(54) Title: COLOR TUNABLE LIGHT EMITTING DEVICE

Fig. 1A

Fig. 1B

Fig. 1C

(57) Abstract: A color/color temperature tunable light emitting device comprises: an excitation source (LED) operable to generate light of a first wavelength range and a wavelength converting component comprising a phosphor material which is operable to convert at least a part of the light into light of a second wavelength range. Light emitted by the device comprises the combined light of the first and second wavelength ranges. The wavelength converting component has a wavelength converting property (phosphor material concentration per unit area) that varies spatially. The color of light generated by the source is tunable by relative movement of the wavelength converting component and excitation source such that the light of the first wavelength range is incident on a different part of the wavelength converting component and the generated light comprises different relative proportions of light of the first and second wavelength ranges.

COLOR TUNABLE LIGHT EMITTING DEVICE

CLAIM OF PRIORITY

[0001] U.S. Patent Application No. 11/906,532 entitled COLOR TUNABLE LIGHT
5 EMITTING DEVICE, by James Caruso *et al.*, filed October 1, 2007 (Attorney Docket No. ITMX-00228US0).

BACKGROUND OF THE INVENTION

[0002] 1. Field of the invention

10 [0003] This invention relates to color/color temperature tunable light emitting devices and in particular to solid state light sources, such as light emitting diodes, which include a wavelength converting phosphor material to generate a specific color of light.

[0004] 2. Description of the Related Art

[0005] The color of light generated by a light source, in particular light emitting diodes
15 (LEDs), is determined predominantly by the device architecture and materials selection used to generate the light. For example, many LEDs incorporate one or more phosphor materials, which are photo-luminescent materials, which absorb a portion of the radiation emitted by the LED chip/die and re-emit radiation of a different color (wavelength). This is the state of the art in the production of "white" LED light sources. The net color of light generated by such
20 LEDs is the combined native color (wavelength) of light from the LED chip and color re-emitted by the phosphor which is fixed and determined when the LED light is fabricated.

[0006] Color switchable light sources are known which comprise red, green and blue LEDs. The color of light output from such a source can be controlled by selective activation of one or more of the different colored LEDs. For example, activation of the blue and red
25 LEDs will generate light which appears purple in color and activation of all three LEDs produces light which appears white in color. A disadvantage of such light sources is the complexity of driver circuitry required to operate these sources.

[0007] US 7,014,336 discloses systems and methods of generating colored light. One lighting fixture comprises an array of component illumination sources (different color LEDs)
30 and a processor for controlling the collection of component illumination sources. The processor controls the intensity of the different color LEDs in the array to produce illumination of a selected color within a range bounded by the spectra of the individual LEDs and any filters or other spectrum-altering devices associated with the lighting fixture.

[0008] White LEDs are known in the art and are a relatively recent innovation. It was
35 not until LEDs emitting in the blue/ultraviolet part of the electromagnetic spectrum were developed that it became practical to develop white light sources based on LEDs. As taught

for example in US 5,998,925, white light generating LEDs ("white LEDs") include one or more phosphor materials, that is photo-luminescent materials, which absorb a portion of the radiation emitted by the LED and re-emit radiation of a different color (wavelength). Typically, the LED chip or die generates blue light and the phosphor(s) absorb a percentage of the blue light and re-emits yellow light or a combination of green and red light, green and yellow light or yellow and red light. The portion of the blue light generated by the LED that is not absorbed by the phosphor is combined with the light emitted by the phosphor and provides light which appears to the human eye as being nearly white in color.

[0009] As is known, the correlated color temperature (CCT) of a white light source is determined by comparing its hue with a theoretical, heated black-body radiator. CCT is specified in Kelvin (K) and corresponds to the temperature of the black-body radiator which radiates the same hue of white light as the light source. The CCT of a white LED is generally determined by the phosphor composition and the quantity of phosphor incorporated in the LED.

[0010] White LEDs are often fabricated by mounting the LED chip in a metallic or ceramic cup using an adhesive and then bonding lead wires to the chip. The cup will often have a reflecting inner surface to reflect light out of the device. The phosphor material, which is in powder form, is typically mixed with a silicone binder and the phosphor mixture is then placed on top of the LED chip. A problem in fabricating white LEDs is variation of CCT and color hue between LEDs that are supposed to be nominally the same. This problem is compounded by the fact that the human eye is extremely sensitive to subtle changes in color hue especially in the "white" color range. A further problem with white LEDs is that their CCT can change over the operating lifetime of the device and such color change is particularly noticeable in lighting sources that comprise a plurality of white LEDs such as LED lighting bars.

[0011] To alleviate the problem of color variation in LEDs with phosphor wavelength conversion as is described above, in particular white LEDs, LEDs are categorized post-production using a system of "bin out" or "binning." In binning, each LED is operated and the actual color of its emitted light measured. The LED is then categorized or binned according to the actual color of light the device generates, not based on the target CCT with which it was produced. Typically, nine or more bins (regions of color space or color bins) are used to categorize white LEDs. A disadvantage of binning is increased production costs and a low yield rate as often only two out of the nine bins are acceptable for an intended application resulting in supply chain challenges for white LED suppliers and customers.

[0012] It is predicted that white LEDs could potentially replace incandescent, fluorescent and neon light sources due to their long operating lifetimes, potentially many hundreds of

thousands of hours, and their high efficiency in terms of low power consumption. Recently high brightness white LEDs have been used to replace conventional white fluorescent, mercury vapor lamps and neon lights. Like other lighting sources, the CCT of a white LED is fixed and is determined by the phosphor composition used to fabricate the LED.

5 [0013] US 7,014,336 discloses systems and methods of generating high-quality white light, which is white light having a substantially continuous spectrum within the photopic response (spectral transfer function) of the human eye. Since the eye's photopic response gives a measure of the limits of what the eye can see this sets boundaries on high-quality white light having a wavelength range 400nm (ultraviolet) to 700nm (infrared). One system
10 for creating white light comprises three hundred LEDs each of which has a narrow spectral width and a maximum spectral peak spanning a predetermined portion of the 400 to 700 nm wavelength range. By selectively controlling the intensity of each of the LEDs the color temperature (and also color) can be controlled. A further lighting fixture comprises nine LEDs having a spectral width of 25 nm spaced every 25 nm over the wavelength range. The
15 powers of the LEDs can be adjusted to generate a range of color temperatures (and colors as well) by adjusting the relative intensities of the nine LEDs. It is also proposed to use fewer LEDs to generate white light, provided each LED has an increased spectral width to maintain a substantially continuous spectrum that fills the photopic response of the eye. Another lighting fixture comprises using one or more white LEDs and providing an optical high-pass
20 filter to change the color temperature of the white light. By providing a series of interchangeable filters this enables a single light fixture to produce white light of any temperature by specifying a series of ranges for the various filters. Whilst such systems can produce high-quality white light such fixtures are too expensive for many applications due to the complexity of fabricating a plurality of discrete single color LEDs and due to the control
25 circuitry required for operating them.

[0014] A need exists therefore for a color tunable light source that overcomes the limitations of the known sources and in particular an inexpensive solid state light source such as an LED which includes a wavelength converting phosphor material, whose color and/or
30 CCT of light emission is at least in part tunable.

SUMMARY OF THE INVENTION

[0015] The present invention arose in an endeavor to provide a light emitting device whose color is at least in part tunable. Moreover, the present invention, at least in part,
35 addresses the problem of color hue variation of LEDs that include phosphor wavelength conversion and attempts to reduce or even eliminate the need for binning. A further object of

the invention is to provide an inexpensive color tunable light source compared with multi-colored LED packages.

[0016] According to the invention there is provided a color tunable light emitting device comprising: an excitation source, such as a LED, that is operable to generate light of a first wavelength range and a wavelength converting component comprising at least one phosphor material which is operable to convert at least a part of the light into light of a second wavelength range, wherein light emitted by the device comprises the combined light of the first and second wavelength ranges, wherein the wavelength converting component has a wavelength converting property that varies spatially and wherein color of light generated by the source is tunable by a relative movement of the wavelength converting component and excitation source such that the light of the first wavelength range is incident on a different part of the wavelength converting component. A particular advantage of the light emitting device of the invention is that since its color temperature can be accurately set post-production this eliminates the need for expensive binning. As well as the manufacturer or installer setting the color/color temperature a user can periodically adjust the color/color temperature throughout the lifetime of the device or more frequently for "mood" lighting.

[0017] The wavelength converting component can be moveable relative to the excitation source and can have a wavelength converting property that varies: along a single dimension, along two dimensions or rotationally. The wavelength converting properties of the component can be configured to vary by a spatial variation in a concentration (density) per unit area of the phosphor material. Such a variation can comprise a spatial variation in thickness of the at least one phosphor material such as a thickness that varies substantially linearly. In one arrangement, the at least one phosphor is incorporated in a transparent material, such as an acrylic or silicone material, with a concentration of phosphor material per unit volume of transparent material that is substantially constant and the thickness of the wavelength converting component varies spatially. An example of one such component is wedge-shaped and has a thickness that tapers along the length of the component. In an alternative arrangement the wavelength converting component comprises a transparent carrier on a surface of which the phosphor material is provided. In a preferred implementation, the phosphor material is provided as a spatially varying pattern, such as for example a pattern of dots or lines of varying size and/or spacing, such that the concentration per unit area of the at least one phosphor material varies spatially. In such an arrangement the thickness and concentration of the phosphor material can be substantially constant. The phosphor material can be deposited on the carrier using a dispenser to selectively dispense the phosphor material or printed using screen printing.

[0018] The wavelength converting component can further comprise a second phosphor

material which is operable to convert at least a part of the light of the first wavelength range into light of a third wavelength range, such that light emitted by the device comprises the combined light of the first, second and third wavelength ranges and a concentration per unit area of the second phosphor material varied spatially.

5 **[0019]** The light emitting device can further comprise a second wavelength converting component comprising a second phosphor material which is operable to convert at least a part of the light of the first wavelength range into light of a third wavelength range, wherein light emitted by the device comprises the combined light of the first, second and third wavelength ranges wherein the second wavelength converting component has a wavelength
10 converting property that varies spatially and wherein color of light generated by the source is tunable by moving the first and second wavelength converting components relative to the excitation source such that the light of the first wavelength range is incident on different parts of the first and second wavelength converting components. Preferably, the first and second wavelength converting components are independently moveable with respect to one another
15 and to the excitation source. Such an arrangement enables color tuning over an area of color space.

[0020] As in the first wavelength converting component the concentration of the second phosphor per unit area can vary spatially with, for example, a variation in phosphor thickness or a variation in a pattern of phosphor material.

20 **[0021]** In a further embodiment of the invention there is provided a color tunable light emitting device comprising: a plurality of light emitting diodes operable to generate light of a first wavelength and a wavelength converting component which is operable to convert at least a part of the excitation radiation into light of a second wavelength, wherein light emitted
25 by the device comprises the combined light of the first and second wavelength ranges and wherein the wavelength converting component comprises a plurality of wavelength converting regions comprising at least one phosphor material in which a respective region is associated with a respective one of the light emitting diode and wherein each region has a wavelength converting property that varies spatially and wherein color of light generated by
30 the device is tunable by moving the component relative to the light emitting diodes such that the light of the first wavelength range from each light emitting diode is incident on a different part of its respective wavelength converting region.

[0022] In one arrangement the plurality of light emitting diodes comprises a linear array and the wavelength converting regions comprise a corresponding linear array and the source
35 is tunable by linearly displacing the component relative to the array of light emitting diodes. Alternatively, the plurality of light emitting diodes comprise a two dimensional array and the

wavelength converting regions comprise a corresponding two dimensional array and wherein the source is tunable by displacing the component relative to the array of light emitting diodes along two dimensions.

5 [0023] In a yet further arrangement, the plurality of light emitting diodes comprise a circular array and the wavelength converting regions comprise a corresponding circular array and the device is tunable by rotationally displacing the component relative to array of light emitting diodes.

BRIEF DESCRIPTION OF THE DRAWINGS

10 [0024] In order that the present invention is better understood embodiments of the invention will now be described, by way of example only, with reference to the accompanying drawings in which:

[0025] Figures 1(a) to (c) are schematic representations of the principle of operation of a color tunable light emitting device in accordance with the invention;

15 [0026] Figure 2 is a CIE (Commission Internationale de l'Eclairage) 1931 chromaticity diagram illustrating color tuning for the device of Figure 1;

[0027] Figures 3(a) to (f) are schematic representations of the operation of a color tunable light emitting device in accordance with a further embodiment of the invention;

20 [0028] Figure 4 is a CIE 1931 chromaticity diagram illustrating color tuning for the light source of Figure 3;

[0029] Figure 5 is a schematic representation of a wavelength converting component in accordance with the invention;

[0030] Figures 6(a) to (d) are schematic representations of the operation of a color tunable light emitting device in accordance with a further embodiment of the invention;

25 [0031] Figure 7 is a CIE 1931 chromaticity diagram illustrating color tuning for the light source of Figure 6;

[0032] Figures 8(a) to (c) are representations of a color temperature tunable white light emitting lighting bar in accordance with the invention;

30 [0033] Figure 9 is a schematic representation of a color temperature tunable white light emitting device in accordance with a further embodiment of the invention in which the wavelength converting component is rotatable; and

[0034] Figure 10 is a schematic representation of a color tunable light emitting device in accordance with a further embodiment of the invention in which the wavelength converting component is movable in two directions.

DETAILED DESCRIPTION OF THE INVENTION

[0035] Embodiments of the invention are based on a wavelength converting component that has a wavelength converting property (characteristic) that varies spatially and which is used to convert light from an excitation source, typically a light emitting diode (LED), which is of one wavelength range (color) into light of a different wavelength range (color). The color of light generated by the device, which comprises the combined light of the first and second wavelength ranges, can be controlled (tuned) by moving the component relative to the excitation source to change the total proportion of light of the second wavelength range.

[0036] Referring to Figures 1(a) to (c) there are shown schematic representations of the principle of operation of a color tunable light emitting device 10 in accordance with the invention. The device 10 comprises an excitation source 12 operable to generate excitation radiation 14 (light) of wavelength range λ_1 and a moveable wavelength converting component 16. Typically, the excitation source 12 comprises a light emitting diode (LED) such as an InGaN/GaN (indium gallium nitride/gallium nitride) based LED chip which is operable to generate blue light of wavelength 400 to 465nm.

[0037] In the example embodiment illustrated, the wavelength converting component 16 is tapered in form (wedge-shaped) and tapers in thickness between thicknesses t and T along its direction 18 of intended movement. The wavelength conversion component 16 can be fabricated from a transparent substrate material, for example an acrylic or silicone material such as GE's RTV615, which incorporates a phosphor (photo luminescent or wavelength converting) material. As is known, phosphor materials absorb excitation radiation (light) of a first wavelength and re-emit light of a longer wavelength λ_2 , for example green in color. The phosphor material, which is in powder form, is substantially uniformly distributed throughout the acrylic material and has a weight ratio loading of phosphor to acrylic in a typical range 5 to 50% depending on the intended color range of operation of the light device 10. Since the phosphor material is uniformly distributed throughout the component, that is the concentration of phosphor per unit volume of substrate material is substantially constant, and the component varies in thickness along its length, the quantity of phosphor per unit area (grams per square meter - g/m^2) varies in a linear manner along the length of the component. In other words the wavelength converting component 16 has a wavelength converting property (characteristic) that varies along its length.

[0038] As represented in Figure 1, a light blocking element 20 is provided to confine the area of incidence of the excitation radiation (blue light) 14 to a small portion of the wavelength converting component 16. In preferred implementations, the LED chip 12 is packaged in a ceramic or metallic housing and the wavelength converting component mounted in close proximity, or even in sliding contact with, the housing opening. In such an

arrangement the housing walls function as the light blocking element. To optimize the overall efficiency of the device, the inner surface of the housing walls 20 are preferably highly reflective.

[0039] Operation of the device 10 will now be described by way of reference to Figures 1(a) to (c) and Figure 2 which is a CIE (Commission Internationale de l'Eclairage) 1931 chromaticity diagram illustrating color tuning of the device. In Figure 1(a) the wavelength converting component is shown in a fully retracted position such that light 22 generated by the device 10 comprises light 14 from the LED chip only. Consequently light generated by the device is of wavelength λ_1 , which is blue in color, and corresponds to point 24 in Figure 2.

[0040] In Figure 1(b) the wavelength converting component 16 has been translated in a direction 18 such that light 14 from the LED is now incident on a region of the component. The phosphor material within the component absorbs a part of the excitation radiation (light) 14 and re-emits light of wavelength λ_2 that is green in color in this example in which a blue activated green emitting phosphor material is incorporated in the wavelength converting component 16. Now, the light 22 generated by the device comprises a combination of blue (λ_1) and green (λ_2) light and will appear turquoise in color. The proportion of green (λ_2) light in the output light depends on the concentration of phosphor per unit area (g/m^2) which will depend on the position of the component relative to the LED. For a given location, and a given thickness of the component 16, such resultant light will have a color dependant on the phosphor unit area loading at that location. This resulting color will be consistent with a point on line 28 of the CIE diagram in Figure 2, the exact position of which depends on the choice of phosphor and loading of such phosphor in the wavelength converting component 16.

[0041] In Figure 1(c) the wavelength converting component 16 has been further translated such that the thickest part T of the component is now positioned over the LED chip. The concentration of phosphor within the component and the thickness T are configured such the phosphor now absorbs all light from the LED and re-emits green light. Thus the light 22 generated by device now comprises green (λ_2) light generated by the phosphor only and this is indicated as point 26 on the chromaticity diagram of Figure 2. It will be appreciated that the color of light emitted by the device is tunable between the points 24 and 26 along a line 28 and depends on the position of the wavelength selective component.

[0042] It is intended that light emitting devices in accordance with the invention use inorganic phosphor materials such as for example silicate-based phosphor of a general composition $\text{A}_3\text{Si}(\text{OD})_6$ or $\text{A}_2\text{Si}(\text{OD})_4$ in which Si is silicon, O is oxygen, A comprises strontium (Sr), barium (Ba), magnesium (Mg) or calcium (Ca) and D comprises chlorine (Cl), fluorine (F), nitrogen (N) or sulfur (S). Examples of silicate-based phosphors are disclosed in

our co-pending patent applications US2006/0145123, US2006/028122, US2006/261309 and US2007029526 the content of each of which is hereby incorporated by way of reference thereto.

[0043] As taught in US2006/0145123, a europium (Eu^{2+}) activated silicate-based green phosphor has the general formula $(\text{Sr}, \text{A1})_x(\text{Si}, \text{A2})(\text{O}, \text{A3})_{2+x}:\text{Eu}^{2+}$ in which: A1 is at least one of a 2+ cation, a combination of 1+ and 3+ cations such as for example Mg, Ca, Ba, zinc (Zn), sodium (Na), lithium (Li), bismuth (Bi), yttrium (Y) or cerium (Ce); A2 is a 3+, 4+ or 5+ cation such as for example boron (B), aluminum (Al), gallium (Ga), carbon (C), germanium (Ge), N or phosphorus (P); and A3 is a 1-, 2- or 3- anion such as for example F, Cl, bromine (Br), N or S. The formula is written to indicate that the A1 cation replaces Sr; the A2 cation replaces Si and the A3 anion replaces O. The value of x is an integer or non-integer between 2.5 and 3.5.

[0044] US2006/028122 discloses a silicate-based yellow-green phosphor having a formula $\text{A}_2\text{SiO}_4:\text{Eu}^{2+} \text{D}$, where A is at least one of a divalent metal comprising Sr, Ca, Ba, Mg, Zn or cadmium (Cd); and D is a dopant comprising F, Cl, Br, iodine (I), P, S and N. The dopant D can be present in the phosphor in an amount ranging from about 0.01 to 20 mole percent. The phosphor can comprise $(\text{Sr}_{1-x}\text{Ba}_x\text{M}_y)\text{SiO}_4:\text{Eu}^{2+}\text{F}$ in which M comprises Ca, Mg, Zn or Cd.

[0045] US2006/261309 teaches a two phase silicate-based phosphor having a first phase with a crystal structure substantially the same as that of $(\text{M1})_2\text{SiO}_4$; and a second phase with a crystal structure substantially the same as that of $(\text{M2})_3\text{SiO}_5$ in which M1 and M2 each comprise Sr, Ba, Mg, Ca or Zn. At least one phase is activated with divalent europium (Eu^{2+}) and at least one of the phases contains a dopant D comprising F, Cl, Br, S or N. It is believed that at least some of the dopant atoms are located on oxygen atom lattice sites of the host silicate crystal.

[0046] US2007/029526 discloses a silicate-based orange phosphor having the formula $(\text{Sr}_{1-x}\text{M}_x)_y\text{Eu}_z\text{SiO}_5$ in which M is at least one of a divalent metal comprising Ba, Mg, Ca or Zn; $0 < x < 0.5$; $2.6 < y < 3.3$; and $0.001 < z < 0.5$. The phosphor is configured to emit visible light having a peak emission wavelength greater than about 565 nm.

[0047] The phosphor can also comprise an aluminate-based material such as is taught in our co-pending patent applications US2006/0158090 and US2006/0027786 the content of each of which is hereby incorporated by way of reference thereto.

[0048] US2006/0158090 teaches an aluminate-based green phosphor of formula $\text{M}_{1-x}\text{Eu}_x\text{Al}_y\text{O}_{[1+3y/2]}$ in which M is at least one of a divalent metal comprising Ba, Sr, Ca, Mg, Mn, Zn, Cu, Cd, Sm and thulium (Tm) and in which $0.1 < x < 0.9$ and $0.5 \leq y \leq 12$.

[0049] US2006/0027786 discloses an aluminate-based phosphor having the formula

$(M_{1-x}Eu_x)_{2-z}Mg_zAl_yO_{[1+3y/2]}$ in which M is at least one of a divalent metal of Ba or Sr. In one composition the phosphor is configured to absorb radiation in a wavelength ranging from about 280 nm to 420 nm, and to emit visible light having a wavelength ranging from about 420 nm to 560 nm and $0.05 < x < 0.5$ or $0.2 < x < 0.5$; $3 \leq y \leq 12$ and $0.8 \leq z \leq 1.2$. The phosphor can be further doped with a halogen dopant H such as Cl, Br or I and be of general composition $(M_{1-x}Eu_x)_{2-z}Mg_zAl_yO_{[1+3y/2]}\cdot H$.

[0050] It will be appreciated that the phosphor is not limited to the examples described herein and can comprise any inorganic or organic phosphor material including for example nitride and sulfate phosphor materials, oxy-nitrides and oxy-sulfate phosphors or garnet materials (YAG).

[0051] Figures 3(a) to (f) are schematic representations of the operation of a color tunable light emitting device in accordance with a further embodiment of the invention. Throughout this specification like components are denoted using like reference numerals. In the embodiment of Figure 3 the wavelength converting component 16 comprises two overlapping tapered parts 16a and 16b that respectively include red (R) and green (G) light emitting phosphor materials. Figure 4 is a CIE (Commission Internationale de l'Eclairage) 1931 chromaticity diagram illustrating color tuning for the device of Figure 3.

[0052] In Figure 3(a) the wavelength converting component 16 is shown in a fully retracted position such that light 22 generated by the device 10 comprises light from the LED chip only. Consequently light generated by the device is blue (B) in color, and corresponds to point 30 in Figure 4.

[0053] In Figure 3(b) the wavelength converting component 16 has been translated in a direction 18 such that light 14 from the LED is now incident on the red light generating part 16a of the component. Now the red light emitting phosphor material within the component will absorb a part of the excitation radiation and re-emit red light. Consequently, the light 22 generated by the devices comprises a combination of blue and red light and will appear warm white (WW) to indigo in color depending on the relative proportions of blue and red light. The proportion of red light in the output light depends on the concentration of phosphor per unit area which will depend on the position of the component relative to the LED.

[0054] In Figure 3(c) the wavelength converting component 16 has been further translated such that the thickest portion of the component part 16a is now positioned over the LED chip. The concentration of phosphor within and thickness of the part 16a are selected such the red light generating phosphor now absorbs all the blue light from the LED and re-emits red light. Thus the light 22 generated by device now comprises red light generated by the phosphor only and this is indicated as point 34 on the chromaticity diagram of Figure 4. It will be appreciated that the color of light emitted by the device is tunable between the points

30 and 34 along a line 32 and depends on the position of the wavelength selective component.

[0055] In Figure 3(d) the wavelength converting component 16 has been further translated in a direction 18 such that light 14 from the LED is now incident on a region of the component that comprises both red and green light generating parts 16a and 16b. As illustrated, the component is positioned such that the thickness of the green light generating part 16b is greater than that of the red light generating part 16a and hence the proportion of green light is correspondingly greater. Now the red and green light emitting phosphor materials within the component parts 16a and 16b will between them absorb substantially all of the excitation radiation and respectively re-emit red and green light. Consequently, the light 22 generated by the device comprises a combination of red and green light and will appear yellow/green in color. The relative proportions of red and green light in the output light depend on the relative densities of phosphor per unit area which will depend on the position of the component relative to the LED.

[0056] In Figure 3(e) the wavelength converting component 16 has been further translated such that the thickest portion of the component part 16b is now positioned over the LED chip. At this point the part 16a makes no contribution to the emitted light. The concentration of phosphor within and thickness of the part 16b are selected such the green light generating phosphor now absorbs all light from the LED and re-emits green light. Thus the light 22 generated by device now comprises green light generated by the phosphor only and this indicated as point 38 on the chromaticity diagram of Figure 4. It will be appreciated that the color of light emitted by the device is tunable between the points 34 and 38 along a line 36 and depends on the position of the wavelength selective component.

[0057] In Figure 3(f) the wavelength converting component 16 has been further translated such that a relatively thinner portion of the component part 16b is now positioned over the LED chip. Now the green light emitting phosphor material within the component will absorb a part of the excitation radiation and re-emit green light. Consequently, the light 22 generated by the device comprises a combination of blue and green light and will appear turquoise in color. The proportion of green light in the output light depends on the concentration of phosphor per unit area which will depend on the position of the component relative to the LED. It will be appreciated that the color of light emitted by the source is tunable between the points 38 and 30 along a line 40 and depends on the position of the wavelength selective component.

[0058] The wavelength converting component has been described as having a tapering thickness such that the concentration of phosphor per unit area varies spatially as a function of position on the component. Figure 5 is a schematic representation of a wavelength

converting component 16 in accordance with an alternative implementation. In this implementation the wavelength converting component comprises a transparent carrier 42 of substrate material having on a surface a pattern of phosphor material. The phosphor pattern can be provided on the carrier by depositing the phosphor material using screen printing, ink jet printing or other deposition techniques. In the example illustrated the phosphor pattern comprises a pattern of circular dots 44 of phosphor material. The relative size and/or spacing of the dots 42 is selected such that the phosphor concentration per unit area varies along the intended direction 18 of movement of the component. The dots 42 can also be provided as an array of equally spaced non-overlapping areas (dots) of varying size using a halftone system. The wavelength converting component of Figure 3 can be fabricated by a pattern of two or more phosphor materials. Moreover, it will be appreciated that any pattern of phosphor material can be used provided the phosphor concentration per unit area changes spatially with position on the surface of the component. For example, the pattern can comprise a pattern of lines of varying width and/or spacing. Alternatively, or in addition the concentration of the phosphor material (that is loading of phosphor to binder material) within different parts of the pattern can be used to achieve a spatially varying phosphor pattern. An advantage of such a component is ease of fabrication and being of substantially uniform thickness enables the component to be moveably mounted within a simple guide arrangement.

[0059] Figures 6(a) to (d) are schematic representations of the operation of a color tunable light emitting device in accordance with a further embodiment of the invention which includes two independently moveably wavelength converting components 16₁ and 16₂. In this embodiment each wavelength converting component 16₁ and 16₂ is fabricated in accordance with the implementation of Figure 5 and includes a pattern of phosphor material which respectively generates light of wavelength λ_2 (red) and λ_3 (green). The phosphor pattern is represented in Figure 6 as a series of lines passing through the thickness of the component whose change of spacing represents the change in concentration of the phosphor material.

[0060] In Figure 6(a) both wavelength converting components 16₁ and 16₂ are shown in a retracted position such that light 14, excitation radiation, from the LED is incident on an end portion of each component which contains a very low concentration per unit area of phosphor material, or no phosphor material. Consequently light 22 generated by the device 10 comprises the light 14 from the LED chip 12 only and is blue in color (wavelength λ_1). This corresponds to point 46 in the CIE diagram of Figure 7.

[0061] In Figure 6(b) the wavelength converting component 16₁ has been translated such that light 14 from the LED is now incident on the opposite end portion of the component

16₁ which contains the highest concentration of phosphor material. The position of the component 16₂ remains unchanged. Now, the red light emitting phosphor material within the component 16₁ will absorb all of the excitation radiation and re-emit red light (λ_2). This corresponds to point 48 of the chromaticity diagram of Figure 7. The color of light emitted by the device can be tuned along a line connecting points 46 and 48 by moving the component 16₁ such that the excitation radiation is incident on intermediate portions of the component having a differing concentration of phosphor per unit area whilst keeping the component 16₂.

[0062] In Figure 6(c), which is the converse of situation in Figure 6(b), the wavelength converting component 16₂ has been translated such that light 14 from the LED is incident on the end portion of the component which contains the highest concentration of phosphor material. The first component 16₁ is in a retracted position such that light from the LED is incident on the end portion of this component containing no of phosphor material. With the components in these positions the green light emitting phosphor material within the component 16₂ will absorb all of the excitation radiation and re-emit green light (λ_3). This corresponds to point 50 of the chromaticity diagram of Figure 7. It will be appreciated that the color of light emitted by the device can be tuned along a line connecting points 46 and 50 by moving the component 16₂ such that the excitation radiation is incident on intermediate portions of the component having a differing concentration of phosphor per unit area.

[0063] In Figure 6(d) the wavelength converting components 16₁ and 16₂ are positioned such that light 14 from the LED is incident on the portion of the components approximately midway between the ends, that the portion of each component having an intermediate concentration of phosphor material. Now, the red and green light emitting phosphor materials within the components 16₁ and 16₂ will between them absorb a substantial proportion of the excitation radiation and re-emit a combination of red light (λ_2) and green light (λ_3). This corresponds to a point along a line connecting the points 48 and 50 of the chromaticity diagram of Figure 7.

[0064] An advantage of using two different independently controllable wavelength converting components is that the color of generated light 22 is tunable within a color space as is indicated by the cross hatched region 52 of the chromaticity diagram of Figure 7.

[0065] Figures 8(a) to (c) show a color temperature tunable white light emitting bar 80 in accordance with the invention. The light bar 80 is intended for use in lighting applications and is capable of generating white light whose correlated color temperature (CCT) is tunable and can be set by a manufacturer and/or user between cool white (CW) of CCT \approx 7000K and warm white (WW) of CCT \approx 3000K. Figures 8(a) and (b) respectively show edge and plan views of the lighting bar 80 and Figure 8(c) a further plan view in which the lighting bar has

been tuned to a different CCT.

[0066] The lighting bar 80 comprises seven LEDs 82 that are mounted as a linear array along the length of a bar 84. The bar 84 provides both electrical power to each LED and thermal management of the LEDs and can be mounted to a suitable heat sink (not shown).

Each LED 82 comprises an InGaN/GaN (indium gallium nitride/gallium nitride) based LED chip which is packaged in a square housing and includes one or more phosphor materials such that each is operable to generate cold white (CW) light. Typically, the phosphor material can comprise a green-silicate based phosphor material. The area of light emission of each LED is indicated by a circle 86.

[0067] The lighting bar 80 further comprises a wavelength converting component in the form of a transparent carrier bar 88 made of a transparent material, such as acrylic, that includes seven wavelength converting regions 90 along its length. The wavelength converting regions 90 have substantially identical wavelength converting characteristics that vary in a direction along the length of the carrier with a respective region 90 corresponding to a respective one of the LEDs 82. Each wavelength converting region can comprises a yellow-silicate based light emitting phosphor material whose concentration per unit area varies substantially linearly along its length. As with the lighting devices described above, the change of concentration can be implemented by incorporating the phosphor material with a transparent binder and varying the thickness of each region along its length as illustrated or by depositing the phosphor material in the form of a pattern whose concentration varies spatially. The carrier bar 88 is movably mounted to the bar 84 by pairs of guides 92 with an underside of the carrier 88 in sliding contact with the LEDs. A thumb lever 94 is pivotally mounted to the bar 84 and a slot in the lever is coupled to stud 96 extending from the upper surface of the carrier 88. Movement of the lever in a direction 98 causes a translation of the carrier relative the LEDs. A locking screw 100 is provided to lock the position of the carrier in relation to bar 88.

[0068] In operation, a manufacturer or installer can set the lighting bar 80 to a selected color temperature by loosening the locking screw 100 and operating the lever 94 until the lighting bar generates the required color temperature of output light. It will be appreciated that operation of the lever causes a translation of the carrier and the wavelength converting regions 90 relative to the bar and their respective LED (Figure 8(c)). This results in the proportion of light (yellow) in the output generated by the wavelength converting regions to change and hence the color temperature of the output to change. Once the selected color temperature is set the locking screw is tightened to lock the carrier in position. A particular benefit of the lighting bar is that since its color temperature can be tuned post-production this eliminates the need for expensive binning. As well as the manufacturer or installer setting

the color temperature a user can periodically adjust the color temperature of the bar throughout the lifetime of the device.

[0069] In alternative arrangements where it is required to adjust the color temperature more frequently, such as for example "mood" lighting, the carrier can be moved automatically using a motor or actuator such as a piezoelectric or magnetostrictive actuator. Although the LEDs are illustrated as being equally spaced it will be appreciated that they can be unequally spaced provided the spacing of the wavelength converting regions corresponds to the LEDs.

[0070] Figure 9 is a schematic representation of a color temperature tunable white light emitting device 120 in accordance with a further embodiment of the invention in which the wavelength converting component is rotatable. The white light emitting device 120 is capable of generating white light whose CCT is tunable between cool white (CW) and warm white (WW). In this implementation the device comprises a circular array of twenty four LEDs 122 arranged around three concentric circles. The wavelength converting component comprises a rotatable transparent disc 124 having a corresponding array of twenty four wavelength converting regions 126 on its upper surface. Each wavelength converting region 126 has a wavelength converting property that varies in a substantially identical way for a given angular rotation in a given sense of rotation. As a result the wavelength converting regions nearer to the axis of rotation are shorter in length than those located nearer the periphery of the disc 124. In Figure 9 the wavelength converting component is illustrated as being in a position such that a central portion of each wavelength converting region 126 overlies its associated LED 122. It will be appreciated that color temperature of light emitted by the device can be tuned between CW and WW by rotation of the disc 124 between positions 128 and 130.

[0071] Figure 10 is a schematic representation of a color tunable light emitting device 140 in accordance with a yet further embodiment of the invention in which the wavelength converting component is movable (translatable) in two directions x, y. In this embodiment four LEDs 142 are arranged in the form of a square array and the wavelength converting component comprises a transparent square plate 144 which is movable in two directions corresponding to the axes x and y. A corresponding square array of four square wavelength converting regions 146 is provided on the transparent plate 144. In this example each wavelength converting region 146 includes two different phosphor materials, represented by lines and dots respectively, each of which whose concentration per unit area varies over the wavelength converting region. The wavelength converting properties of each wavelength converting region vary in a substantially identical way in the directions of x and y. In Figure 10 the wavelength converting component is illustrated as being in a position such that a central portion of each wavelength converting region 146 overlies its associated LED 142.

The color of light generated by the device can be tuned by translation of the plate in the directions x and y. The range of movement of the plate 144 is indicated by a dashed line 148.

[0072] A particular benefit of the light emitting devices in accordance with the invention is that they can eliminate the need for binning. A further advantage is cost reduction compared with multi-colored LED packages and their associated complex control systems.

[0073] It will be further appreciated that the present invention is not restricted to the specific embodiments described and that variations can be made that are within the scope of the invention. For example the number and arrangements of LEDs and/or configuration of the wavelength converting component can be adapted for a given application.

CLAIMS

What is claimed is:

1. A color tunable light emitting device comprising: an excitation source operable to generate light of a first wavelength range and a wavelength converting component
5 comprising at least one phosphor material which is operable to convert at least a part of the light into light of a second wavelength range, wherein light emitted by the device comprises the combined light of the first and second wavelength ranges, wherein the wavelength converting component has a wavelength converting property that varies spatially and wherein color of light generated by the source is tunable by a relative movement of the
10 wavelength converting component and excitation source such that the light of the first wavelength range is incident on a different part of the wavelength converting component.
2. The device according to Claim 1, wherein a concentration per unit area of the at least one phosphor material varies spatially.
3. The device according to Claim 1, wherein a thickness of the at least one phosphor
15 material varies spatially.
4. The device according to Claim 3, wherein the thickness varies substantially linearly.
5. The device according to Claim 3, wherein the at least one phosphor is incorporated in a transparent material with a concentration of the at least one phosphor material per unit volume of transparent material that is substantially constant and wherein a thickness of the
20 wavelength converting component varies spatially.
6. The device according to Claim 1, wherein the wavelength converting component comprises a transparent carrier on a surface of which the at least one phosphor material is provided.
7. The device according to Claim 6, wherein the at least one phosphor is provided as a
25 spatially varying pattern.
8. The device according to Claim 1, wherein the wavelength converting component further comprises a second phosphor material which is operable to convert at least a part of the light of the first wavelength range into light of a third wavelength range, wherein light emitted by the device comprises the combined light of the first, second and third wavelength
30 ranges and wherein a concentration per unit area of the second phosphor material varies spatially.
9. The device according to Claim 1, wherein the wavelength converting component is moveable relative to the excitation source and has a wavelength converting property that varies and is selected from the group consisting of varying: along a single dimension; along
35 two dimensions; and rotationally.
10. The device according to Claim 1, and further comprising a second wavelength

converting component comprising a second phosphor material which is operable to convert at least a part of the light of the first wavelength range into light of a third wavelength range, wherein light emitted by the device comprises the combined light of the first, second and third wavelength ranges wherein the second wavelength converting component has a wavelength
5 converting property that varies spatially and wherein color of light generated by the source is tunable by moving the first and second wavelength converting components relative to the excitation source such that the light of the first wavelength range is incident on different parts of the first and second wavelength converting components.

11. The device according to Claim 10, wherein the first and second wavelength
10 converting components are independently moveable with respect to one another and to the excitation source.

12. The device according to Claim 10, wherein a concentration per unit area of the second phosphor material varies spatially.

13. The device according to Claim 12, wherein a thickness of the second phosphor
15 material varies spatially.

14. The device according to Claim 13, wherein the thickness varies substantially linearly.

15. The device according to Claim 10, wherein the second phosphor is incorporated in a transparent material with a concentration of the second phosphor material per unit volume of transparent material that is substantially constant and wherein a thickness of the wavelength
20 converting component varies spatially.

16. The device according to Claim 10, wherein the second wavelength converting component comprises a transparent carrier on a surface of which the second phosphor material is provided.

17. The device according to Claim 16, wherein the second phosphor material is provided
25 as a pattern that varies spatially such that the concentration per unit area of the second phosphor material varies spatially.

18. The device according to Claim 1, wherein the excitation source comprises a light emitting diode.

19. A color tunable light emitting device comprising: a plurality of light emitting diodes
30 operable to generate light of a first wavelength and a wavelength converting component which is operable to convert at least a part of the excitation radiation into light of a second wavelength, wherein light emitted by the device comprises the combined light of the first and second wavelength ranges and wherein the wavelength converting component comprises a plurality of wavelength converting regions comprising at least one phosphor material in which
35 a respective region is associated with a respective one of the light emitting diode and wherein each region has a wavelength converting property that varies spatially and wherein

color of light generated by the device is tunable by moving the component relative to the light emitting diodes such that the light of the first wavelength range from each light emitting diode is incident on a different part of its respective wavelength converting region.

20. The device according to Claim 19, wherein the plurality of light emitting diodes
5 comprise a linear array and the wavelength converting regions comprise a corresponding linear array and wherein the source is tunable by linearly displacing the component relative to the array of light emitting diodes.

21. The device according to Claim 19, wherein the plurality of light emitting diodes
10 comprise a two dimensional array and the wavelength converting regions comprise a corresponding two dimensional array and wherein the source is tunable by displacing the component relative to the array of light emitting diodes along two dimensions.

22. The device according to Claim 19, wherein the plurality of light emitting diodes
15 comprise a circular array and the wavelength converting regions comprise a corresponding circular array and wherein the device is tunable by rotationally displacing the component relative to array of light emitting diodes.
