[57] A B S T R A C T

A method is disclosed for polishing geothermal brines containing iron-rich silica scale and silica particles suspended therein while removing and recovering copper, silver and other precious metals dissolved therein. The method comprises passing brine having a pH just below about 5.0 through a conduit packed with a metal higher in the electromotive series than silver to sufficient for substantially all of the silver and other precious metals therein to precipitate onto the packing. Preferably, the packing comprises coiled zinc-galvanized steel chicken wire mesh packed in a sufficient density to act as a filter for said suspended particles. Dissolving the packing in a suitable acid will leave a precious metal-rich residue behind for subsequent recovery. When the brine is treated this process, the useful life of injection wells used to return cooled brine back to the geothermal field is extended by at least about 3 times as compared to that observed with untreated brine.

RECOVERY OF PRECIOUS METALS FROM
AQUEOUS MEDIA

BACKGROUND OF THE INVENTION

1. Field of the Invention

5 This invention relates to the treatment of a hot aqueous brine solution containing various dissolved components, such as iron, silver and silica, to inhibit precipitation of undesirable scale, such as iron silicate scale, while enhancing deposition and recovery of a
10 valuable silver-containing scale. More particularly, the invention relates to such a treatment wherein the scale is formed in a geothermal brine which is being processed to recover its heat content and the brine is handled prior to injecting it back into a geothermal reservoir.

15 2. Description of Prior Art

 The solubility of most ions in solution decreases with a decrease in temperature or pressure of the solution. If dissolved ions are present near their saturation concentration in the solution, a slight reduction in
20 the temperature or pressure of the system can result in precipitation of a portion of these ions, which often combine and deposit as a scale on any solid surface with which they come into contact, such as the vessel or conduit in which the solution is confined.

25 One example of such a solution is a liquid stream containing hot water which is passed through a conduit in

an industrial operation under conditions, such as a lowering of the pressure, which flash at least a portion of the hot water to steam. If the hot water is a brine containing appreciable amounts of dissolved salts, this flashing is often accompanied by the formation of scale on the surface of the conduit contacted by the fluid stream. Scale deposits tend to build up over a period of time and restrict further fluid flow through the conduit requiring either operation at a reduced flow rate or an increase in the amount of power used to move the fluid through the conduit. In extreme cases, the conduit can become completely plugged with scale and the industrial operation must be shut down for maintenance. Industrial operations for generating steam power often are hampered by the buildup of scale deposits caused by flashing of hot water containing dissolved salts.

Geothermal steam and hot brines are found in naturally occurring, large subterranean reservoirs in many regions of the world. When hot geothermal fluids can be used to generate electric power, pressurized geothermal water or brine, having a temperature above about 400°F, is flashed to a lower pressure and the steam generated thereby drives a steam turbine in combination with an electric generator. However, formidable problems are generally encountered in handling and disposing of large amounts of heavily contaminated and frequently highly saline geothermal liquids. Consequently, production of

electricity from geothermal waters on a commercial scale has been difficult and costly to achieve.

One of the most serious problems encountered in using hot geothermal liquids for producing electric power results from scaling of the equipment used to confine and contain the liquid. Because geothermal liquids have usually been confined in subterranean reservoirs for extraordinarily long periods of time at elevated temperatures, large amounts of minerals are leached from the reservoirs into the brine. Typically, salts and oxides of heavy metals such as lead, zinc, iron, silver, cadmium and molybdenum, are found in geothermal brine. Other more common minerals, such as calcium and sodium, are also dissolved in the brine, as are naturally occurring gases, including carbon dioxide, hydrogen sulfide and methane. An especially troublesome component and the hot brine may be silica, which is found in large concentrations in the form of silicic acid oligomers. These tend to precipitate out at almost every stage of brine processing, either as substantially pure silica or as a tightly adherent iron-silica scale. If this scale is not removed, or prevented from forming, serious problems can arise with conduit plugging. Even when the brine has completed its passage through the plant, it typically retains some small amount of silica, which if not removed, will eventually result in the plugging of the injection wells used to return the now

cooled brine to the geothermal field.

Various proposals can be made to decrease the scale formation in equipment used in producing and handling geothermal brine. In "Field Evaluation of Scale Control Methods: Acidification," by J.Z. Grens et al, Lawrence Livermore Laboratory, Geothermal Resources Council, Transactions, Vol. 1, May 1977, there is described an investigation of the scaling of turbine components wherein a geothermal brine at a pressure of 220 to 320 p.s.i.g. and a temperature of 200° to 230°C. (392° to 446°F.) was expanded through nozzles and impinged against static wearblades to a pressure of 1 atmosphere and a temperature of 102°C. (215°F.) In the nozzles, the primary scale was heavy metal sulfides, such as lead sulfide, copper iron sulfide, zinc sulfide and cuprous sulfide. Thin basal layers of fine-grained, iron-rich amorphous silica promote adherence of the primary scale to the metal substrate. By contrast, the scale formed on the wearblades was cuprous sulfide, native silver and lead sulfide in an iron-rich amorphous silica matrix. When the brine which originally had a pH of 5.4 to 5.8 was acidified with sufficient hydrochloric acid to reduce the pH of the expanded brine to values between 1.5 to 5.0, scaling was eliminated. However, such acidification of hot brines increases the corrosion of the brine-handling equipment to such levels that it often defeats the purpose of using acid for scale control.

It is known to recover metal values and salts from

brine, such as geothermal brine produced from a subterranean reservoir. U.S. Pat. No. 4,127,989 to Michelson discloses a method in which brine is pressurized and maintained above the bubble point pressure and thereafter a precipitating agent, such as a soluble sulfide, is added to the brine to enhance formation of insoluble metal sulfide precipitates. Soluble salts and metals values are recovered from the brine effluent after the hot brine has been processed to recover energy therefrom. Silver sulfides among the mineral values recovered by this process.

While the aforementioned treatments have met with some success in particular applications, the need exists for a further improved treating process to better control the scaling process and to efficiently recover the mineral values in geothermal brines containing silver and/or other precious metals.

Accordingly, it is the object of this invention to provide an improved method for recovering valuable precious metal-containing scales from clarified geothermal brines, inhibiting the overall precipitation of scale, particularly iron-silicate scale, inhibiting corrosion, and polishing the fluid so as to prevent the transport of residual silica and other particulate material suspended therein to an injection well.

Other objects, advantages and features of the invention will be apparent from the following

description, drawings and appended claims.

SUMMARY OF THE INVENTION

The present invention provides a method for inhibiting the deposition of iron silicate and other scales from an aqueous fluid, such as a geothermal brine and polishing said fluid to remove suspended silica and/or other particulates therefrom, while promoting the recovery of silver and other precious metals in the brine.

10 In the present invention, a stream of pressurized hot water or brine solution, particularly a geothermal brine, containing precious metals such as silver, gold and platinum, trivalent metal ions, especially those of iron and manganese, together with silica species
15 dissolved or suspended therein, is first acidified with a water-soluble acid, which is added thereto in an amount sufficient to lower the pH of the aqueous solution, typically between about 0.1 and about 0.5 pH units, so that the pH of the overall solution is below, preferably
20 just below, about 5.0, and then passed through a conduit packed with one or more metals higher in the electromotive series than silver and preferably, higher than copper. At this pH, the overall formation of scale in the system, especially iron silicate, is inhibited,
25 while corrosion is minimized, with a substantial proportion of the precious metals in the brine precipitating out. The brine is preferably treated just

prior to being deep-well injected into the earth for disposal with the packing metal preferably being of a form adapted to act as a filter for any particles of scale suspended in the brine at the time of treatment.

5 When this is done, both corrosion and scale deposition in the piping and bore hole of the injection well are substantially reduced. The precious metals deposited on the packing may be recovered by a variety of methods. Where coiled steel wire is used as the packing medium, a

10 precious metal-rich scale may be recovered simply by dissolving the steel wire substrate in hydrochloric acid.

BRIEF DESCRIPTION OF THE DRAWING

The present invention will be more readily understood by reference to the drawing which depicts, in

15 diagram form, relevant portions of an exemplary geothermal brine production well and power plant with which the method of scale control of the present invention may be used to advantage.

DETAILED DESCRIPTION OF THE INVENTION

20 In producing and utilizing hot pressurized brine solutions which contain dissolved metal salts at or near their saturation concentration so that the pressure and/or temperature of the solutions are reduced, a portion of the metals salts can precipitate and deposit

25 as scale on the surfaces of the vessel or conduit

confining the brine. Examples of such hot pressurized brine solutions include geothermal brines and other brines used in a wide variety of industrial operations. A number of different types of scale can form depending on the nature and concentration of the metals in solution. However, the addition of acid into the system usually results in severe corrosion of the ferrous metals normally used in the manufacture of the confining vessels and conduits because the brine is usually at high temperature, for example, between 250° and 500°F. While corrosion inhibitors are known for most acids, these inhibitors do not function well under the severe temperature conditions of many systems. Thus the use of acid to dissolve such scale has been limited and most often is confined to systems employing corrosion resistant but expensive metals rather than the ferrous metals found in most industrial equipment.

The concentration of ferric and trivalent manganese ions, and silica species contributed by iron, manganese and silica containing minerals dissolved from the reservoir by the hot brine is normally high so that iron/manganese silicates are among the most pervasive and troublesome scales formed in the equipment used to handle and process geothermal brines. In particular, it is important that these and other heavy metal scale forming entities be removed so that, when the brine is injected back into the geothermal pool, scaling will not occur in the injection well. A failure to do so

often results in these entities being deposited in the well bore and greatly increasing the resistance to flow therein. However, the corrosion of ferrous metals caused by an excessive addition of acid to the system further
5 increases the concentration of ferric ions potentially available to form these scales. Therefore, any acid addition must be carefully monitored and controlled.

It has now been found that scale formation from brine can be reduced, precious metals recovery enhanced,
10 and silica and scale previously formed and still suspended in the brine can be removed, prior to deep-well injection of the brine by adding thereto a brine-soluble acid in an amount sufficient to lower the pH of the brine to below, preferably just below about 5.0, (i.e. to about
15 4.9), just prior to passing the brine through a conduit packed with one or more metals higher than silver, and preferably higher than copper. Typically, the processed brine has a pH such that the required pH reduction is
20 between about 0.1 and about 0.5 pH units. Generally, about 20 to about 180 weight parts per million of the water-soluble acid are required. Higher concentrations of the acid can interfere with the activity of certain of the reducing agents listed hereinafter. While any acid
25 used may be employed in concentrated form, it is common to employ aqueous solutions of such acids. For example, an aqueous solution containing about 13 per cent by weight hydrochloric acid is often used. Of course, when the brine solution already has a pH of about 4.9, further

acid addition may be omitted.

Brine-soluble acids suitable for use in this invention are inorganic mineral acids, organic carboxylic acids, mixtures thereof, and combinations of inorganic and organic acids. Mineral acids which may be used are hydrochloric, sulfuric, nitric and perchloric acid. Suitable organic carboxylic acids are those that forms water-soluble or acid-soluble salts of alkali metals and alkaline earth metals. Aromatic and aliphatic monocarboxylic, dicarboxylic and tribcarboxylic acids having about 1 to 6 carbon atoms can also be used. The carboxylic acids can be saturated or unsaturated and substituted or unsubstituted. When a substituted carboxylic acid is used, the common substituent is the chloride ion. For example, benzoic, formic, acetic, chloroacetic, peracetic, trichloroacetic, citric, oxalic and maleic acids can be used. The most preferred brine-soluble acid is hydrochloric acid.

To minimize the increased corrosion of ferrous metal components that tends to occur upon the addition of even small amounts of acid, a reducing agent may be added, usually in an amount slightly greater than that stoichiometrically required to reduce any trivalent iron and trivalent manganese cations contained in the fluid stream to divalent cations. As described in the Assignee's U.S. Pat. No. 4,765,888, dated July 12, 1988, the teachings of which are incorporated in their

entirety herein by reference, the reducing agent also acids in the reduction of scale by reducing the number of trivalent iron and manganese cations contributed to the brine during corrosion from the containing vessels and
5 conduits.

While the acid can be injected from source 60 downhole at producing formation 30 so as to lower the pH of the brine as close as is practical to its origin, the pH of the brine usually increases further as it passes
10 through power plant 10, for example, as non-condensable gases are removed at separators 12 and 14, and as the brine is flashed in vessel 16. Thus, it is preferred to inject further quantities of the acid into the brine flow to reduce scaling in places where significant pH
15 increases otherwise occur. By so doing, a more uniform brine treatment may be achieved. Alternatively, the amount of brine treatment may be varied according to the amount required at various locations.

While the acid treatment of this invention is
20 effective in reducing the occurrence of a wide variety of scales, of particular importance are metals silicate scales, especially iron-silicate scales. Such scales are believed to be formed first by the reaction of hydrated ferric oxyhydroxide with silicic acid oligomers, and then
25 subsequent condensation, as follows:

5 Further acidizing the already acidic geothermal
brine is believed to shift equilibrium conditions away
from the formation of a precipitate and/or to interfere
with the precipitation reaction involved. The hydrogen
ions (H+) added to the brine by addition of further acid
10 are believed to tie up the ferric oxyhydroxide and
thereby inhibit the indicated reaction of ferric
oxyhydroxide with silicic acid which forms insoluble
iron-rich silicates. The addition of reducing agents
capable of reducing trivalent iron and trivalent
15 manganese cations is believed to further inhibit the
formation of the precipitate by interfering with the
formation of ferric and other heavy metal oxyhydroxides.
However, regardless of the specific nature of the
reaction involved and the specific effects upon the
20 reaction of the acid and reducing agent, it has
nevertheless been demonstrated that the method of this
invention is effective in reducing the amount of iron-
silica scales deposited from geothermal brine and

preventing the plugging of injection wells, while inhibiting the corrosion of the metal vessels and conduits.

5 The application of the method of the present invention is illustrated in simplified form in the drawing which shows the relevant portions of an exemplary geothermal brine power plant 10. Comprising generally power plant 10 are first wellhead separator 12, second wellhead separator 14 and flash vessel 16. Shown includ-
10 ed in power plant 10 are glass cleaning means 18 and steam turbine generator 20. Associated with power plant 10, but not actually forming part thereof, are brine extraction well 28 and brine injection well 26. Extraction well 28 penetrates into earth 24 a depth " d_1 "
15 to brine producing formation 30 which has a thickness of " d_2 ". Ordinarily, injection well 26 is similar to extraction well 28, and may penetrate to the same producing formation 30.

In a preferred embodiment, the downhole apparatus
20 employed in the method of this invention includes anchor 72 attached to nozzle 70 by connecting rod or conduit 74. Anchor 72 helps maintain the position of nozzle 70 in well 28 during the injection of the acid down conduit 66. Conduit 66 can be a small diameter coiled tubing
25 extending several thousand feet down well 28 from wellhead 76, which in the absence of an anchor 72, may permit nozzle 70 to move about undesirably in well 28.

Anchor 72 helps maintain nozzle 70 adjacent to brine producing formation 30, the location where it is desired to inject the mixture of acid and reducing agent into the flow of geothermal brine. For convenience, anchor 72 may be positioned anywhere in the vicinity of nozzle 70. Since brine producing formation 30 is sometimes incompatible with systems operation, with respect to scaling, it is preferred to position anchor 72 in well 28 below producing formation 30 as shown in the drawing. Anchor 72 can be of any conventional design, for example, an anchor having three or more locking arms 78 which fold up independently as collars while anchor 72 is being lowered downhole. To set locking arms 78 against the formation when the desired depth is reached, conduit 66 is retracted a short distance so that the locking arms unfold. Later, when it is desired to remove nozzle 70 from the well, a stronger upward pull on conduit 66 shears a pin (not shown) in anchor 72, allowing locking arms 78 to collapse and the apparatus to be pulled out of well 28. Since the acid exits conduit 66 via nozzle 70, connecting rod or conduit 74 does not transport any fluid. The purpose of conduit 74 is merely to attach nozzle 70 firmly to anchor 72. Conduit is used in this embodiment to attach the anchor to the nozzle simply because conduit material is readily available and provides mechanical strength.

Since the portion of conduit 66 extending below wellhead 74 is exposed to the high temperature environment

of the geothermal fluid being produced, it is preferred that conduit 66 and nozzle 70 be made of a corrosion resistant metal, e.g., stainless steel, Hastelloy, Inconel, or the like. In operation, hot geothermal brine is introduced under pressure from extraction well 28 through conduit 32 into the side region of first separator 12.

This brine typically contains large quantities of dissolved and/or suspended silica. Consequently, to avoid plugging the brine handling system, the power plant may also include one or more clarifiers (not shown) to remove this silica from the brine as it progresses through the plant. In addition, there may also be secondary sand-filters or other clarifiers which are used as the brine exits the plant to remove any residual suspended silica and scale prior to injecting the now cooled brine back into the field through well 36. Such systems are shown in Assignee's U.S. Patent No. 4,728,438, dated March 1, 1988, the teachings of which are incorporated in their entirety herein by reference.

Within separator 12, non-condensable gases, including hydrogen sulfide, carbon dioxide and ammonia, are stripped out from the hot brine.

The effective pH of the brine as it enters well 28 from formation 30 is believed typically to be between about 4 and 4.5. However, due to removal of acidic non-condensable gases, the pH of the brine typically increases to between about 5 and 6 by the time it enters

flashing vessel 16. Ordinarily, as the brine enters well 28 from formation 30, flashing occurs to an extent causing release of about 1 to 1.5 percent of the steam contained in the brine, and by the time the brine reaches the top of well 28, additional flashing usually has occurred to an extent that between about 10 and 20 percent of the steam has been released. Brine temperature at producing formation 30 varies considerably from well to well, but is usually in the broad range of from about 350° to 600°F, with a brine temperature of between about 450° to 500°F. being typical of many localities.

At pH values above about 5.3, the formation of an iron/manganese-rich silica scale seems to be accelerated. To retard or even prevent the formation of such scale, a small amount of the water soluble acid is injected into brine conduits 32 and 40 through acid conduits 80 and 84. The amount of acid added is typically enough to maintain the pH of the brine in the range of about 5.0 to about 5.3. The non-condensable gases are discharged from the top of separator 12 through gas conduit 38 into gas cleaning means 18 and the brine is discharged from the bottom of separator 12 through conduit 40 into the side region of second separator 14, in which any remaining amounts of non-condensable gases are stripped from the brine. These remaining gases are discharged from separator 14 through gas conduit 42 into conduit 38, to be directed thereby into gas cleaning means 18. Included

in gas cleaning means 18 may be heat exchangers (not shown) which enable heat to be extracted from the hot non-condensable gases to create additional steam from steam condensate in a manner known to those skilled in the art.

From separator 14, the brine is discharged through conduit 44 into flashing vessel 16. Within flashing vessel 16, the brine is flashed to a substantially lower pressure, for example, from an initial pressure of about 450 p.s.i.g. to the lower pressure of about 50 p.s.i.g., so as to release steam being routed from vessel 16 through conduit 46 to steam turbine/generator 20. Condensate and/or steam are discharged from turbine/generator 20 through conduit 48 for disposal or for routing to exchanger portions of gas cleaning means 18. Flashed brine is discharged from flashing vessel 16 through conduit 54 to pump 56 which pumps the brine through conduit 58 into injection well 26. Alternatively, pump 56 may pump the brine to other means of disposal or to other uses (not shown).

In the present invention, any convenient means of introducing the acid and, when it is used, the reducing agent to the brine can be used. However, when an acid and reducing agent are selected which evolve gases (e.g., hydrochloric acid and zinc metal, hydrochloric acid and potassium cyanide), care should be taken to avoid evolution of gases during the mixing of the acid and

reducing agent, for example, by mixing the reducing agent upstream of the acid component or by mixing the reducing agent into a relatively dilute acidic solution. Usually, however, a mixture of acid and reducing agent is introduced from source 60, through conduit 62 containing valve 64 into conduit 66 which extends downwell 28, inside of well casing 68, terminating in nozzle 70 positioned approximately opposite brine producing formation 30.

Thus, in addition to being injected downhole, acid either alone, or in combination with a reducing agent, is typically injected at the following locations: (1) into brine conduit 32 between wellhead 76 and first separator 12 via conduit 80 containing valve 82; (2) into brine conduit 40 between first and second separators 12 and 14 via conduit 48 containing valve 86; (3) into brine conduit 44 between second separator 14 and flash vessel 16 via conduit 88 containing valve 90; and/or (4) into conduit 58 just upstream of injection well 26 via conduit 92 containing valve 94. Conduits 80, 84, 88 and 92 each are connected to acid source 60 (connections not shown), such additions tend to reduce, if not eliminate the formation of iron/manganese-silicate scale and, it is found that the scale which does form is much more tightly adhering than would otherwise be the case.

The location at which precious metals-containing scale will deposit also depends upon the type of scale-

reducing treatment used. In general, scale in geothermal systems forms when the brine is subjected to flashing or other scale-forming conditions wherein a supersaturated solution of dissolved solids forms in a liquid phase, followed by precipitation of scale. In the usual case, with unacidified brine, the constituents of the scale will deposit randomly in the brine handling equipment. Typically, after the brine has passed through all of the flashing, and clarification stages in a geothermal power plant, the residual brine received in conduit 58 for deep-well injection has a temperature of about 220°F., a pH of about 5.2, a suspended solids concentration between about 10 and about 20 ppm and a total dissolved solids content of about 270,000 to about 300,000 ppm, including a silver concentration of about 0.2 to about 1 ppm. Concentrations of gold and platinum, when detected, are typically in the ppb range.

The controlled recovery of the silver (and other precious metals such as gold and platinum, when present) from clarified brine can be accomplished when the brine is first acidified to a pH below 5.0, preferably about 4.9, and then passed through an agitation spool 96 which is packed with one of more metals at least higher in the electromotive series than silver, and preferably higher than copper, said spool being placed in conduit 58. To accomplish the secondary objective of filtering the brine stream to remove suspended silica and scale particles

therein, it is preferred that the packing have a relatively large surface-to-volume ratio without unduly impeding fluid flow in the conduit. To this end small (3/8 to 5/8 inch diameter) balls, flakes and coiled wire have all been found satisfactory, with coiled piano or "chicken" wire mesh being preferred. While at least some of the precious metals will also deposit out of a brine having a pH above about 5.0, it is found that acidifying the brine to have a controlled pH below about 5.0, just before it contacts the packing tends to enhance the effectiveness of said contacting and is therefore preferred. To this end, conduit 92 and valve 94 are provided for acid injection upstream of agitation spool 96. Of course if the brine in conduit 58 is already at a pH below 5.0 (an unusual occurrence) no acid need be injected at this time.

The higher electromotive series metals used for this purpose, in addition to having higher electromotive potentials than silver, are preferably essentially non-reactive when exposed to the acidified brine. Thus, metals such as magnesium and aluminum are normally found to be too reactive for this use. Metals which are suitable for purposes of this invention include steel and elemental metals such as zinc, iron, nickel, cobalt, cadmium, lead and copper (and suitable alloys thereof), with steel, zinc, and lead being preferred, steel and zinc being more preferred and zinc galvanized mild steel

being most preferred.

The agitation spool 76 preferably comprises a packed conduit sufficiently long to provide a residence time adequate for a substantial proportion, preferably
5 essentially all of the copper, silver and other precious metals therein to precipitate out. For a typical geothermal plant, this will be accomplished with a residence time in the range of 1 to about 10 minutes, e.g., up to about 5 minutes. However, as the precious
10 metal scales form on the packing and as other materials deposit, e.g., silica scale, iron/manganese scale and other particulates in the stream deposit thereon, the pressure drop across spool 76 will increase. Normally, the packing can be left in place until the pressure drop
15 across the packing become excessive, i.e., until about 50% or greater loss in pressure drop across the spool is observed.

The silver and other plated metals on the packing can be recovered by a variety of methods. For example,
20 iron or steel wire can be easily dissolved in hydrochloric acid, leaving a silver-rich residue which can be refined by conventional smelting operations. Where ball bearings are used, they can be cleaned by milling, with the removed scale being collected for
25 recovery, and the balls being recycled back into the process. In practice, it is recommended that a parallel system be employed so that, when one side is shut down

for cleaning, the other side can be utilized without stopping the operation of the geothermal facility.

5 In use, it is also found that the packing will also remove at least some of any suspended particulate matter, e.g., silicon containing scale, which may still be in suspension in the brine at this time. In a pilot plant run in which the discharge from the spool packed with small steel balls was passed through a 15-20 micron cartridge filter, no problems were observed after 120
10 hours of operation whereas a similar filter in a line without a packed spool, as hereinabove described, became completely plugged with solids and scale deposition in just 23 hours. Consequently, even through the amount of suspended materials is relatively low, the large volume
15 of brine typically handled in a megawatt geothermal facility will still carry an amount of suspended material with it which, in a relatively short period of time, will be sufficient to cause serious problems with well plugging.

20 Furthermore, the combination of acidifying the brine and then passing it through a packed agitation spool, as hereinabove described, polishes the brine reducing the concentrations of iron and other heavy metals therein. As a result, the deposition of heavy
25 metal-rich scale and nodules in the outlet piping and injection well is substantially reduced, with the result that the useful life of the injection well is extended by

anywhere from 3 to 5 times, or more, as compared to that observed with brine which is not treated as hereinabove described.

EXAMPLES 1 TO 10

5 A pilot plant test apparatus was set up and operated with clarified brine taken at a rate about 20 GPM from the overflow, at a temperature of about 220° F and pressure of about 100 PSI, in a series of tests, each test lasting for up to about 120 hours. For tests 1
10 through 6, as described below, the clarified geothermal fluid comprises of about 90 percent by weight brine and about 10 percent by weight steam as produced from a production well at a temperature of 455° F. and a pressure of 400 p.s.i.g. was used. The brine contained
15 about 251,000 weight parts per million of various elements dissolved therein: less than 0.3 aluminium, 0.2 silver, 1.0 antimony, 12.8 arsenic, 319 boron, 1,070 barium, 103 bromine, 1.2 cadmium, 25,000 calcium, 149,000 chlorine, 0.06 chromium, 12 cesium, 5.2 copper, 0.4
20 flourine, 459 iron, 5 iodine, 13,500 potassium, 1,770 lithium, 49 magnesium, 793 manganese, 50,000 sodium, less than 0.1 nickel, 81 lead, 73 rubidium, and less than 1 selenium, 200 silicon, 400 strontium, and 302 zinc.

 The apparatus utilized in the tests includes a
25 three inch conduit containing a portal for injecting the and acid along with a first corrosion/scale inspection

spool and a static mixing spool. The static mixer is a 12 inch section of conduit housing a helix formed of stainless steel through which the fluid is forced as it moves along the three-inch conduit to provide the turbulence needed to thoroughly mix the acid into the brine. The pH of the brine is measured above and below the acid mixing spool. The brine next enters an agitation spool packed with a metal higher in the electromotive series than silver for a distance of about 24 inches. After passing through the packed spool, the brine was (in some test) filtered through a cartridge filter and then exited the system through a second corrosion/scale inspection spool. The two corrosion/scaling spools are sections of conduit which hold conventional carbon steel corrosion strips to monitor the corrosiveness of brine upstream and downstream of the acid injection point. The second corrosion/scale spool was of a length sufficient to provide a total residence time of about 1 minute for the brine flowing through the test apparatus. At the exit from the simulated injection conduit the brine is normally at a temperature of about 220° F. In tests with acidified brine, sufficient concentrated hydrochloric acid is added to achieve and maintain a concentration of about 20 ppm, which was sufficient to lower the pH to about 4.9.

Scale buildup on the piping can be measured by gamma radiographic techniques employing an Iridium 92

source; the source and film plate being positioned on opposite sides of the area of interest. The differences in gamma absorption of the brine, scale and steel results in sufficient contrast to produce a radiograph from which projected thickness of scale can be measured. At the conclusion of each test, the packings were removed and inspected, with the results observed being discussed below and summarized in Table I.

Test 1. This was a baseline test in which the center spool was left empty and the total brine flow was 1.44 MMlb. Average suspended solids in the brine was 30 ppm upstream and 33 ppm downstream of the center spool. Scales deposited in the three spools consisted primarily of copper and iron with the center spool scale having a silver concentration of about 84 oz/ton,.

Test 2. The center spool which was packed with steel wool pads became completely plugged after about 2 hours of operation. Solids removed from the compacted pads were rich in copper and iron.

Test 3. Test 1 was repeated with the center spool being filled with 5/8 inch diameter carbon steel ball bearings of a size sufficient to increase the available scale deposition area by about a factor of 6 as compared to the unpacked spool and the run continued for 120 hours. At the conclusion of this time, the suspended solids had slightly increased from about 45 ppm upstream to about 52 ppm downstream. Although brine

analyses showed that the concentration of silver, antimony and copper were all reduced in center spool, the deposited scale on the balls was also rich in copper. iron and arsenic. The scale deposited on the balls had
5 silver, gold and platinum concentrations of about 408, 0.0.41 and 0.0035 oz/ton respectively. As seen in test 5 below, the silver recovered in this test was only about 46 percent of that recovered when the brine was acidified according to the present invention.

10 Test 4. Test 1 was repeated with the center spool being repacked with mossy zinc chips. The center spool completely plugged after about 4 hours of operation. Scale recovered from the zinc chips was primarily comprised to arsenic, copper and lead.

15 Test 5. Test 1 was repeated with the center spool being packed with a mixture of steel balls and mossy zinc chips and with the brine being acidified with hydrochloric acid. The center spool scaling rate was slightly higher than that observed in Test 1 while the
20 downstream scaling rate was considerably lower. The upstream suspended solids concentration was about 76 ppm while that down stream was only about 41 ppm, i.e., there was a substantial decrease. The silver, gold and platinum concentrations in the scale were 892, 0.0.008
25 and 0.0023 oz/ton respectively.

 Test 6. Test 1 was repeated with the center spool being repacked with coiled steel chicken wire mesh

galvanized with a layer of zinc on the surface thereof. While the rate of upstream scaling was basically similar to that in Test 1, the down stream rate was considerably lower. The wire collected approximately 2000 ppb of material with the average suspended solids being 52 ppb upstream and 78 ppb, i.e., suspended particle concentration increased. This may be due to small flakes of zinc and iron corrosion products spalling off during the test. The amount of silver, gold and platinum in the scale was 646, 0.008 and 0.0023 oz/ton respectively. Chicken wire mesh is cheap and, therefore, expendable. It can be sold directly to a metal reclaimer without any supplemental leaching or other chemical or mechanical cleaning operation being required.

Test 7. Test 6 was repeated with the brine being acidified with hydrochloric acid and with a cartridge filter being inserted between the packed spool and the downstream unpacked spool. This test run for the full 120 hours as compared to just 23 hours in a comparison test using just the filter alone. The concentration of silver, gold and platinum in the scale was 350, 0.004 and 0.014 oz/ton respectively. Although these results are lower than those observed with unacidified brine, an analysis of the clarified brine provided showed that the concentrations of precious metals therein were noticeably lower than was the case with test 1-6. Particulate concentrations were also very low (20 ppm) and the

downstream scaling was somewhat greater than that observed upstream. The deposit in the filter was mainly barite, silica and fluorite.

5 Test 8. Test 1 was repeated with the packing being lead wire. Scale deposition upstream of the lead wire was about the same as that observed downstream. The scale on the lead wire showed concentrations of 359, 0.002 and 0.016 oz/ton for silver, gold and platinum, respectively.

10 Test 9. Test 8 was repeated with the brine being acidified with hydrochloric acid. The silver recovery was only slightly lower than in test 8 and the remainder of the test results were essentially identical.

15 Test 10. Test 1 was repeated with the center spool being packed with copper wire. While the test run lasted the full 120 hours, the recovery of silver, gold and platinum was lower than that observed with the lead wire. From this, appears that the less noble the packing metal, the better the recovery of precious metals in the
20 brine. Scaling in both the upstream and downstream spools was essentially the same but the concentration of suspended material was slightly higher downstream. As reported in test 11 below, the amount of silver recovered was about 75 percent less than was recovered when the
25 brine was acidified according to the present invention.

 Test 11. Test 10 was repeated with the brine being acidified with hydrochloric acid. The amount of

silver recovered was considerably higher than in Test 10, but were still below the amounts recovered in either of the lead wire tests. As in Test 10 upstream and downstream scaling rates were about the same but the downstream concentration of suspended material was considerably higher than that observed upstream from the packing. Since the scale can be removed from the wire merely by twisting it, it appears that, with acidified brine, the scale does not adhere tightly to the packing wire, and the normal vibration of the system may be enough to knock some of it off during the displacement operation.

As noted in the above test description, the difference in the test results observed for tests 6 and 7 appears to be explainable by an unanticipated change in the brine source in the operating plant. At the beginning of these tests, the brine had a nominal pH of about 5.2 and a silver concentration of between about 2.2 and about 2.4 oz/MMlb of brine (0.14-0.20 ppmw). However, prior to the start of test 7 and continuing through test 11, the brine source was changed and the copper and precious metals content of the clarified brine were observed to be from 20 to almost 50 percent lower than before. It is also noted that the levels of suspended scale observed in these tests is on the order of about 50% lower as well. There is no explanation for this difference since the two brine sources are physically located near each other and were expected to

be substantially identical in composition. Consequently,
the difference in the test results observed when
unacidified and acidified brines were used, particularly
with ball bearings (tests 3 and 5), wherein the amount of
5 precious metals recovered was doubled when the brine was
acidified as described hereinabove and copper wire (tests
10 and 11), wherein it was tripled, should be considered
as showing more clearly the efficacy of acidifying the
brine prior to passing it into the agitation spool.

10 While particular embodiments of the invention have
been described, it will be understood that the invention
is not limited thereto since many obvious modifications
can be made. It is intended to include with this
invention any such modifications as will fall within the
15 scope of the appended claims.

TABLE I

5

COMPARISON OF TEST RESULTS USING A PACKED AGITATION SPOOL WITH ACIDIFIED AND UNACIDIFIED CLARIFIED GEOTHERMAL BRINES							
Example Number	Metal Packing	<u>Injection Brine Solids</u>		<u>Precious Metals Recovery</u>			
		Upstream	Downstream, ppm	Ag	Au	Pt (oz/ton)	
10	1	none	30	33	84		
	3	Mild steel ball bearings No acid	45	52	408	0.041	0.0035
15	5	Ball bearings with Zn chips and acid	76	41	892	0.008	0.0023
	6	Iron Chicken wire - no acid	52	78	646	0.008	0.0018
20	7*	Iron Chicken wire and acid	26	20	350	0.004	0.014
	8*	Lead wire No acid	29	26	359	0.002	0.016
25	9*	Lead wire and acid	34	29	350	0.003	0.017
	10*	Copper wire No acid	21	28	83	0.002	>0.001
	11*	Copper wire and acid	22	37	318	0.001	0.019
30	* Different brine source. See explanation in text.						

26502

WE CLAIM:

1. A method for treating a feed brine containing suspended and dissolved scale forming constituents, at least some of which comprise silicon containing components and some of which comprise one or more recoverable metals selected from the group consisting of copper and metals below copper in the electromotive series, said method comprising passing the brine at an elevated temperature and pressure and a pH below about 5.0 through a conduit packed with one or more metals higher in the electromotive series than copper for a time sufficient for a substantial portion of the recoverable metals and a substantial portion of the the silicon-containing scale components to precipitate onto said packing, with the brine received from said packed conduit containing trivalent metal cations.
2. The method of claim 1 further comprising adding thereto an amount of a brine soluble acid or acid precursor sufficient to lower the pH of the brine to a pH below about 5.0.
3. The method of claim 2 wherein said brine soluble acid is an inorganic mineral acid selected from the group consisting of hydrochloric, sulfuric, nitric and perchloric acids or an organic carboxylic acid selected from the group consisting of substituted and unsubstituted aromatic and aliphatic monocarboxylic, dicarboxylic and tricarboxylic acids having from about 1

to about 6 carbon atoms and the water-soluble or acid-soluble alkali metals and alkaline earth metal salts thereof.

4. The method of claim 2 wherein said acid is
5 hydrochloric acid.

5. The method of claim 1 wherein said recoverable metal is one or more metals selected from the group consisting of copper, silver, gold and platinum.

6. The method of claim 1 wherein said recoverable
10 metal is silver.

7. The method of claim 1 wherein said recoverable metals are copper and silver.

8. The method of claim 1 wherein said higher electromotive series metal is selected from the group
15 consisting of steel, zinc, iron, nickel, cobalt, cadmium, lead, and alloys thereof.

9. The method of claim 1 wherein the form of said metal packing is selected from the group consisting of coiled piano wire, coiled chicken wire mesh, small balls
20 and flakes.

10. The method of claim 1 wherein said metal packing is steel chicken wire mesh galvanized with a layer of zinc on the surface thereof.

11. The method of claim 1 wherein said metal packing is
25 steel piano wire.

12. The method of claim 1 wherein said brine is clarified to remove excess silica therefrom before being

passed through said packed conduit.

13. The method of claim 1 wherein the residence time of said brine in said packed conduit is up to about 5 minutes.

5 14. The method of claim 1 further comprising operating until a substantial pressure drop is observed across said packed conduit, removing said packing from said conduit and recovering the recoverable metals deposited thereon.

10 15. The method of claim 1 further comprising removing said packing from said conduit when the pressure drop across said packed conduit reaches a level of about 50 percent and recovering a precious metals-rich residue therefrom.

15 16. The method of claim 14 comprising dissolving said removed packing in an acid.

17. The method of claim 1 wherein the pH of said brine is in the range between about 4.5 and about 5.0 when it enters said packed conduit.

20 18. The method of claim 1 wherein the pH of said brine is about 4.9 just before it enters said packed conduit.

19. The method of claim 1 further comprising adding a reducing agent to said brine prior to its entering into said packed conduit.

25 20. The method of claim 1 wherein said brine is a geothermal brine.

21. The method of claim 1 wherein said brine is injected into a deep well after it leaves said packed

conduit.

22. The method of claim 1 wherein the temperature of said brine is no more than about 220° F. at the time it enters said packed conduit.

5 23. The method of claim 1 wherein said brine further contains trivalent iron ions dissolved therein.

24. The method of claim 1 wherein said brine further contains trivalent manganese ions dissolved therein.

10 25. The method of claim 1 wherein said brine further contains trivalent iron and trivalent manganese ions dissolved therein.

26. The method of claim 1 wherein said silicon-containing component comprises silica.

15 27. The method of claim 1 wherein said silicon-containing component comprises silica with trivalent iron.

28. The method of claim 1 wherein said silicon-containing component comprises silica, trivalent iron and trivalent manganese.

20 29. The method of claim 1 wherein the amount of recoverable metals found on said packing is at least about double that which would be observed with an unacidified brine.

25 30. The method of claim 1 wherein the amount of recoverable metals found on said packing is at least about triple that which would be observed with an unacidified brine.

31. A method for treating an aqueous geothermal fluid

at an elevated temperature and pressure, said geothermal fluid containing trivalent iron and manganese cations suspended particles comprising iron and manganese silicate and silica, and one or more dissolved precious metals selected from the group consisting of silver, gold, and platinum, said method comprising the steps of adding acid to lower the pH of the fluid by between about 0.1 and about 0.5 pH units, passing said acidified fluid through a conduit packed with a coiled steel chicken wire mesh having a layer of zinc deposited thereon for a time sufficient to cause a substantial amount of the precious metals and at least some of said suspended particles therein to deposit thereon but insufficient to reduce all of said trivalent iron and manganese cations, removing said packing and dissolving it with a suitable acid to recover a precious metal-rich residue therefrom containing at least about twice the amount of precious metals as compared to that observed without said adding step.

32. The method of claim 31 wherein the step of lowering the pH of said brine comprises adding thereto a water soluble acid selected from the group consisting of hydrochloric, sulfuric, nitric and perchloric acids, an organic carboxylic acid selected from the group consisting of substituted and unsubstituted aromatic and aliphatic monocarboxylic, dicarboxylic and tricarboxylic acids having from about 1 to about 6 carbon atoms and the

water-soluble or acid-soluble alkali metal and alkaline earth metal salts thereof, and mixtures thereof, in an amount sufficient to lower the pH to below 5.0.

5 33. The method of claim 32 wherein said acid is hydrochloric acid.

34. The method of claim 31 wherein said brine is clarified to remove excess silica therefrom before being passed through said packed conduit.

10 35. The method of claim 31 wherein the residence of time of said brine in said packed conduit is up to about 5 minutes.

36. The method of claim 31 further comprising operating until a substantial drop is observed across said packed conduit.

15 37. The method of claim 31 wherein the pH of said brine is between about 4.7 and about 5.0 when it enters said packed conduit.

38. The method of claim 31 wherein the pH of said brine is about 4.9 just before it enters said packed conduit.

20 39. The method of claim 31 further comprising adding a reducing agent to said brine prior to its entering into said packed conduit.

40. The method of claim 31 wherein the amount of precious metals found on said packing is at least about
25 triple that which would be observed when said geothermal fluid is passed through said conduit under the aforesaid method except without said step of lowering the pH.

41. The method of claim 21 wherein the useful life of said deep injection well is increased by a factor of at least about 3 times longer than would be observed with injecting a brine in the absence of pH lowering and passing through said packing.

42. The method of claim 31 wherein said brine is injected into deep well after it leaves said packed conduit.

43. The method of claim 42 wherein the useful life of said deep injection well is at least about 3 times longer than would be observed when said geothermal fluid is injected under the aforesaid method for except without said steps lowering the pH and passing said brine through said packing.

44. The method for extending the useful lifetime of an injection well used to recieve a feed brine containing suspended and dissolved scale forming constituents, at least some of which comprise silicon containing components and some of which comprise one or more recoverable metals selected from the group consisting of copper and metals below copper in the electromotive series, said method comprising passing the brine at an elevated temperature and pressure and a pH below about 5.0 through a conduit packed with one or more metals higher in the electromotive series than copper for a time sufficient for a substantial portion of the silicon containing scale components to precipitate

onto said packing, with the brine received from said packed conduit containing trivalent metal cations and less suspended particulate material than the feed brine so that the useful life of the well is extended by at least three times as compared to that observed without said passing step.

45. The method of claim 44 further comprising adding thereto an amount of a brine soluble acid or acid precursor sufficient to lower the pH of the brine to a pH below about 5.0.

46. The method of claim 45 wherein said brine soluble acid is an inorganic mineral acid selected from the group consisting of hydrochloric, sulfuric, nitric and perchloric acids or an organic carboxylic acid selected from the group consisting of substituted and unsubstituted aromatic and aliphatic monocarboxylic, dicarboxylic and tricarboxylic acids having from 1 to about 6 carbon atoms and the water-soluble or acid-soluble alkali metals and alkaline earth metal salts thereof, and combinations of said inorganic and organic acids.

47. The method of claim 45 wherein said acid is hydrochloric acid.

48. the method of claim 44 wherein said recoverable metal is one or more metals selected from the group consisting of copper, silver, gold and platinum.

49. The method of claim 44 wherein said higher

electromotive series metal is selected from the group consisting of steel, zinc, iron, nickel, cobalt, cadmium, lead and alloys thereof.

50. The method of claim 44 wherein the form of said metal packing is selected from coiled piano wire, coiled chicken wire mesh, small ball and flakes.

51. The method of claim 44 wherein said brine is clarified to remove excess silica therefrom before being passed through said packed conduit.

52. The method of claim 45 wherein the useful life of the injection well is extended by at least about five times.

53. A method for treating an aqueous geothermal fluid at an elevated temperature and pressure, said geothermal fluid also containing dissolved and/or suspended materials comprising precious metal and silicon components, said method comprising the steps of:

lowering the pH of the fluid to below about 5.0;
and passing said lower pH fluid through a conduit packed with a wire mesh causing some of said materials to deposit on said mesh and wherein said passed fluid comprises trivalent metal cations.

54. The method of claim 53 which also comprises the step of injecting said passed fluid to an injection well.
