A code division multiple access (CDMA) mobile communication system with improvements to permit stable reception with a minimum of bit error. The system comprises a voltage-controlled oscillator for supplying a carrier to a radio frequency quadrature demodulator, and a frequency controller for detecting a frequency error from a phase correction signal of the first step to generate a control signal that controls the oscillator. The frequency controller includes an extracting circuit and an integrating circuit. The extracting circuit extracts a phase change based on the frequency error derived from the phase correction signal of the first step and outputs a signal that can be used to determine a predetermined delay time. The integrating circuit integrates the phase change to obtain the integrated result as the control signal. The predetermined delay time is preferably set within a range not exceeding the delay time needed for averaging by an averaging circuit that receives the phase correction signal of the first step and outputs a phase correction signal. The carrier to a radio frequency quadrature modulator is preferably supplied from the voltage-controlled oscillator.

BACKGROUND OF THE INVENTION

The present invention relates to a mobile communication system operating on what is known as the code division multiple access (CDMA) system.

The CDMA system involves multiplexing a plurality of communication channels using spread spectrum codes, each channel being assigned a different spread spectrum code. A given signal to be transmitted is multiplied (i.e., spread) by the spread code assigned to the own channel, and is multiplexed with other similarly spread signals on different channels before being transmitted. At a receiver, the multiplexed signals are multiplied (i.e., despread) by the same spread code so that only the target signal will be extracted correlated on the own channel. The signals on the other channels are perceived merely as noise because these signals with their different spread codes remain uncorrelated. The level of the noise may be sufficiently lowered so as not to disturb the signal reception. The CDMA system is attracting attention as a system fit for drastically improving the efficiency of frequency utilization and has been commercialized in some areas.

Where CDMA communication is implemented using spread codes, some kind of signal modulation (e.g., quadrature phase shift keying or QPSK) precedes the spreading of the signal for transmission. At a receiving point, the despreading of the signal is followed by demodulation. Despreading and demodulation both represent the detection process whereby the transmitted signal is reconstructed. Commonly used detection methods include a coherent detection method based on the PLL (phase locked loop) circuit and a differential detection method. There also exists a recently proposed coherent detection method that utilizes pilot signals.

Where the CDMA system is applied to a mobile communication system adopting the conventional coherent detection method, the bit error rate of data in a mobile station deteriorates if a fading occurs while the station is moving. In a CDMA mobile communication system utilizing the differential detection method, the bit error rate of data in a mobile station can worsen due to the noise on the air transmission channel even if the station is stationary. The pilot signal-based coherent detection method has been proposed for a system to minimize the deterioration of the bit error rate whether the mobile station is in motion or at rest. The method was discussed at the Autumn 1994 Symposium of the Institute of Electronics, Information and Communication Engineers of Japan as disclosed in the IIECE collection of papers B-5 on radio communication systems A and B, p. 306, “Coherent detection for CDMA Mobile Communication Systems” by Yasuo Ohgosho et al.

Described below is a conventional mobile communication system that uses pilot signals with reference to the above-cited paper supplemented by some details. The description will first center on the down link of the system (i.e., a link from the base station to a mobile station). FIG. 13 shows a modulation circuit 51 of a base station 1 that transmits data and a first half 52 of the detection circuit of a mobile station 2. The base station 1 actually transmits signals to a plurality of mobile stations 2, and FIG. 13 shows one station as the representative example.

In the modulation circuit 51 (left-hand half of FIG. 13), data first undergoes QPSK modulation, not shown, to divide into an in-phase signal I and a quadrature signal Q. The signals I and Q are spread (i.e., multiplied) respectively by spread code signals PN_ID and PN_QD. The two spread code signals are supplied from a spread code generator 91. The rates of the spread code signals PN_ID and PN_QD (called the chip rates) are used to multiply by k (k: spreading ratio) the pre-spread rates (called the symbol rates) of the signals I and Q so that the latter will attain the chip rates. The signals thus spread pass through a radio frequency quadrature modulator 54 to become mutually perpendicular signals that are transmitted on a radio frequency band from an antenna. A temperature compensated crystal oscillator 61 is provided to furnish the modulator 54 with a carrier C_b.

The pilot signals will now be described. The transmission circuit is substantially the same as the left-hand half of FIG. 13 and is omitted. An in-phase signal IP and a quadrature signal Q_P of the pilot signals are spread respectively by spread code signals PN_ID and PN_QD. Both spread code signals have the same chip rate as in the case of data. The pilot signals thus spread are subject to radio frequency quadrature modulation by the same carrier C_b and a carrier C_b as with data, turning into mutually perpendicular signals transmitted on the same radio frequency band as with data. The pilot signals serve as reference signals for demodulation and are common to all channels utilized.

In the first half 52 (right-hand half of FIG. 13) of the detection circuit of the mobile station 2, the received signals from the antenna (data and the pilot signals) pass through a radio frequency quadrature demodulator 57 to reach a low-pass filter 56. The low-pass filter 56 removes the radio frequency components from the signals to yield signals S_I and S_Q. A crystal oscillator 60 supplies the demodulator 57 with a carrier C_b. The signals S_I and S_Q are composed of the spread signals I and Q (those destined to the own channel as well as to other channels) and of the spread pilot signals I_P and Q_P. As such, the signals S_I and S_Q include a phase error caused by fading and a frequency error attributable to the precision of the oscillator 60.

The errors included in the signals S_I and S_Q produce a phase difference therein. When the mutually perpendicular pilot signals are plotted in orthogonal coordinates, the received pilot signals are rotated exactly by the phase shift, as shown in FIG. 14. If the phase shift is represented by φ and the orthogonal coordinates after quadrature demodulation are designated by X_i and Y_i, then the coordinate axes X and Y of the received signals are rotated by φ displacing the pilot signals. Consequently, the undispersed signals I and Q that should have resulted with no phase shift become i_1 and q_1, respectively. Such changes are caused by the mixing of one of the two mutually perpendicular signals into the other signal. The phenomenon is expressed by the following formulas:

\[ i_1 = i \cos \phi - q \sin \phi \]
\[ q_1 = i \sin \phi + q \cos \phi \]

The pilot signals are signals that stay constant following the despreading. Generally, i_1 and q_1. The signal changes into i_1, and q_1, permit acquisition of a signal CS with the value cos φ and a signal SN with the value sin φ. With the
two signals known, it is possible to correct the phase rotation of the data. Since the data includes the same phase shift, the despread data signals are inversely rotated by φ using the signals CS and SN whereby the initial signals I and Q are correctly reconstructed. Thus the signals CS and SN serve as phase correction signals.

The signals S_I and S_Q output by the first half 52 of the detection circuit are subject to despreadings and phase correction by the second half of the detection circuit shown in FIG. 15. A pilot signal despreads unit 21 in the upper left portion of FIG. 15 despreads the signals S_I and S_Q by use of the spread code signals PN_{-2P} and PN_{-2P} from a spread code generator 25, whereby the pilot signals are extracted. The extracted pilot signals are then added and subtracted mutually, becoming a signal CS_P with a chip rate of cos φ and a signal SN_P with a chip rate of sin φ. The two signals are converted to the symbol rates by an accumulator 41 and thereby turn into phase correction signals CS_P and SN_P of the preliminary stage. The phase correction signals are averaged by an averaging circuit 43 for noise reduction. The averaging provides the phase correction signals CS and SN of the final stage.

FIG. 16 shows a typical circuit constitution of the averaging circuit 43. Reference numerals 430 through 433 are delay gates (Ds) for delaying a signal by a one-symbol period each. In this example, three consecutive symbol values are averaged when added up by adders 235 and 236. It is through this noise reduction arrangement that the phase correction signals CS and SN are obtained. The delay time (average delay time) T required for the averaging by the averaging circuit 43 is given as

\[ T = Ds(N-1)/2 \]

where N denotes the number of symbols used for the averaging operation.

The data signals S_I and S_Q are both despreads by an inverse data spreading unit 42 (bottom left in FIG. 15) using the spread code signal PN_{+2P} for the signal I and the spread code signal PN_{+2P} for the signal Q. The operation causes four signals to be extracted. The four chip rate signals are converted by an accumulator 44 into symbol rates to become signals D_I through D_Q. After this, the signals D_I through D_Q are each delayed by a data delaying unit 48 (FIG. 17) by the average delay time T of the averaging circuit 43. The operation yields signals D_{I0} through D_{Q0}. Where the data delaying unit 48 is constituted by a number of delay gates (Ds) in stages of cascade connection each gate providing one-symbol period delay, the gate count M per stage is given as

\[ M = (N-1)/2 \]

In the above example, N=3 and thus M=1, so that the delay gates 480 through 483 of the data delaying unit 48 are each composed of a one-symbol delay gate (Ds). The signals D_{I0} through D_{Q0} are fed to a phase correction circuit 49 in which the signals are corrected in phase rotation by use of the correction signals CS and SN. A typical constitution of the phase correction circuit 49 is shown in FIG. 18. The phase correction circuit 49 performs phase correction as follows: the signals D_{I0} and D_{Q0} are multiplied by the correction signal CS and the signals D_{I0} and D_{Q0} by the correction signal SN. The multiplied results are added and subtracted mutually so as to rotate the orthogonal axes of the received data by -φ in phase (i.e., the phase shift φ is reduced to zero in FIG. 14). The phase correction provides reconstructed signals I_P and Q_P of the original signals I and Q. The signals I_P and Q_P then undergo QPSK demodulation, not shown, to become the original data.

One disadvantage of the conventional detection circuit above is that the restored signals I_P and Q_P are unavoidably affected by the frequency precision of the crystal oscillator 60 (right-hand side in FIG. 13). A transmitter 60 used in the mobile station necessarily includes a certain practical frequency error because the mobile station is for use by general users. That is, on the one hand, if the frequency error involved in the data is large enough to cause apparent phase irregularities over the average delay time T during data demodulation, no precise correction signals can be acquired and the bit error rate of the detected data worsens. On the other hand, if the average delay time T is shortened to avert the deterioration of the bit error rate, the adverse effects of the frequency error are diminished but the line noise becomes more pronounced.

On the up link (i.e., a link from the mobile station to the base station), the carrier C_M from the crystal oscillator 60 often doubles as a carrier for use in radio frequency quadrature modulation by the modulation circuit of the mobile station. In that case, the signals transmitted by the mobile station and received by the base station include both the phase error caused by fading and the frequency error originating from the crystal oscillator. The frequency error results in the inevitable deterioration of the bit error rate in the detection process of the base station.

The deficiencies above are conventionally circumvented, particularly where data of lower bit rates than normal are transmitted, by the method of burst data transmission with no change in the spreading ratio, as stipulated by the U.S. digital radio communication standard IS (Interim Standard)-95. Under the system, transmitting data at 1/r of the standard bit rate compresses the data to 1/r in temporal terms. The time-compressed data is transmitted in bursts at fixed intervals.

How the burst signals are sent intermittently is illustrated in FIG. 19. In FIG. 19, the axis of abscissa represents time and the axis of ordinate denotes transmission power. Reference numeral 140 is a radio signal waveform of standard bit rate data. Reference numerals 141, 142 and 143 stand respectively for radio signal waveforms of data at 1/2, 1/4 and 1/8 of the standard bit rate. The number of burst signals varies with the bit rate. All burst signals have the same standard bit rate when temporally compressed as described. It follows that every burst signal has the same symbol rate and thus the spreading ratio remains unchanged.

The arrangements above are necessitated by the following reasons: if compression is not carried out, the one-symbol period gets longer the lower the data rate. Meanwhile, the number of symbols N for use by the averaging circuit 43 (FIG. 15) in the demodulation circuit remains substantially the same regardless of the bit rate in view of noise reduction. Thus the average delay time T becomes longer the lower the data rate. A prolonged delay time T prompts the frequency error to deteriorate the bit error rate as discussed above. The lower the bit rate, the more deteriorated the bit error rate. To avoid this deficiency requires keeping the symbol rate constant. The requirement necessitates the use of complicated circuits in the mobile station, which runs counter to the inherent need for the mobile station to simplify its circuitry.

SUMMARY OF THE INVENTION

It is therefore an object of the present invention to overcome the above and other deficiencies and disadvantage of the prior art and to provide an improved CDMA mobile communication system permitting stable signal reception with a minimum of bit error.
In carrying out the invention and according to one aspect thereof, there is provided a CDMA mobile communication system including a mobile station comprising a voltage-controlled oscillator and a frequency controller. The voltage-controlled oscillator acts as a circuit to supply a carrier to a radio frequency quadrature demodulator. The frequency controller detects a frequency error from a phase correction signal of the first step and uses the detected frequency error as the basis for generating a control signal for use by the oscillator. The frequency controller may illustratively be composed of two circuits: a circuit for detecting a phase change caused by the frequency error derived from the phase correction signal of the first step and from a signal preceding the correction signal by a predetermined delay time; and an integrating circuit for integrating the phase change and outputting the result as the above control signal.

The voltage-controlled oscillator and the frequency controller operate to establish within the detection circuit of the mobile station a control loop whereby the phase change is reduced substantially to zero. This minimizes the frequency error. Because the frequency of the oscillator is kept as precise as that of the oscillator of the base station, the phase shift attributable to the frequency error is significantly reduced. This provides a detection circuit that works stably with a minimum of bit error.

The predetermined delay time may preferably be set within a range not exceeding the delay time needed for the averaging operation by the averaging circuit which admits the phase correction signal of the first step and outputs a phase correction signal.

The carrier to a radio frequency quadrature modulator may preferably be supplied by the voltage-controlled oscillator. Because the frequency of the radio signal sent to the base station is kept accurate, the base station is allowed to implement pilot signal-based coherent detection stably with a minimum of bit error. Where the mobile station transmits data at a low bit rate, the system allows the terminal to keep the chip rate of the spread code constant and to transmit data with varying spreading ratios but without time compression. Such data transmission is readily implemented by changing the circuit constant in keeping with the symbol rate of the data, with no change in the circuit constitution.

These and other objects and many of the attendant advantages of the invention will be readily appreciated as the same becomes better understood by reference to the following detailed description when considered in connection with the accompanying drawings.

**BRIEF DESCRIPTION OF THE DRAWINGS**

FIG. 1 is a circuit diagram of a CDMA mobile communication system based on a CDMA detection circuit and practiced as a first embodiment of the invention;

FIG. 2 is a schematic view showing a pilot signal as it is related to data in a signal transmitted by the base station of the first embodiment;

FIG. 3 is a circuit diagram of the second half of the detection circuit in a mobile station of the first embodiment;

FIG. 4 is a circuit diagram of a frequency controller used by the first embodiment;

FIG. 5 is a circuit diagram of another frequency controller for use by the first embodiment;

FIG. 6 is a schematic view depicting a pilot signal as it is related to data in a signal transmitted by the mobile station of the first embodiment;

FIG. 7 is a circuit diagram of the second half of the detection circuit in the base station of the first embodiment;

FIG. 8 is a schematic view illustrating pilot signals as they are related to data in a signal transmitted by the mobile station of the first embodiment;

FIG. 18 is a circuit diagram of a phase correction circuit in the second half of the detection circuit and;

FIG. 19 is a schematic view depicting data transmission by the conventional mobile station.

**DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS**

Preferred embodiments of the invention relating to a CDMA mobile communication system will now be described in detail with reference to the accompanying drawings. In FIGS. 1 through 12, the component parts with their functionally identical or equivalent counterparts included in the prior art examples of FIGS. 13 through 18 are designated by like reference numerals.

**First Embodiment**

FIG. 1 is a circuit diagram showing the overall constitution of a CDMA mobile communication system practiced as the first embodiment of the invention. The base station, which transmits data usually to a plurality of mobile stations, is shown sending data to a single mobile station in FIG. 1.

In the left-hand half of FIG. 1, reference numeral 1 is a base station; 51 is a modulation circuit; 91 is a spread code generator; 54 is a radio frequency quadrature modulator; 61 is a temperature compensated crystal oscillator; 58 is a circulator for separating a transmitted radio signal from a received radio signal; 12 is the first half of a detection circuit; 62 is a radio frequency quadrature demodulator; and 64 is a low-pass filter. Reference characters I and Q are in-phase component signal and a quadrature signal respectively; P, and P are spread code signals for the signals I and Q respectively; S, and S, are in-phase component signal and an opposite-phase component signal, respectively, subject to the spreading of the output of the detection circuit first half 12; C, is a carrier output by the oscillator 61; and 55 is an air transmission channel.

In the right-hand half of FIG. 1, reference numeral 2 is a mobile station; 52 is the first half of a detection circuit; 59 is a circulator for separating a received radio signal from a transmitted radio signal; 57 is a radio frequency quadrature demodulator; 56 is a low-pass filter; and 63 is a voltage-controlled oscillator. Reference characters C, stand for a carrier output by the oscillator 63, and AFC for a control
signal for controlling the frequency of the oscillator 63. Reference numeral 70 denotes a frequency controller for generating the control signal AFC. Reference characters CS₂ and SN₂ stand for phase correction signals of the first step, to be described later; and S₁ and S₀ for an in-phase component signal and an opposite-phase component signal subject to the spreading of the output of the detection circuit first half 52. Reference numeral 61 is a demodulation circuit; 25 is a spread code generator; and 66 is a radio frequency quadrature modulator. Reference characters I₁ and Q₁ represent an in-phase component signal and a quadrature component signal, respectively, of the data transmitted by the mobile station to the base station; and PN₋₀ and PN₋₀₋₀ denote spread code signals for the signals I₁ and Q₁, respectively, output by the generator 25.

Described below is the case in which the base station 1 transmits data and a pilot signal over a down link to the mobile station 2. The modulation circuit 51 is substantially the same in constitution as its conventional counterpart in FIG. 13. The data to be transmitted passes through a QPSK modulator, not shown, to become signals I and Q. The signals I₀ and Q₀ are spread by use of the spread codes PN₋₀ and PN₋₀₋₀. The spread signals are turned by the radio frequency quadrature modulation circuit 54 into mutually perpendicular radio frequency band signals that are transmitted from an antenna past the circulator 58. The temperature compensated crystal oscillator 61 supplies the modulator 54 with the carrier Cₚ.

Although not shown, an in-phase signal I₁₀ and a quadrature signal Q₁₀ of the pilot signals are spread respectively by spread code signals PN₋₀₋₀ and PN₋₀₋₀₋₀. Both spread code signals have the same chip rate as in the case of data. The pilot signals thus spread are subject to radio frequency quadrature modulation by the same carrier Cₚ as with data. Following the modulation, the signals turn into mutually perpendicular signals transmitted on the radio frequency band as with data.

FIG. 2 schematically shows a radio frequency band signal transmitted by the base station 1. In FIG. 2, reference numeral 92 is a radio frequency band signal representing the pilot signal, and 93 is a radio frequency band signal that carries data. Data 2 in the signal 93 is destined to the mobile station 52; data 1 and 2 are directed to other mobile stations. The data signals 1 and 2 are each spread by a different spread code Cₚ₁₀ signal.

The data and pilot signals are thus transmitted on the same radio frequency band and received by the mobile station 2 (right-hand half of FIG. 1). The received signals are fed to the radio frequency quadrature demodulator 57 past the circulator 59. The output of the demodulator 57, from which the low-pass filter 56 removes the spurious part, becomes the signals S₁ and S₀. The voltage-controlled oscillator 63 supplies the demodulator 57 with the carrier Cₚ₁₀.

The signals S₁ and S₀ are despread and phase-corrected by the second half of the detection circuit. This yields restored signals I₁₀ and Q₁₀ originating from the initial signals I₁ and Q. FIG. 3 is a circuit diagram of the second half of the detection circuit in the mobile station. The output terminals of the accumulator 41 are connected to the input terminals of the frequency controller 70 which is fed thereby with the phase correction signals CS₂ and SN₂ of the first step. Except for these connections, the setup of FIG. 3 is the same as that of the conventional circuit in FIG. 15. The component parts having their functionally identical or equivalent counterparts included in the prior art examples will not be described further.

The oscillator 63 (in the right-hand half of FIG. 1) is a known circuit using a variable capacitance diode (not shown) as the element to determine the oscillation frequency. The diode has its capacitance changed when fed with the control signal AFC whereby the oscillation frequency is controlled.

The frequency controller 70 that outputs the control signal AFC works as follows: a phase shift of Δφ is detected as a phase change of about one-symbol period stemming from the frequency error of the oscillator 63. The sine component (sin Δφ) of the phase shift is fed to an integrator so that the latter will output the control signal AFC. FIG. 4 shows the circuit constitution of the frequency controller 70. In FIG. 4, reference numerals 700 and 701 are delay gates (Dₕ) having a delay time of one-symbol period each, 705 and 706 are multipliers, 707 is a subtractor, 708 is a multiplier, and 709 is an integrator.

The signals CS₂ and SN₂ are delayed by the delay gates 700 and 701. The multiplier 706 multiplies the signal SN₂ by a signal succeeding the signal CS₂ by one symbol. The multiplier 705 multiplies the signal CS₂ by a signal succeeding the signal SN₂ by one symbol. The subtractor 707 subtracts the product of the multiplier 706 from that of the multiplier 705, yielding an error signal SNA having a value of sin Δφ. If Δφ is approximately equal to Δφ₀, the error signal SNA having the value of sin Δφ is multiplied by the multiplier 708 to provide a predetermined loop gain. The multiplied result is integrated by the integrator 709 that produces the control signal AFC.

The controller 70, oscillator 63 and radio frequency quadrature demodulator 57 in FIG. 1 as well as the despread unit 21 and accumulator 41 in FIG. 3 constitute a control loop in which the integrator 709 integrates the signal SNA so that the latter will approach zero. This arrangement inhibits the frequency error and keeps the frequency of the oscillator in the mobile station as accurate as that of the oscillator in the base station.

The phase change Δφ is also caused by the phase error attributable to fading. However, the fading-triggered phase change is generally very slow and thus quite small compared with the change caused by frequency error. For a period of one symbol or thereabout, there is practically no harm in assuming that the change Δφ is caused solely by frequency error.

The example explained above is one in which the processing of the controller 70 is carried out in a one-symbol period. If the frequency error is very small during the one-symbol period, it is possible to perform the processing of the controller 70 over a period involving a plurality of consecutive symbols. In this case, the period must not exceed the average delay time T for the averaging circuit 43 (FIG. 16).

Conversely, if the frequency error is relatively large during the one-symbol period, the processing needs to be carried out at a speed higher than the symbol rate. FIG. 5 shows a circuit diagram of an alternative frequency controller 70 performing its processing more quickly than the symbol rate. In FIG. 5, reference numerals 710 and 711 are abstract code circuits, 712 and 713 are delay gates with their delay time shorter than the one-symbol period, 714 and 715 are exclusive-OR gates, and 718 is an integral calculus. The abstract code circuits 710 and 711 extract the signs (plus or minus) from the signals CS₂ and SN₂ respectively. The extracted signs indicate a quadratic movement of the pilot signal coordinates caused by the phase shift φ, as shown in FIG. 14. For example, if the phase shift falls within a range of 180 degrees, the receiving point moves into the third quadrant, and the signals CS₂ and SN₂ have the minus signs. The abstract code circuits 710 and 711 recog-
nize the absence of frequency error (flag “0”) if the signals have the plus signs, or the presence of frequency error (flag “1”) if the signals have the minus signs. The flags “0” and “1” are output as sign signals “cos-flag” and “sin-flag” respectively.

The sign signal “cos-flag” and the sign signal “sin-flag” that has passed the delay gate 713 are fed to the gate 714. The sign signal “sin-flag” and the sign signal “cos-flag” that has passed the delay gate 712 are supplied to the gate 715. The output signals of the gates 714 and 715 are sent to the integral calculators 718. If the gate 714 outputs “1”, then the integrator 718 outputs as the control signal AFC a voltage that raises the frequency of the oscillator 63; if the gate 715 outputs “1”, the integrator 718 outputs as the control signal AFC a voltage that lowers the reference frequency. Where the processing needs to be performed faster than the symbol rate, as in this example, it is possible to implement a high-speed frequency controller that dispenses with multipliers carrying out time-consuming multiplications.

The voltage-controlled oscillator 63 and the two kinds of frequency controller 70 may each be constituted by a known semiconductor integrated circuit. Thus constituted, the inverter described is incorporated advantageously in mobile stations for use by general users.

Returning to Fig. 1, what follows is a description of the case in which the mobile station 2 transmits data and pilot signals over an up link to the base station 1. The data to be transmitted undergoes QPSK modulation (not shown) to become signals $I_1$ and $Q_1$ (bottom right in Fig. 1). The signals $I_1$ and $Q_1$ are spread by the spread code signals $P_{NO}$ and $P_{NQ}$ from the spread code generator 25. The signals thus spread pass through the radio frequency quadrature demodulator 62 past the carrier $C_m$ and are supplied to the carrier $C_m$.

In transmitting the pilot signal to the base station 1, the mobile station 2 multiplexes the signal with the data on a time-division basis. According to this method, the signals $I_1$ and $Q_1$ make up a signal form having the data and pilot signals multiplexed therein. The data and pilot signals are both spread by the spread code signals $P_{NO}$ and $P_{NQ}$. Fig. 6 shows a radio frequency band signal multiplexed in the manner described. In Fig. 6, reference numeral 94 is a pilot signal part, and 95 is a data part.

The signal received by the antenna of the base station 1 is sent to the radio frequency quadrature demodulator 62 past the carrier 58 in the first half 51 of the detection circuit (bottom left in Fig. 1). The output signal of the demodulator 62, from which the low-pass filter 64 removes the spurious part, turns into signals $S_{I1}$ and $S_{Q1}$. The demodulator 62 is supplied with the carrier $C_m$ from the oscillator 61. The signals $S_{I1}$ and $S_{Q1}$ are subject to despreading and phase correction in the second half of the detection circuit, to be described later. The despreading and phase correction processes provide the reconstructed signals $I_{SR}$ and $Q_{SR}$ originating from the initial signals $I_1$ and $Q_1$.

FIG. 7 is a circuit diagram of the second half of the detection circuit in the base station 1. In Fig. 7, reference numeral 80 is a received signal despreading unit; 91 is a spread code generator; 82 is an accumulator; 83 is a phase correction signal extracting unit that extracts phase correction signals $S_{CQ}$ and $S_{CN}$ of the first step; 84 is an averaging circuit that receives the signals $S_{CQ}$ and $S_{CN}$ from the extracting unit 83 and outputs phase correction signals $S_C$ and $S_N$; 85 is a data extracting unit that extracts the data part from the signal converted to the symbol rate; 103 is a data delaying unit that delays the extracted data by the average delay time of the averaging circuit 84; and 88 is a phase correction circuit that rotates in phase the data from the delaying unit 103 and outputs the signals $I_{SR}$ and $Q_{SR}$.

The received signal despreading unit 80 despreads each of the received signals $S_{I1}$ and $S_{Q1}$ using the two spread code signals $P_{NO}$ and $P_{NQ}$ from the spread code generator 91. The four chip rate signals thus obtained are converted by the accumulator 82 into symbol rate signals $A_1$ through $A_4$. The phase correction signal extracting unit 83 is supplied with the sum of the signals $A_1$ and $A_4$ (including the cosine component of the pilot signal) on the one band, and with the difference between the signals $A_2$ and $A_3$ (including the sine component of the pilot signal) on the other. The extracting unit 83 extracts only the pilot signal part from the time-division multiplexed signals so as to output the phase correction signals $S_{CQ}$ and $S_{CN}$ of the first step. The averaging circuit 84 averages a plurality of symbols of the signals $S_{CQ}$ and $S_{CN}$ to output the phase correction signals $S_C$ and $S_N$ for use in data phase rotation.

The signals $A_1$ through $A_4$ are also sent to the data extracting unit 85. The extracting unit 85 extracts only the data part from the time-division multiplexed signals through the four-signal data thus obtained is forwarded to the data delaying unit 103. The delaying unit 103 delays each of the received four signals and outputs data $D_{101}$ through $D_{104}$. The circuit constitution of the phase correction circuit 88 is the same as that shown in Fig. 17.

With the first embodiment, the values of phase rotation by the correction signals $S_C$ and $S_N$ are set as indicated below. Fig. 8 shows the received signal structured in units of symbols. In Fig. 8, a pilot signal of h symbols and a data signal of j symbols are alternately received. Initially, the averaging circuit 84 averages the h symbols of a pilot signal 96 and the h symbols of a pilot signal 100. The averaging operation determines phase rotation quantities of $\phi1$ and $\phi2$. The amount of phase rotation per symbol of data 99 is given as

$$\phi1(1-s)+\phi2(s)$$

where s stands for the s-th symbol (s=1—j). In this manner, the phase rotation is accomplished while the pilot signals preceding and succeeding the data part are taken into consideration. This requires delaying the current data with the ensuing pilot signal is received. Thus the average delay time, i.e., the delay time of the delaying unit 103, is determined as the j-symbell period of the data 99 supplemented by the h-symbol period of the pilot signal 100.

Where the up link described above is in effect, the radio frequency quadrature modulator 66 (bottom right in Fig. 1) of the mobile station 2 is supplied with the carrier $C_m$ output and kept precise by the voltage-controlled oscillator 63. This allows the base station 1 to avoid the problem of frequency error and to implement stable detection. That in turn makes it possible to adopt a spreading circuit that keeps the chip rate of the spread code constant where the mobile station transmits data at a bit rate lower than the standard rate. Since it is assumed to represent the spreading ratio in effect when the data bit rate is standard, the spreading ratio is changed to $\beta/k$ where the bit rate is $1/\beta$ ($0 \leq 1$) of the standard bit rate. Fig. 9 shows transmitted signals of different bit rates. In Fig. 9, the axis of abscissa represents time and the axis of ordinate denotes transmission power. Reference numeral 160 is a signal that transmits data at the standard bit rate with a spreading ratio of $k$; 161 is a signal that transmits data at $1/2$ of the standard bit rate with a spreading ratio of 2 $k$, powered by $1/2$ of the power level for the standard bit rate;
A signal that transmits data at ¼ of the standard bit rate with a spreading ratio of 4 k, powered by ⅛ of the standard power level; and 136 is a signal that transmits data at ¼ of the standard bit rate with a spreading ratio of 8 k, powered by ⅛ of the standard power level. In transmitting data at such different bit rates, the first embodiment implements CDMA communication by varying the circuit constant in keeping with the bit rate but without changes in the circuit constellation.

Second Embodiment

Described below is the second embodiment of the inventive CDMA mobile communication system in which a plurality of mobile stations are assigned different spread codes for their pilot signals, each mobile station transmitting the pilot signal using the assigned spread code over an up link to the base station. Data is transmitted by use of the modulation circuit 11 shown in the right-hand half of FIG. 1. Although not shown, an in-phase signal and a quadrature signal of the pilot signals are spread respectively by spread code signals having the same chip rate as in the case of data. The pilot signals thus spread are subject to radio frequency quadrature modulation by the same carrier Cg as with data. Having undergone the modulation, the signals thus enter mutually perpendicular signals transmitted on the same radio frequency band as with data.

FIG. 10 schematically shows radio frequency band signals transmitted by the mobile station 2. In FIG. 10, reference numeral 96 is a radio frequency band pilot signal, and 97 is a radio frequency band data signal. The pilot signal is transmitted at a power level lower than the data signal. The transmitted signals are received by the base station 1 constituted by the first half of the detection circuit 12 in the bottom left portion of FIG. 1 and by a circuit having the same construction as the second half of the detection circuit in FIG. 3.

The modulation circuit 11 in the mobile station 2 utilizes the carrier Cg kept precise for radio frequency quadrature modulation. This allows the base station 1 to circumvent the problem of frequency error and to implement stable detection.

Third Embodiment

Described below is the third embodiment of the inventive CDMA mobile communication system which derives the phase correction signals of the first step from the phase rotation changes of data, with no use of pilot signals for frequency control. With the third embodiment, the data to be transmitted from the base station 1 is subject to BPSK (binary phase shift keying) modulation. Signals Ip and Qp are acquired through the BPSK modulation. The modulation circuit of the base station 1 and the first half of the detection circuit in the mobile station 2 in connection with the signals Ip and Qp are the same as those shown in FIG. 1. The second half of the detection circuit in the mobile station 2 is illustrated in FIG. 11. In FIG. 11, reference numeral 45 represents a temporary judge circuit. Reference characters CSp, and SNe_p denote input signals to the temporary judge circuit 45, and CSq_p and SNe_q indicate phase correction signals of the first step output by the temporary judge circuit 45.

The data despreadings unit 42, spreading code generator 25, accumulator 44, averaging circuit 43, data delaying unit 48, phase correction circuit 49 and frequency controller 70 in FIG. 11 are the same in function as their counterparts of the first embodiment in FIGS. 3 and 4. The signals CSq and SNe are supplied to the frequency controller 70 generating the control signal AFC for the voltage-controlled oscillator 63 (FIG. 1). The signals CSq and SNe are also fed to the averaging circuit 43 that generates phase correction signal CSq and SNe.
mobile station 2 is allowed to realize data transmission with an appropriate spreading ratio selected.

Although the first through the third embodiments adopt QPSK or BPSK modulation upstream of the spreading process, this is not limiting of the invention. The invention is not dependent on the pre-spread modulation scheme because the invention aims to keep precise the carrier for radio frequency modulation and demodulation. Any system of pre-spread modulation may be adopted in conjunction with the invention. The invention, when suitably embodied, promises stable operation in both coherent detection and differential detection.

According to the invention, the pilot signal acquired from despreading is used to detect frequency error, and the frequency of the carrier is controlled so as to reduce the detected frequency error to zero. This allows the mobile station to implement stable detection with a minimum of bit error. Since the same carrier is used in radio frequency quadrature modulation, the base station is allowed to realize stable detection with reduced bit error. When the mobile station is to transmit data at a low bit rate, an appropriate spreading ratio may be selected in accordance with the bit rate. This arrangement averts the process of keeping the spreading ratio constant—a process that complicates circuitry. The features above make it possible to implement a more practical CDMA mobile communication system of higher performance than ever before.

It is further understood by those skilled in the art that the foregoing description pertains to preferred embodiments of the disclosed system and that various changes and modifications may be made in the invention without departing from the spirit and scope thereof.

What is claimed is:

1. A mobile station for use with a mobile communication system multiplexing a plurality of communication channels using spread spectrum codes, comprising:
   a radio frequency demodulator demodulating a radio frequency band signal transmitted from a base station by use of a signal from said oscillator;
   a spreading circuit spreading a data signal to be transmitted;
   a radio frequency modulator modulating said spread data signal by use of a signal from said oscillator, wherein an oscillation frequency of the oscillator is controlled by use of a change of phase shift detected using a signal representing a phase shift detected from the demodulated radio frequency band signal transmitted from the base station.

2. The mobile station according to claim 1, wherein said spreading circuit spreads the data signal to be transmitted with a spreading ratio according to a bit rate of said data signal.

3. The mobile station according to claim 2, wherein a spread code for spreading the data signal has a constant chip rate.

4. The mobile station according to claim 1, further comprising:
   a despreading circuit despreading the demodulated radio frequency band signal.

5. The mobile station according to claim 4, wherein said despreading circuit extracts a pilot signal by despreading the demodulated radio frequency band signal using the spread spectrum code assigned to the pilot signal, and wherein the phase shift is detected from the extracted pilot signal.

6. A method for transmitting a data signal in a mobile station for use with mobile communication system multiplexing a plurality of communication channels using spread spectrum codes, comprising the steps of:
   demodulating a received radio frequency band signal transmitted from a base station by use of a signal from an oscillator;
   spreading a data signal to be transmitted; and
   modulating said spread data signal by use of a signal from the oscillator, wherein an oscillation frequency of the oscillator is controlled by use of a change of phase shift detected using a signal representing a phase shift detected from the demodulated radio frequency band signal transmitted from the base station.

7. The method for transmitting a data signal according to claim 6, wherein the spreading circuit spreads the data signal to be transmitted with a spreading ratio according to a bit rate of said data signal.

8. The method for transmitting a data signal according to claim 7, wherein a spread code for spreading the data signal has a constant chip rate.

9. The method for transmitting a data signal according to claim 6, further comprising the step of:
   despreading the demodulated radio frequency band signal.

10. The method for transmitting a data signal according to claim 6, further comprising the step of:
    extracting a pilot signal by despreading the demodulated radio frequency band signal using the spread spectrum code assigned to the pilot signal, wherein the phase shift is detected from the extracted pilot signal.

11. A method for detecting a data signal by a mobile station for use with mobile communication system multiplexing a plurality of communication channels using spread spectrum codes, comprising the steps of:
    demodulating a received radio frequency band signal transmitted from a base station by use of a signal from an oscillator;
    detecting a phase shift from the demodulated radio frequency band signal; and
    controlling an oscillation frequency of the oscillator according to a change of the phase shift.

12. The method for detecting a data signal according to claim 11, further comprising the step of:
    extracting a pilot signal by despreading the demodulated radio frequency band signal using the spread spectrum code assigned to the pilot signal, wherein the phase shift is detected from the extracted pilot signal.
