. The disclosed method includes administering a formulation comprising a botulinum toxin or a
5 fragment thereof to the patient, wherein the formulation is injected or topically applied to gingiva, peripheral nerves, oral mucosa, or skin in a facial or peri-oral region.

In another example embodiment, a method of treating chronic nephrotic syndrome in a patient is described. The disclosed method includes administering a formulation comprising a botulinum toxin or a fragment thereof to the patient, wherein the formulation is injected or topically
10 applied to a kidney or surrounding regions, including one or more nerves entering the kidney. Numerous other example embodiments will be apparent to those skilled in the art upon consideration of the subject disclosure.

Definitions and Abbreviations

Unless otherwise defined herein, the following terms have the stated definitions.

15 AMD – age related macular degeneration.

VEGF - vascular endothelial growth factor. VEGF binds to two members of a receptor tyrosine kinase family, VEGF receptor (VEGFR)-1 and VEGFR-2. VEGFR-2 is considered the main VEGF receptor and mediates the proliferative effects of VEGF on vascular endothelial cells. VEGF binding to VEGFR-2 induces the dimerization and subsequent autophosphorylation of
20 receptors by intracellular kinase domains, which leads to a mitogenic and proliferative signal. VEGF-C and VEGF-D bind to VEGFR-3, another member of this family of receptor tyrosine kinases.

Botulinum toxin – any immunotype, fraction of botulinum, subtype, derived from C botulinum species by fermentation or genetic expression in recombinant system.

25 HA - hemagglutinin derived from production of Clostridia botulinum in fermentation or other natural process, or recombinant, or any other expression systems (accessory protein).

RPE- retinal pigment epithelium in a mammal. HA is also a botulinum accessory protein.

OCT- Spectral domain, or any other version or enhancement of ocular coherence tomography.

30 NHNT - Non-neurotoxin, non-hemagglutinin protein produced by fermentation of C botulinum or by recombinant production. NHNT is also an accessory protein.

Anti VEGF - any known VEGF monoclonal or fusion protein, or VEGF agent which suppresses angiogenesis and /or leakage. Anti-VEGF terms used herein refers to an agent which recognized multiple isoforms of VEGF. Agents may include pieces of the VEGF receptors or entire receptor structures.

5 Complement protein - any complement factor involved in complement activation cascade.
Injection – administration of botulinum toxin (and other compounds, if applicable) with any form of a needed or microneedle.

Blepharospasm – condition treated with peri-ocular administration of botulinum toxin (commonly with a dosing range of between 10 and 300 units).

10 Neuropeptide - any know neuropeptide including but not limited to Substance P, CGRP, VIP.

ELM - external limiting membrane of the retina.

IS/OS – line defining the inner and outer segments of photoreceptors.

Stress fiber - condensation of contractile actin and associated proteins which distorts cell
15 membranes and disrupted barrier effect in a given tissue or epithelial layer.

CRVO - central retinal veins occlusion.

BRVO - branch retinal vein occlusion.

nAMD- stage 2, 3 AMD with neovascularization (active angiogenesis stages with leakage).

Biologic barrier - any biologic barrier depending on cell to cell adhesion and cell to
20 basement membrane adhesion to maintain tissue function.

mRNA - messenger RNA.

Conventional dosing - any FDA-approved dosing of botulinum toxin for an indication of the head or neck.

Formulation – as used herein, the term ‘formulation’ refers to a composition of one or more
25 biologic agents with or without excipient present.

Fusion protein - addition of one or more proteins produced industrially for the purpose of preserving the biologic activity of each protein to enhance the utility of the composition.

Generally, the fusion protein represents ligated genes or gene fragments fusion and expressed in appropriate cell system often using PCR to enhance quantity of the genes present for the expression
30 system.

Macromolecule – a large molecule having a relatively large molecular weight, such as a nucleic acid, protein, carbohydrate, or lipid.

Activity – the term “activity” refers to the specific activity or biologic activity of a given compound as measured using conventional, industry-accepted methods. The activity of a compound is used to quantify purity or concentration and is calculated as units per mass.

Rho - Rho family GTPase.

5 Ras - related C3 botulinum toxin substrate maintaining epithelial differentiation, cytoskeletal reorganization, cell growth.

Ras 2 - protein involved in cyto skeletal reorganization.

Ras 3 -- protein involved in intercellular signaling pathways.

10 ROCK1 - protein kinase regulator of actomycin cytoskeleton promotes contractile force generation, important in angiogenesis, cell motility. Major downstream effector of RhoA.

IU - Botulinum LD 50 for 20-30 gm Swiss Webster mouse, “Mouse unit.”

HcA- Fragment of botulinum type A heavy chain serving as binding domain to nerve cells.

15 SNAP-25 - Synaptosomal-associated protein 25 is a component of the trans-SNARE complex, which is proposed to account for the specificity of membrane fusion and to directly execute fusion by forming a tight complex that brings the synaptic vesicle and plasma membranes together. Substrate for L chain botulinum activity.

Regular hexagon – six-sided closed figure with equal sides.

Ophthalmologist - A medical doctor trained to treat medical and surgical diseases of the eye. Duties include injecting the globe and periocular region.

20 EMT – epithelium mesenchymal cell transformation.

GA - geographic atrophy (end stage form of dry AMD).

RPE atrophy- shrinking, flattening and loss of vital physiology of the retinal pigment epithelium.

25 CNV- choroidal angiogenesis (neovascularization protein to leak fluid and hemorrhage. Occurs under the RPE, under retina and intra neuroretina.

Leakage – abnormal and pathological movement of fluid through a biologic barriers into intra-ocular structures. The term “leakage” is used herein to refer to fluid accumulation in the neuroretina, subretina space, or choroid (sub RPE). Such leakage is commonly associated with distortion of vision and obstruction of photoreceptors.

30

CLAIMS

1. A method of treating age-related macular degeneration, the method comprising:

administering a botulinum neurotoxin or a fragment thereof to a human or mammalian patient suffering from or at risk for macular degeneration.
- 5 2. The method of claim 1, wherein the administration of the botulinum neurotoxin mitigates wet and exudative macular degeneration by reducing sub-retinal leakage, intra retinal leakage, choroidal leakage, and restores and prevents loss of vision.
3. The method of claim 1, wherein the botulinum neurotoxin is injected into or near one or more of: a forehead of the patient, a periocular region of the patient, a nasal region of the patient, a
10 neck of the patient, a nasal mucosa of the patient, a sinus of the patient, a para-orbital region of the patient, and a pterygopalatine fossa of the patient, and the botulinum neurotoxin is not injected into an intra-ocular region of the patient.
4. The method of claim 3, wherein the administration of the botulinum neurotoxin avoids complications from intra-ocular injection, including but not limited to intra-ocular hemorrhage,
15 endophthalmitis, retinal detachment, retinal breaks, lens dislocations, cataract formation, and increases in intra-ocular pressure.
5. The method of claim 4, wherein the botulinum neurotoxin is administered as a dose of from 0.5 to 25,000 LD 50 units.
6. The method of claim 3, wherein the botulinum neurotoxin is administered as a dose that
20 conforms with conventional dosing.
7. The method of claim 1, wherein the botulinum neurotoxin is injected into a vitreous or aqueous humor of an eye of the patient.
8. The method of claim 7, wherein the botulinum neurotoxin is administered as a dose of from 0.01 to 3,000 LD 50 units.
- 25 9. The method of claim 7, wherein the botulinum neurotoxin is administered as a dose that conforms with conventional dosing.
10. The method of claim 1, wherein the botulinum neurotoxin is administered via epibulbar injection or topical administration to the patient.

11. The method of claim 1, wherein the administration of the botulinum neurotoxin improves and/or preserves vision of the patient.
12. The method of claim 1, wherein the botulinum neurotoxin or fragment thereof is selected from the group consisting of: botulinum toxin A1-A5, B, C1-3, D, E, F, G and H.
- 5 13. The method of claim 1, wherein the botulinum neurotoxin is administered with a polycationic protein or a macromolecule.
14. The method of claim 1, wherein the macular degeneration is dry and not exudative as determined by OCT or fluorescein angiography.
15. The method of claim 14, wherein the macular degeneration is assessed by analysis of
10 choroid, retinal pigment epithelium, and neuro-retina by OCT and/or fundus photography.
16. The method of claim 1, wherein the botulinum neurotoxin is administered with one or more accessory proteins.
17. The method of claim 1, wherein the botulinum neurotoxin is administered as a pure neurotoxin.
- 15 18. A method of treating age-related macular degeneration, the method comprising:

administering a formulation to a patient, wherein the formulation comprises a botulinum toxin-derived complexing protein devoid of neurotoxin and containing one or more isolated hemagglutinin proteins or fragments thereof, wherein the hemagglutinin is present in a quantity that corresponds to a specific botulinum neurotoxin dosing activity.
- 20 19. The method of claim 18, wherein the formulation is administered by injection or by topical administration.
20. An injectable formulation comprising:

a botulinum neurotoxin or a fragment thereof;

a fusion protein addition of an anti-VEGF agent; and

25 a stabilizing excipient.
21. The injectable formulation of claim 20, wherein the botulinum toxin or fragment thereof is selected from the group consisting of: botulinum toxin A1-A5, B, C1-3, D, E, F, G, and H.

22. The injectable formulation of claim 20, wherein the fusion protein addition is ranibizumab, abicipar, bevacizumab, or aflibercept.
23. An injectable formulation comprising:
- 5 a botulinum toxin or a fragment thereof;
- a non-covalent addition of an anti-VEGF agent; and
- a stabilizing agent.
24. The injectable formulation of claim 23, wherein the botulinum toxin or fragment thereof is selected from the group consisting of: botulinum toxin A1-A5, B, C1-3, D, E, F, G, and H.
25. The injectable formulation of claim 23, wherein the anti-VEGF agent is ranibizumab,
- 10 abicipar, bevacizumab, or aflibercept.
