ABSTRACT
A vented automatic dispensing cap for use with a flexible container may generally include a body and a retainer cap attached to the body. A pressure chamber is formed between the body and retainer cap. A set of resilient spring members spaced around the body holds the retainer cap against the body, which seats a valve within a dispensing hole extending through the cap. When the container is squeezed, product in the container may be forced into the pressure chamber expanding the pressure chamber and unseating the valve, thereby allowing product to exit the dispensing opening. A lip seal around the upper circumferential edge of the body prevents fluid from leaking out of the sides of the chamber but allows air to enter the chamber for venting the flexible container.
AUTOMATIC DISPENSING CAP FOR A SQUEEZEABLE BOTTLE

CROSS REFERENCE TO RELATED APPLICATIONS

FIELD OF THE INVENTION

[0002] The invention is generally related to squeeze bottles, and more particularly to automatic dispensing caps.

BACKGROUND OF THE INVENTION

[0003] The squeezable tube and the squeezable bottle are common containers for products such as creams, lotions, and soaps. The most common devices for opening and closing these squeezable containers are removable caps that are threaded to the container or flip top dispensing closures. In either case, a two handed effort is required to open the cap before the products can be dispensed and also to close the cap to seal the container. Quite often the cap is not replaced or flipped down, thereby leaving the container unsealed.

[0004] To overcome the necessity of a two handed effort to both open and close the containers, a self opening and closing device or automatic dispensing cap is described below.

SUMMARY OF THE INVENTION

[0005] In one embodiment, an automatic dispensing cap for use with a container includes a body and a retainer cap. The body, which may be connected to the container, includes a protrusion. The retainer cap is connected to the body and includes a chamber and a dispensing aperture. The retainer cap can move relative to the body between a closed position wherein the protrusion is seated in the dispensing aperture to prevent fluid flow through the dispensing aperture, and an open position wherein the protrusion is unseated from the dispensing aperture to allow fluid flow through the dispensing aperture.

[0006] The retainer cap may be resiliently biased toward the closed position. The body may further include a sealing lip that is resiliently biased against the retainer cap. The sealing lip acts as a one-way valve to prevent fluid from exiting the chamber and to allow air to enter the chamber. The sealing lip may be a plastic membrane less than approximately 0.5 mm in thickness. The dispensing cap may also include a spring member that resiliently biases the retainer cap toward the closed position. The body may have a plurality of spring members and may be positioned in the interior of the retainer cap with the spring members contacting an inner surface of the retainer cap. The retainer cap may also be rotatable between a locked position where the retainer cap is constrained from moving into the open position, and unlocked position where the retainer cap is not constrained from moving into the open position.

[0007] In another embodiment, a valve member for an automatic dispensing cap includes a cylindrical body having a longitudinal axis defining upward and downward directions and a circumferential outer wall having upper and lower edges. The valve also includes a protrusion disposed upwardly along the longitudinal axis. A plurality of openings are disposed radially between the protrusion and the circumferential outer wall and are suitable for the passage of fluid upwardly through the cylindrical body. The valve also includes a plurality of spring members disposed radially outward from the outer circumferential wall and spaced to allow air to pass upwardly between the spring members and along the outer circumferential wall. The valve also includes a circumferential sealing lip having inner and outer surfaces extending upwardly from the upper edge of the wall, the lip sufficiently flexible to bend radially inward as a result of a difference in air pressure between inner and outer surfaces thereof.

[0008] In another embodiment, the automatic dispensing cap may include the aforementioned valve member in conjunction with a retaining cap that has an upper surface with an aperture sized and positioned to receive the protrusion and an annular outer wall with an inner surface positioned around the cylindrical body such that the circumferential sealing lip presses against the inner surface forming a one-way seal that prevents fluid from exiting the cap but permits air to enter the cap. The inner surface of the outer wall of the retaining cap also engages the spring members to resiliently bias the retaining cap against the valve member such that the protrusion is seated in the aperture.

[0009] The retaining cap may be responsive to upward pressure on its upper surface such that when the cap is attached to a squeeze bottle, squeezing the bottle results in sufficient pressure to move the retaining cap against the resilient bias of the spring members and unseat the protrusion, allowing product to dispense through the aperture.

[0010] In another embodiment, an automatic dispensing cap for use with a container includes a body connected to the container and a retainer cap connected to the body. A pressure chamber within the retainer cap is in fluid communication with the interior of the container. A dispensing hole exits the pressure chamber. The dispensing cap has a closed position where the protrusion seals the dispensing hole and an open position where the dispensing hole is open. A spring member biases the automatic dispensing cap in the closed position. A sealing lip is configured to contact the interior surface of the retaining cap, the sealing lip further configured to permit air to enter the pressure chamber in order to vent the container.

[0011] In another embodiment, a squeeze container includes the aforementioned dispensing cap and a resiliently deformable container having liquid therein. The container is coupled to the automatic dispensing cap such that squeezing the container results in the automatic dispensing cap moving from a closed position to an open position. Liquid then dispenses from the container through the dispensing hole, the automatic dispensing cap moves back from an open position to a closed position, and air vents past the sealing lip into the container.

BRIEF DESCRIPTION OF THE DRAWINGS

[0012] FIG. 1 is an external view of a conventional tube with a removable automatic dispensing cap.
FIG. 2 is a top view of the automatic dispensing cap shown in FIG. 1.

FIG. 3 is a section through a removable non-vented automatic dispensing cap using a coil spring as a piston return device. Side A shows the automatic dispensing cap in the operating position and side B shows the automatic dispensing cap in the locked position.

FIG. 4 is a section through a removable non-vented automatic dispensing cap using multiple leaf springs, which are integral with the body, to provide a piston return means.

FIG. 5 is a section taken along line 5-5 of FIG. 4 showing the rotation limiter that stops the retainer cap at the operating position.

FIG. 6 is a view taken along line 6-6 of FIG. 4 showing a top view of the multiple leaf springs that are integral with the body.

FIG. 7 is a section taken along line 7-7 of FIG. 4 showing a side view of the leaf spring integral with the body.

FIG. 8 is a section through a removable non-vented automatic dispensing cap having a nozzle type retainer cap.

FIG. 9 is a section taken along line 9-9 of FIG. 8 showing the configuration of the piston and integral shutoff valve.

FIG. 10 is a section taken along line 10-10 of FIG. 3 showing the rotation limiter that stops the retainer cap at the operating position.

FIG. 11 is a section through a retainer cap having a floatation collar for use with a non-vented automatic dispensing cap. This arrangement allows the tube containing the product to float.

FIG. 12 is a section through a class 1 (inverted), vented automatic dispensing cap.

FIG. 13 is a top view of the vented automatic dispensing cap shown in FIG. 12.

FIG. 14 is an enlarged, partial section of the piston and flapper valve shown in FIG. 12 with a flapper valve in the venting position.

FIG. 15 is a top view of the piston shown in FIG. 14 without the flapper valve.

FIG. 16 is a section through a class 2 (upright), vented automatic dispensing cap.

FIG. 17 is a top view of the automatic dispensing cap shown in FIG. 16.

FIG. 18 is an enlarged partial section of the body and flapper valve shown in FIG. 16 with the flapper valve in the venting position.

FIG. 19 is a bottom view of the body shown in FIG. 18 without the flapper valve.

FIG. 20 is a view of a class 2, vented automatic dispensing cap having a side outlet dispenser spout.

FIG. 21 is a top view of the automatic dispensing cap shown in FIG. 20.

FIG. 22 is an external view of a conventional tube with a removable automatic dispensing cap.

FIG. 23 is a top view of the automatic dispensing cap and tube shown in FIG. 22.

FIG. 24 is an external view of a squeezable bottle with a vented automatic dispensing cap.

FIG. 25 is a top view of the automatic dispensing cap and bottle shown in FIG. 24.

FIG. 26 is section shown through a removable, non-vented, two-piece automatic dispensing cap. Side A shows the automatic dispensing cap in the sealed position, side B shows the automatic dispensing cap open during the dispensing cycle.

FIG. 26C shows the automatic dispensing cap having an alternate design to provide the simpler mold requirements and less costly to change dispensing hole size.

FIG. 27 is a section taken along line 27-27 of FIG. 26 showing the relationship of the two parts when they are initially assembled.

FIG. 28 is a section taken along line 27-27 of FIG. 26 showing the relationship of the two parts when they have been rotated to the automatic dispensing position.

FIG. 29 is a roll-out view taken along circular line 29-29 of FIG. 28 showing the relationship of the two parts when they are initially assembled.

FIG. 30 is a roll-out view taken along circular line 30-30 of FIG. 28 showing the relationship of the two parts when the automatic dispensing cap is in the automatic dispensing position and ready for a user to dispense product, see FIG. 26B.

FIG. 31 is a roll-out view taken along circular line 30-30 of FIG. 28 showing the relationship of the two parts when they are in the automatic dispensing position while product is being dispensed.

FIG. 32 is a roll-out view taken along circular line 30-30 of FIG. 28 showing the relationship of the two parts when automatic dispensing cap is sealed and rotated to the locked position to prevent accidental dispensing of product.

FIG. 33 is a section through an inverted, vented automatic dispensing cap secured to a squeezable bottle.

FIG. 34 is a view taken along line 34-34 of FIG. 33.

FIG. 35 is an enlarged section taken along line 35-35 of FIG. 34.

FIG. 36 is a section through an upright, vented automatic dispensing cap secured to a squeezable bottle.

FIG. 37 is a view of an upright, vented automatic dispensing cap having a side outlet dispensing spout.

FIG. 38 is a top view of the automatic dispensing cap shown in FIG. 37.

FIG. 39 is a section through a removable two-piece non-vented nozzle type automatic dispensing cap. Side A shows the automatic dispensing cap in the sealed and locked position. Side B shows the automatic dispensing cap during the dispensing cycle.

FIG. 40 is a section taken along the section line 40-40 of FIG. 39 showing the configuration of the body and integral shut off valve.

FIG. 41 is a perspective view of an inverted, vented automatic dispensing cap with an annular lip seal secured to a squeezable bottle.

FIG. 42A is an exploded view of the dispensing cap of FIG. 41.

FIG. 42B is a section view of the dispensing cap of FIG. 42A.

FIG. 43A is a section view of the dispensing cap of FIG. 41 shown in a closed position.

FIG. 43B is a section view of the dispensing cap of FIG. 41 shown in an open, dispensing position.

FIG. 43C is a section view of the dispensing cap of FIG. 41 shown with flow lines illustrating venting through the cap.

FIG. 43D is a partial view of the lip seal shown venting in FIG. 43C.
FIG. 44 is a partial view of the neck of a bottle with features to mate with the dispensing cap of FIG. 41.

FIG. 45 is a roll-out view of the threads of the neck of FIG. 44.

FIG. 46 is a cross sectional view of the dispensing cap and bottle neck taken along line 46-46 of FIG. 43A showing locked and unlocked positions.

FIG. 47 is a partial view of the neck of a bottle with an alternative embodiment of features that mate with the dispensing cap of FIG. 41.

FIG. 48 is a roll-out view of the threads of the neck of FIG. 47.

FIG. 49 is a partial view of a bottle neck adapter for use with the dispensing cap of FIG. 41.

DETAILED DESCRIPTION

To operate the automatic dispensing cap, the consumer squeezes the container until the desired amount of product has been dispensed. When the squeezing ceases the consumer merely wipes off the flush surface of the automatic dispensing cap with a finger or washcloth. In some cases, an automatic dispensing cap, having a side outlet dispensing spout is used, which dispenses the product directly into the consumers hand or in some cases an automatic dispensing cap with a nozzle to dispense a product on a surface can be used.

There are two types of automatic dispensing caps, vented and non-vented. The non-vented automatic dispensing cap is used with tubes that remain collapsed and do not revert back to their original shape after being squeezed. It can operate under severe moisture conditions, such as in a shower, without inhaling or sucking in ambient moisture or other matter that may contaminate or dilute the product remaining in the container. In addition to shower use, an automatic dispensing cap having a floatation collar incorporated for bathtub use, allows the consumer to have one or more floating tubes of soap, body lotion, shampoo, etc. at the tip of their fingers while in the bathtub, whirlpool tub, or hot tub.

The vented automatic dispensing cap is used with squeezable containers or bottles that revert back to their original shape after squeezing. These types of containers require a closure that will permit atmospheric pressure to introduce air into the container to replace the product that was removed during dispensing.

There are two orientations of vented automatic dispensing caps. The first orientation requires that the bottle be stored and/or operated in the inverted position with the cap down, this allows fluid like products to flow to the automatic dispensing cap for dispensing, also referred to herein as class 1 caps. Existing closures that have a self-opening and self-closing feature also have this requirement. The second orientation of vented automatic dispensing cap is an important departure from this requirement. It is designed to dispense the product with the container stored and operated in the upright position with the cap up, also referred to herein as class 2 caps. In some cases the upright, vented automatic dispensing cap can be used in place of a counter top pump type dispenser, especially if it has a side outlet dispensing spout.

At certain times, it is desirable to disable the dispensing mechanism of the automatic dispensing cap. For this purpose the automatic dispensing cap is provided with a disabled or locked position that prevents the product from being dispensed when the container is squeezed.

The non-vented automatic dispensing cap is generally formed of a body, a two diameter piston having a hollow rod and an integral valve, a coil spring and a retainer cap. The body is threadably secured to a squeezable tube and has a hole in which the smaller diameter of the piston operates. The retainer cap is threaded to the body, which forms a cylinder in which the large diameter of the piston operates. The coil spring operates between the lower side of the large diameter of the piston and the body and biases the piston toward the retainer cap, which has a dispensing hole in which the integral piston valve is seated. The portion of the cylinder between the top of the large diameter of the piston and the retainer cap is referred to as the pressure chamber. The portion of the cylinder between the lower side of larger diameter of the piston and the body is vented to atmosphere.

When the tube is squeezed, the product is forced through the hollow rod of the piston into the pressure chamber. The product pressure will cause the piston to compress the spring and move the valve away from the dispensing hole in the retainer cap, thus allowing the product to be dispensed. When the container is released, the product pressure drops and the spring returns the piston and integral valve to the sealing position preventing any air or foreign matter from entering. Since there is no venting of the tube, the tube volume will be reduced by the amount of product dispensed, this causes the tube to collapse. It will continue to collapse with each dispensing cycle.

The class 1 (inverted), vented automatic dispensing cap is similar to the non-vented automatic dispensing cap described above with the exception of adding vent holes and a shallow venting groove on the pressure side of the large piston face that would port the pressure chamber to the vented area.

In order to maintain pressure in the pressure chamber, a flat donut shaped highly flexible and elastic flapper valve is used. The lower face of flapper valve near the outside diameter is secured to the pressure side of the piston. The lower face of the flapper valve near its inside diameter is seated against and is stretched over a shallow conical shaped portion of the pressure side of the piston, thus sealing the shallow venting groove.

Containers that require venting are made of a resilient material that returns to the original shape or volume prior to squeezing. When the inverted container is squeezed, the product is forced through the hollow rod of the piston into the pressure chamber. Since the flapper valve is stretched over the conical face of the piston thus forming a seal against the piston face, the product cannot enter the vented area under the piston, therefore, the product pressure will cause the piston to compress the spring and move the integral valve away from the dispensing hole in the retainer cap, thus allowing the product to be dispensed.

When the container is released the product pressure drops and the spring returns the piston and valve to the sealing position. As the container tries to return to its original volume, it must make up for the amount of product dispensed. This causes a slight vacuum to occur in the container which in turn will cause atmospheric pressure, present in the vented side of the piston, to enter the venting ports on the face of the large diameter of the piston and unseat the flexible flapper valve, thus allowing air to enter the pressure chamber, flow through the hollow piston rod and into the container, thereby making up the volume lost during dispensing. After the replacement air volume is introduced in the container, the flapper valve reseals the pressure side of the piston.
The class 2 (upright) vented automatic dispensing cap is a variation of the class 1 vented automatic dispensing cap. The class 2 vented automatic dispensing cap moves the flapper valve from the top side of the piston to the container side of the body. The same principle of a highly elastic flat donut shape valve stretched over and sealing against a conical shaped surface applies. The venting in the case brings replacement air directly into the container instead of the pressure chamber. In addition to relocating the flapper valve, a tube is secured to the body and extends to the lower part of the container.

When the container is squeezed, the pressure in the container forces the product through the tube and the hollow rod of the piston into the pressure chamber. The product pressure will cause the piston to compress the spring and move the valve away from the dispensing hole in the retainer cap, thus allowing the product to be dispensed. When the container is released, the product pressure drops and the spring returns the piston and valve to the sealing position. As the container tries to return to its original volume, it must make up for the amount of product dispensed. This causes a slight vacuum to occur in the container. Since the dispensing hole is closed and there is no venting in the pressure chamber, the container will cause atmospheric pressure present in the vented area between the lower side of the piston and the upper face of the body to unseat the flapper valve secured to the container side of the body, thereby allowing replacement air to enter the container directly. Having the air enter the container directly prevents any belching. Belching occurs when air is trapped in the pressure chamber and is expelled during the next dispensing cycle.

To lock out the automatic dispensing feature, the retainer cap is rotated to the locked position. This will move the piston and valve, compressing the spring until the large diameter piston is seated against the body. This will cause the dispensing hole in the retainer cap to be sealed by the valve, and will prevent any product pressure caused by squeezing the container to move the piston and unseat the valve. When the retainer cap is rotated in the opposite direction, a rotation limiter stops the retainer cap at the operating position.

Another group of non-vented automatic dispensing caps, also for use with tubes are formed of two pieces: a body and a cap. The cap is a two diameter cup shaped port, having a dispensing hole, two integral cantilever springs spaced equally and extending from the inside diameter and at the open edge of the walls of the cup. The springs are formed as though they are two partial inside diameter flanges approximately ninety degrees in length and are disconnected from the walls of the cup for most of their length to permit the flanges to flex when a force is applied to the disconnected ends. The springs are molded to be at an angle to the open face of the cup.

The body is threadably secured to a squeezable tube and formed to have a lip seal at the upper end that engages inside the smaller diameter of the cap. The body has an integral valve that engages and seals the dispensing hole in the cap. A port in the end of the body permits the product in the tube to flow into a pressure chamber formed by the inside of the cap and the seal of the body.

Extending from the body are two horizontal lugs spaced equally and two primary vertical lugs spaced equally and at ninety degrees out of phase with the horizontal lugs. Two secondary vertical lugs are adjacent to the primary vertical lugs. The body also has a flange used to tighten it onto the thread of the tube. The horizontal lugs have an angled end, a stepped and notched portion followed by an angled surface. The primary vertical lugs have a rectangular outer surface. The secondary vertical lugs have a rectangular outer surface and are somewhat shorter than the primary vertical lugs.

When the cap is initially assembled to the body, it is first aligned so the spring portion falls between the vertical and horizontal lugs of the body, then it is advanced onto the body and rotated until the attached ends of the cantilever springs on the cap engage the bottom of the primary vertical lugs of the body. The automatic dispensing cap will then be in the locked or disabled position with the valve of the body sealing the dispensing hole in the cap. The rotation will also cause the detached ends of the cantilever springs to be deflected becoming engaged with the horizontal lugs. The ends of the cantilever springs will be in contact with the angled portion of the horizontal lugs, which provide some resistance to rotating the cap from the locked position.

To dispense the product in the tube, the consumer sets the automatic dispensing cap to the automatic dispensing position by reversing the rotation of the cap until it reaches a positive stop. At this point the cantilever springs will still be engaged with the horizontal lugs and limited from further rotation by the ends of the cantilever springs being against the stepped portion of the horizontal lugs. Slightly raised bumps on the ends of the cantilever springs are seated in the notches of the horizontal lugs to prevent accidental rotation of the cap from the automatic dispensing position. With the cap in the automatic dispensing position the force from the cantilever springs of the cap on the horizontal lugs of the body will provide sufficient force on the dispensing hole in the cap on the valve of the body to seal the dispensing hole in the cap. The secondary vertical lugs will contract the attached ends of the cantilever springs to prevent any excess strain that might cause the springs to fail if an accidental separating force is applied to the cap when in the automatic dispensing position.

When the tube is squeezed with the automatic dispensing cap in the automatic dispensing position, the product is forced through the port in the body to the pressure chamber. The product pressure will cause the cap to move away from the body, which will deflect the cantilever springs and move the dispensing hole away from the valve thus allowing the product to be dispensed.

When the tube is released, the product pressure drops and the cantilever springs return the cap so that the dispensing hole in the cap is sealed by the valve of the body. Since a positive pressure in the pressure chamber exists, both before the cap moves during dispensing and for a short time after the cap is sealed, when the tube is released, there is no opportunity for air, foreign matter or water to enter the automatic dispensing cap during dispensing. This makes it an ideal device to use in the shower or even in the bathtub. It can operate under water with no product contamination. Since there is no venting of the tube, the tube volume will be reduced by the amount of product dispensed. This causes the tube to collapse. It will continue to collapse with each dispensing cycle.

The class 1, or inverted, vented automatic dispensing cap is similar to the non-vented automatic dispensing cap described above with the exception of adding a side entry venting port connected to a groove on the bottle side of the body, just above the bottle neck. The port allows replacement air to enter directly into the bottle.
In order to pressurize the bottle and pressure chamber when the bottle is squeezed, a flat donut shaped highly flexible and elastic flapper valve is used to seal the venting groove. The outside diameter of the flapper valve is retained by and sealed against the bottle side of the body by a combination valve retainer and bottle seal. The upper face of the flapper valve near its inside diameter is seated against and is stretched over a shallow conical shaped portion of the container side of the body, thus sealing the shallow groove.

Bottles that require venting are made of a resilient material that returns to the original shape or volume prior to squeezing. When the inverted bottle is squeezed, the product is forced through the port of the body and into the pressure chamber. Since the flapper valve is sealed against the body, the product cannot enter the venting groove of the bottle, therefore, the product pressure will cause the cap to move way front the body which will deflect the cantilever springs and move the dispensing hole away from the valve, thus allowing the product to be dispensed.

When the bottle is released, the product pressure drops and the cantilever springs return the cap to its original position so the dispensing hole in the cap is sealed by the valve of the body. As the bottle attempts to return to its original volume it must make up for the amount of product dispensed. This causes a slight vacuum to occur in the bottle. Since the dispensing hole is sealed, and there is no venting in the pressure chamber, the vacuum in the bottle will cause atmospheric pressure present on the vented side of the body to enter the venting port and groove and unseat the flapper valve secured to the bottle side of the body, thereby allowing replacement air to enter the container directly. After the replacement air is introduced in the bottle, the flapper valve reseals the pressure side of the body.

The class 2 (upright) vented automatic dispensing cap is identical to the class 1 (inverted) vented automatic dispensing cap with the exception of adding a pressure tube that is secured into the port on the bottle side of the body and extends to the lower part of the bottle. When the upright bottle is squeezed, the pressure in the bottle forces the product through the tube and the port in the body and into the pressure chamber. All functions relating to the dispensing cycle and the introduction of replacement air back into the bottle are the same as the class 1, vented automatic dispensing cap. Beltching into the bottle as the previously described and cannot enter the pressure chamber because the tube isolates the pressure chamber from the air in the bottle.

Several variations of the above are described in the following text and drawings. They include a nozzle type retainer cap for applying product to a specific area, a non-vented automatic dispensing cap having a floatation collar that causes the tube to float when used in a bath tub for such products as soap, shampoo and body lotion, and a side outlet dispensing spout for use when the automatic dispensing cap can be operated with the container in the vertical or near vertical position such as the non-vented automatic dispensing cap or the class 2, vented automatic dispensing cap.

Now turning to the Drawings, FIG. 3 shows a removable type of a non-vented automatic dispensing cap formed of body 4 that is threaded to conventional tube 5. Threadably secured to body 4 is retainer cap 1 having product-dispensing hole 8 shown in FIG. 2, which operates in a two chamber cylinder formed by body 4 and retainer cap 1. The large diameter of piston 2 has a sealing lip that contacts the inner surface of retainer cap 1. The hollow rod of piston 2 has a sealing lip that contacts the inner surface of body 4. Piston 2 has integral valve 6 that engages and seals product-dispensing hole 8. Coil spring 3 operates between piston 2 and body 4. Chamber 10 is vented to the atmosphere by venting hole 11.

When tube 5 is squeezed, a pressure develops causing the product in tube 5 to flow through port 7 of piston 2 into pressure chamber 9 formed by piston 2 and retainer cap 1. As the pressure increases on piston 2 in chamber 9, the preset biasing force of coil spring 3 is exceeded, causing piston 2 and valve 6 to move away from the position that seals dispensing hole 8, thus allowing the product to flow through dispensing hole 8 until the squeezing action on tube 5 ceases.

When the squeezing action ceases, the pressure will drop and the force from coil spring 3 will cause piston 2 and valve 6 to return to the sealing position. As this occurs, any product at dispensing hole 8 will be expelled as valve 6 seals hole 8, therefore preventing any opportunity for ambient material or air to enter hole 8. After the squeezing action ceases, the consumer merely wipes the product from the flat surface of retainer cap 1 and the nearly flush surface of valve 6.

FIG. 3B shows the automatic dispensing cap in the locked position. To lock the automatic dispensing cap, retainer cap 1 is generally rotated in a clockwise direction, advancing on threads 15 until retainer cap 1, being engaged with valve 6 at dispensing hole 8, forces piston shoulder 16 against face 17 of body 4. When this occurs, the rotation of retainer cap 1 is stopped and dispensing hole 8 is sealed by valve 6.

To return the automatic dispensing cap to the operating position, as shown in FIG. 3A, retainer cap 1 is rotated in the opposite direction until rotation stop 12, shown in FIG. 10, engages stop lug 13. Deflection of stop lug 13 is limited by lug 14. The configuration of lugs 13 and 14 allows rotation stop 12 to deflect stop lug 13 sufficiently for rotation stop 12 to pass over lug 14, during the assembly of retainer cap 1.

FIG. 4 shows a removable type of a non-vented automatic dispensing cap formed of body 20 that is threaded to conventional tube 28. Threadably secured to body 20 is retainer cap 24 having product-dispensing hole 8 shown in FIG. 2. Piston 2 operates in a two chamber cylinder formed by body 20 and retainer cap 24. The large diameter of piston 2 has a sealing lip that contacts the inner surface of retainer cap 24. The hollow rod of piston 2 has a sealing lip that contacts the inner surface of body 20. Piston 2 has integral valve 6 that engages and seals product-dispensing hole 8. Leaf springs 21, seen in FIG. 7, which are integral with body 20, operate between piston 2 and body 20. Chamber 26 is vented to atmosphere by venting hole 27.

The operation of the automatic dispensing cap 4 is identical to the operation of the automatic dispensing cap in FIG. 3.

FIG. 4 shows the automatic dispensing cap in the operating position. The locking feature works the same as the automatic dispensing cap in FIG. 3. However, when retainer cap 24 is rotated to the operating position, rotation stop 23, seen in FIG. 5, engages stop lug 22, thereby preventing any further rotation. The configuration of stop lug 22 allows it to be deflected by rotation stop 23 during the assembly of retainer cap 24 to body 20.

The automatic dispensing cap in FIG. 8 has a retainer cap 30 with an extended nozzle 33. Piston 34 has
valve extension 31 and integral valve 32. Valve 32 is configured to seat in the tapered dispensing hole of nozzle 33.

[0102] The operation of the automatic dispensing cap in FIG. 8 is identical to the operation of the automatic dispensing cap in FIG. 3. The locking feature also is the same.

[0103] FIG. 11 shows a variation of a retainer cap for a non-vented automatic dispensing cap modified to provide a floatation ring. Retainer cap 37 is provided with an outer air chamber 38 formed by integral circular base wall 40, and integral outer ring 39. Sealing cap 41 is secured to retainer cap 37 and outer ring 39, thereby forming air chamber 38 to provide the desired floatation.

[0104] FIG. 12 shows a class 1, removable type of vented automatic dispensing cap formed of body 46 that is threaded to squeezy bottle 59. Threadably secured to body 46 is retainer cap 45 having product-dispensing hole 56 shown in FIG. 13. Piston 47 operates in a two chamber cylinder formed by body 46 and retainer cap 45. The large diameter of piston 47 has a sealing lip that contacts the inner surface of retainer cap 45. The hollow rod of piston 47 has a sealing lip that contacts the inner surface of body 46. Piston 47 has integral valve 51 that engages and seals product-dispensing hole 56. Coil spring 49 operates between piston 47 and body 46. Chamber 50 is vented to atmosphere by vent hole 53. Piston 47 has shallow venting groove 58 and venting hole 57 shown in enlarged section in FIG. 14. The lower face near the outside diameter of flapper valve 48 is secured to piston 47. The lower face near the inside diameter of flapper valve 48 is stretched over shallow conical surface 60 of piston 47, thereby providing a seal between pressure chamber 54 and vented chamber 50 when the pressure in both chambers are nearly equal as shown in FIG. 12.

[0105] Generally the class 1 (inverted), vented automatic dispensing cap is used with a squeezy bottle that is stored in the inverted position. When the inverted bottle 59 is squeezed, a pressure develops causing the product in bottle 59 to flow through port 52 of piston 47 into pressure chamber 54 formed by piston 47 and retainer cap 45. As the pressure increases on piston 47 in chamber 54, the preset biasing force of coil spring 49 is exceeded, causing piston 47 and valve 51 to move away from the position that seals dispensing hole 56, thus allowing the product to flow through dispensing hole 56 until the squeezing action on bottle 59 ceases.

[0106] When the squeezing action ceases on bottle 59, the pressure will drop and the force from coil spring 49 will cause piston 47 and valve 51 to return to a position that seals hole 56. After the squeezing action ceases, the consumer merely wipes the product from the flat surface of retainer cap 45 and the nearly flush surface of valve 51. Since the vented automatic dispensing cap is generally used with a bottle that is stored with the cap down, a shallow concave surface for retainer cap 45 may benefit the stability for storing and provide a slight clearance at dispensing hole 56. As bottle 59 tries to return to its original volume it must make up for the amount of product dispensed. This causes a vacuum to occur in container 59 and in chamber 54, which in turn will cause atmospheric pressure present in the vented side of piston 47 by means of vent hole 53 in body 46 to enter venting port 57 and shallow venting groove 58 of piston 47 and unseat flapper valve 48 as shown in FIG. 14. This allows air to enter container 59 by way of chamber 54 and make up the volume lost during dispensing. Since it requires a pressure differential to unseat flapper valve 48, flapper valve 48 acts as a check valve, therefore there can be no chance of reverse flow or product leakage through flapper valve 48. After the replacement air volume is introduced in container 59, flapper valve 48 reseals the pressure side of piston 47.

[0107] FIG. 16 shows a class 2 (upright), removable type of vented automatic dispensing cap formed of body 75 that is attached to squeezy bottle 78. Threadably secured to body 75 is retainer cap 70 having product-dispensing hole 81 shown in FIG. 17. Piston 73 operates in a two chamber cylinder formed by body 75 and retainer cap 70. The large diameter of piston 73 has a sealing lip that contacts the inner surface of retainer cap 70. The hollow rod of piston 73 has a sealing lip that contacts the inner surface of body 75. Piston 73 has integral valve 72 that engages and seals product-dispensing hole 81. Coil spring 79 operates between piston 73 and body 75. Chamber 74 is vented to atmosphere by vent slot 76 of body 75. Body 75 has shallow groove 80 and venting hole 84 shown in enlarged section in FIG. 18. The upper face near the outside diameter of flapper valve 77 is secured to the lower face of body 75. The upper face near the inside diameter of flapper valve 77 is stretched over shallow conical surface 83 of body 75, thereby providing a seal between container 78 and vented chamber 74 when the pressure in container 78 and chamber 74 are nearly equal, as shown in FIG. 16. Tube 85 is secured to body 75 and extends to the lower portion of bottle 78.

[0108] The class 2 (upright), vented automatic dispensing cap is used with a squeezy bottle that is stored in the upright position. When the upright bottle 78 is squeezed, a pressure develops causing the product in bottle 78 to flow through tube 85 and port 82 of piston 73 into pressure chamber 71 formed by piston 73 and retainer cap 70. As the pressure increases on piston 73 in chamber 71, the preset biasing force of coil spring 79 is exceeded, causing piston 73 and valve 72 to move away from the position that seals dispensing hole 81, thus allowing the product to flow through dispensing hole 81 until the squeezing action on bottle 78 ceases.

[0109] When the squeezing action ceases on bottle 78, the pressure will drop and the force from coil spring 79 will cause piston 73 and valve 72 to return to a position that seals hole 81. After the squeezing ceases, the consumer merely wipes the product from the flat surface of retainer cap 70 and nearly flush surface of valve 72.

[0110] As bottle 78 tries to return to its original volume, it must make up for the amount of product dispensed. This causes a vacuum to occur in container 78, which in turn will cause atmospheric pressure present in chamber 74 to enter venting hole 84 and shallow venting groove 80 of body 75 and unseat flapper valve 77, as shown in FIG. 18. This allows air to enter container 78 and replace with air the product volume lost during dispensing. Since it requires a pressure differential to unseat flapper valve 77, flapper valve 77 acts as a check valve. Therefore, there can be no chance of reverse flow or product leakage through flapper valve 77. After the replacement air volume is introduced in container 78, flapper valve 77 reseals the pressure side of body 75.

[0111] The class 2 (upright) vented automatic dispensing cap shown in FIGS. 20 and 21 has retainer cap 90 with dispensing hole 92 leading through outlet spout 91 to port 93.

[0112] When the upright bottle 78 is squeezed, the product will flow through dispensing hole 92 as described previously for class 2 (upright), vented automatic dispensing cap shown in FIG. 16, from dispensing hole 92, the product will flow through port 93 and exit spout 91. During the squeezing action, the product is dispensed into the palm of the consum-
er's hand. For very low viscosity products a slight angle port may be used to prevent dripage.

[0113] A side outlet retainer similar to the one shown in FIG. 20 can be used with the squeezable tube shown in FIG. 1. For certain applications, this may be preferred by the consumer.

[0114] FIGS. 12 and 16 show the vented automatic dispensing cap in the operating position. A locking feature similar to the one for the non-vented automatic dispensing cap shown in FIG. 3 can be used with the vented automatic dispensing cap.

[0115] FIGS. 22 and 23 show another automatic dispensing cap on a conventional tube 103. FIGS. 24 and 25 show an automatic dispensing cap on a resilient bottle 124.

[0116] FIG. 26 shows a removable non-vented automatic dispensing cap including of body 102 that is threaded to squeezable tube 103. Body 102 has lip seal 105, port 117 and valve 106. In addition, body 102 has two horizontal lugs 107, two primary vertical lugs 108 and two secondary vertical lugs 111 shown in FIG. 27. Operating with body 102 is cap 101 including of dispensing hole 104, two cantilever springs 109 having knob 113 that are attached to inside of cap 101 at area 110. When assembled, diameter 115 of cap 101 engages lip seal 105 of body 102 forming pressure chamber 116.

[0117] After cap 101 is assembled to body 102 and rotated to the locked position of FIG. 32, the lower surfaces of primary vertical lugs 108 are engaged with area 110 of springs 109 forcing dispensing hole 104 of cap 101 against valve 106 of body 102, thereby sealing the automatic dispensing cap for storage. This initial rotation also causes cantilever springs 109 to be deflected by horizontal lugs 107 and for knobs 113 of springs 109 to engage lugs 107 at angled surfaces 112.

[0118] To set the automatic dispensing cap to the automatic dispensing positioning, FIG. 30, the rotation of cap 101 is reversed to a positive stop where knob 113 of springs 109 will then be engaged in notch 114 at stepped portion of lug 107. In this position, the cantilever spring 109 develops a biasing force on cap 101, which causes dispensing hole 104 to engage valve 6 to effectively seal the automatic dispensing cap.

[0119] The engagement of knob 113 in notch 114 provides a detent to prevent cap 101 from accidentally being rotated from the automatic dispensing position. With the automatic dispensing cap in the auto position, secondary vertical lugs 111 will limit the vertical travel of cap 101 contacting area 110 of cantilever spring 109 if an accidental separating force is applied to cap 101.

[0120] When tube 103 is squeezed, while the automatic dispensing cap is in the automatic dispensing position, a pressure develops causing the product in tube 103 to flow through port 117 into pressure chamber 116. As the pressure increases on cap 101 in pressure chamber 116, the biasing force of cantilever springs 109 is exceeded, causing cap 101 to move away from the position that seals dispensing hole 104 with valve 106. FIG. 26B, thus allowing the product to flow through dispensing hole 104 until the squeezing action on tube 103 ceases.

[0121] When the squeezing ceases, the pressure will drop and the force from cantilever springs 109 will cause valve 106 to return into dispensing hole 104 of cap 101. As this occurs, any product at dispensing hole 104 will be expelled as valve 106 seals dispensing hole 104, therefore, preventing any opportunity for ambient material or air to enter hole 104. After squeezing action ceases, the consumer merely wipes the product from the flat surface of cap 101 and the flush surface of valve 106.

[0122] When the squeezing ceases, the pressure will drop and the force from cantilever springs 109 will cause valve 106 to return into dispensing hole 104 of cap 101. As this occurs, any product at dispensing hole 104 will be expelled as valve 106 seals dispensing hole 104, therefore, preventing any opportunity for ambient material or air to enter hole 104. After squeezing action ceases, the consumer merely wipes the product from the flat surface of cap 101 and the flush surface of valve 106.

[0123] FIG. 26C shows cap 101 being formed of cup 101A and spring ring 101B. These separate parts may be produced with less costly molds. Multiple cups 101A having various size dispensing holes 104A may be matched to a common spring ring 118 for further cost consideration. Effectively, cup 10A and spring ring 10B become one piece, i.e. cap when they are pressed together. Alternatively, the manufacturer may consider one piece cap 101, FIG. 26 more efficient because fewer parts need to be handled.

[0124] FIG. 33 shows a class 1 (inverted) vented automatic dispensing cap secured to squeezable bottle 124 and formed of body 121 and cap 120. Cap 120 is configured much like cap 101 shown in FIG. 26 and in some cases can be used interchangeably. Body 121 has many of the elements of body 102 shown in FIG. 26 such as the primary and secondary vertical lugs shown as item 128 and horizontal lug 129. Referring to enlarged section FIG. 35, body 121 has venting hole 125 that connect to venting groove 131. Highly flexible flapper valve 126 is secured to body 127 by retaining seal 126A that is pressed into body 121 and engages the neck face of bottle 124. During installation, flapper valve 126 is stretched over conical face 128 of body 121 effectively sealing venting groove 131. Again referring to FIG. 33, a tapered ring 123 of bottle 124 is shown engaging and securing taper ring 122, of body 121 such that when body 121 is pressed onto the neck of bottle 124, the taper rings will deflect sufficiently to cause the engagement indicated. If required, slots in appropriate portions around hub 132 of body 121 could be added to allow easier assembly of body 121 to bottle 124. It should be noted that the above is one of several means of securing the vented automatic dispensing cap to a squeezable bottle.

[0125] It should also be noted that the elements and function shown in FIGS. 27, 28, 29, 30, 31, and 32 and described in previous text apply to the vented automatic dispensing cap.

[0126] Generally the Class 1 vented automatic dispensing cap is used with a squeezable bottle that is stored in the inverted position. When the inverted bottle 124 with the automatic dispensing cap in the automatic dispensing position (FIG. 30) is squeezed, a pressure develops causing the product in bottle 124 to flow through port 133 of body 121 into pressure chamber 134 formed by lip seal 129 and inside diameter of cap 120. As pressure increases on cap 120 in pressure chamber 134, the preset biasing force of cantilever springs 134 is exceeded causing cap 120 to move away from the position that seals dispensing hole 130 of cap 120 with valve 128 of body 121, thus allowing the product to flow through dispensing hole 130 until the squeezing action on bottle 124 ceases.

[0127] When the squeezing action ceases, the pressure drops and the force from cantilever springs 135 will cause cap 120 to return dispensing hole 130 to seal against valve 128. As this occurs, any product at dispensing hole 130 will be expelled as valve 128 seals dispensing hole 130. At this point, the consumer merely wipes off the product from the flat surface of cap 120.
As bottle 124 tries to return to its original volume to make up for the amount of product dispensed, a vacuum occurs in container 124, which in turn causes atmospheric pressure to enter venting port 125 and venting groove 131 of body 121 and unseal flapper valve 126 as shown in FIG. 35. This allows replacement air to enter container 124 and make up the product volume lost during dispensing. Since it requires a pressure differential to unseal flapper valve 126, flapper valve 126 acts as a check valve, therefore there can be no chance of reverse flow of product leakage through flapper valve 126. After the makeup volume is introduced in container 124, flapper valve 126 reseals the pressure side of body 121.

The class 2 (upright) vented automatic dispensing cap is shown in FIG. 36. It is identical to the class 1 automatic dispensing cap shown in FIGS. 33, 34, 35 with the exception of adding pressure tube 140. Pressure tube 140 is secured into port 133 of body 121 and extends to the lower port of the bottle.

When upright bottle 124 is squeezed with the automatic dispensing cap in the automatic dispensing position, the pressure in bottle 124 forces the product through tube 140 and port 133 into pressure chamber 134. All functions relating to the dispensing cycle and the introduction of replacement air back into bottle 124 are the same as the class 1 automatic dispensing cap described above and shown in FIG. 33.

The class 2 vented automatic dispensing cap shown in FIGS. 37 and 38 has cap 141, dispensing hole 142, outlet port 143 and side outlet spout 144.

When the upright bottle 124 is squeezed, the product will flow through dispensing hole 142 as described previously for class 2 vented automatic dispensing cap shown in FIG. 36. From dispensing hole 142, the product will flow through outlet port 143 and exit spout 144. During the squeezing action, the product is dispensed into the palm of the consumer's hand. For very low viscosity products, a portion that is angled slightly upward may be used to prevent dripping.

The automatic dispensing cap in FIG. 39 has a cap 148 with an extended nozzle 150. Body 149 has valve extension and integral valve 151. Valve 151 is configured to seal in tapered dispensing hole 152 of nozzle 150. The operation of the automatic dispensing cap in FIG. 39 is identical to the operation of the automatic dispensing cap in FIG. 26. The locking feature is also the same.

The valve that is integral with the piston or body can be configured to suit the application. The drawings disclose a flat face seal, a spherical faced seal and a tapered seal.

FIG. 41 depicts an exemplary class 1 (inverted) vented automatic dispensing cap 200 on a squeeze bottle 250 having features similar to those noted above but with some modifications and additional features. As shown in FIGS. 42A and 42B, the dispensing cap 200 has two separable components: the retaining cap 202 and the body 220.

The dispensing cap 200 is removably secured to the neck 240 of the squeeze bottle 250, which includes a set of locking threads 242 around its outside surface which interface with the retaining cap 202, as further described below, and an upper lip 244 upon which the body 220 rests, as further described and shown. The primary design constraints of the bottle neck 240 are that it form a suitable component of the squeeze bottle 250, and that the placement of the locking threads 242 are the correct distance from the upper lip 244 to correctly limit the motion of the retaining cap 202 relative to the body 220 as shown.
seal 228 allows for venting of the bottle 250 to occur, this feature may partially or fully replace the need for a flapper valve for venting air as described above. In one embodiment, the lip seal 228 may represent a tapering plastic membrane approximately 0.13 mm thick at its upper edge. The lip seal 228 may be made of any appropriate material; for example, a thermoplastic elastomer such as the copolyester ARNITEL®, manufactured by DSM Engineering Plastics, may be used.

[0141] In FIGS. 44-46 a variation of the locking feature is shown wherein locking threads 242 provide the locked and unlocked positions described above. Here, nubs 208 on opposing sides of the interior of the retaining cap 202 interface with the threads 242 to limit the venting of the retaining cap 202. When each nub 208 is aligned at the lowest portion of its thread 242b, the dispensing cap 200 is in a locked position. The horizontal thread portion 242b prevents the external cap member 202 from moving sufficiently to unseat the valve member 226, and the dispensing cap 200 stays closed. When each nub 208 is aligned with the upper portion of its thread 242a, the dispensing cap 200 is in its unlocked position. The valve member 226 can fully unseat sufficient to allow dispensing of the liquid, while the position of the nubs 208 under the threads 242 still secures the retaining cap 202 so that it does not completely detach from the other components. Although the threads 242 are shown with steps, will be understood that an angled thread may also serve to control the flow and allow the user to alternate between locked and unlocked positions.

[0142] In another embodiment, shown in FIGS. 47-48, alternative locking threads 242 may be provided. These threads may have, in addition to fully locked and fully unlocked positions as described above, intermediate positions that restrict fluid flow without preventing it altogether. The intermediate positions are represented by intermediate portions 242c of the thread 242. When the nub 208 is aligned with an intermediate portion 242c, the motion of the retaining cap 202 is limited in the maximum distance that the plug 226 can unseat from the aperture 206 upon squeezing the bottle 250, limiting the flow of liquid through the aperture 206. Although the graduated thread 242 is shown as a series of horizontal steps, it will be understood that an angled thread may also serve to control the flow and allow for intermediate positions between fully locked and unlocked positions.

[0143] While dispensing cap 200 has been shown and described herein as interfacing directly with a neck 240 integral with the squeeze bottle 250, it will be appreciated that a separate bottle neck adapter 240l, shown in FIG. 49, could be provided. In such an embodiment, the external thread features suitable for mating with the retaining cap 202 and body 220 as herein disclosed would be included on the adapter, and the adapter 240l would accommodate the neck of the bottle, such as having internal threads 240l adapted for mating with the threads associated with a screw-cap bottle neck as known in the art. In such an embodiment, the features of the neck 240 are essentially separate from the bottle rather than being integral therewith as shown in FIGS. 41-48.

[0144] It should be noted that all configurations of the automatic dispensing cap could alternatively use either the coil spring or the leaf spring design and the associated locking arrangement shown and described above. It should also be noted that a class 2 vented automatic dispensing cap could be used as a class 1 (inverted), vented automatic dispensing cap by eliminating tube 85.

[0145] A resilient material such as plastic may be used to create the automatic dispensing cap. The material selected preferably has the necessary stress relaxation times and rates to perform as described herein.

[0146] Many features have been listed with particular configurations, options, and embodiments. Any one or more of the features described may be added to or combined with any of the other embodiments or other standard devices to create alternate combinations and embodiments.

[0147] Although the examples given include many specificities, they are intended as illustrative of only one possible embodiment of the invention. Other embodiments and modifications will be apparent to those skilled in the art. Thus, the examples given should only be interpreted as illustrations of some of the preferred embodiments of the invention, and the full scope of the invention should be determined by the appended claims and their legal equivalents.

What is claimed is:

1. An automatic dispensing cap for use with a container, the automatic dispensing cap comprising:
   a body comprising a sealing lip and a protrusion, and a retainer cap connected to the body and having a chamber therein and a dispensing aperture in fluid communication with the chamber,
   wherein the retainer cap can move relative to the body between a closed position wherein the protrusion is seated in the dispensing aperture to prevent fluid flow through the dispensing aperture, and an open position wherein the protrusion is unseated from the dispensing aperture to allow fluid flow through the dispensing aperture,
   wherein the retainer cap is resiliently biased toward the closed position, and
   wherein the sealing lip is resiliently biased against the retainer cap and acts as a one-way valve to prevent fluid from exiting the chamber and to allow air to enter the chamber.

2. The automatic dispensing cap of claim 1, wherein the sealing lip is a plastic membrane less than approximately 0.5 mm in thickness.

3. The automatic dispensing cap of claim 1, further comprising a spring member operatively coupled to the retainer cap, the spring member resiliently biasing the retainer cap toward the closed position.

4. The automatic dispensing cap of claim 3, wherein the body has a plurality of spring members protruding therefrom, the body positioned in the interior of the retainer cap with the spring members contacting an inner surface of the retainer cap.

5. The automatic dispensing cap of claim 1, wherein the retainer cap is rotatable between a locked position wherein the retainer cap is constrained from moving into the open position, and an unlocked position wherein the retainer cap is not constrained from moving into the open position.

6. The automatic dispensing cap of claim 5, wherein the retainer cap is rotatable between the locked and unlocked positions and an intermediate position, and wherein the motion of the retainer cap in the intermediate position is sufficient to at least partially unseat the protrusion to allow fluid flow through the dispensing aperture but more constrained than when the retainer cap is in the open position.

7. A valve member for an automatic dispensing cap, comprising:
a cylindrical body having a longitudinal axis defining upwards and downwards directions and a circumferential outer wall having upper and lower edges;

a protrusion disposed upwardly along the longitudinal axis;

a plurality of openings disposed radially between the protrusion and the circumferential outer wall, the openings suitable for the passage of fluid in a direction upwards through the cylindrical body;

a plurality of spring members disposed radially outwardly from the outer circumferential wall, the spring members being spaced to allow air to pass in a direction upwards between the spring members along the outer circumferential wall; and

a circumferential sealing lip having inner and outer surfaces extending upwardly from the upper edge of the circumferential outer wall, the sealing lip sufficiently flexible to bend radially inwardly as a result of a difference in air pressure against the inner and the outer surfaces of the sealing lip.

8. An automatic dispensing cap, comprising:
the valve member of claim 5; and

a retaining cap comprising
an upper surface comprising an aperture, the aperture sized and positioned to receive the protrusion; and
an annular outer wall with an inner surface positioned around the cylindrical body such that the circumferential sealing lip presses against the inner surface forming a one-way seal that prevents fluid from exiting the retaining cap but permits air to enter the retaining cap;

wherein the inner surface of the outer wall of the retaining cap engages the spring members to resiliently bias the retaining cap against the valve member such that the protrusion is seated in the aperture.

9. The automatic dispensing cap of claim 8, wherein the retaining cap is responsive to upward pressure on its upper surface such that when the cap is attached to a squeeze bottle, squeezing the bottle results in sufficient pressure to move the retaining cap against the resilient bias of the spring members and unseat the protrusion, allowing product to dispense through the aperture.

10. An automatic dispensing cap for use with a container, the automatic dispensing cap comprising:
a body operatively coupled to the container;
a retainer cap having an interior surface, the retainer cap connected to the body;
a pressure chamber within the retainer cap, the pressure chamber in fluid communication with an interior of the container;
a dispensing hole exiting the pressure chamber;
a protrusion engageable with the dispensing hole, the automatic dispensing cap having a closed position wherein the protrusion seals the dispensing hole, and an open position wherein the dispensing hole is unobstructed by the protrusion;
a spring member biasing the automatic dispensing cap in the closed position; and

a sealing lip configured to contact the inner surface of the retainer cap, the sealing lip further configured to permit air to enter the pressure chamber in order to vent the container.

11. The automatic dispensing cap of claim 10,
wherein the dispensing cap in the open position permits a first nonzero flow rate through the dispensing hole; and
wherein the automatic dispensing cap has an intermediate position permitting a second nonzero flow rate through the dispensing hole that is less than the first nonzero flow rate.

12. The automatic dispensing cap of claim 11, wherein the closed, intermediate, and open positions are each associated with distinct rotational orientations of the retainer cap such that the dispensing cap can be moved from one position to another by rotation of the retainer cap.

13. A squeeze container for dispensing liquid, comprising:
the automatic dispensing cap of claim 10; and

a resiliently deformable container having liquid therein, the container coupled to the automatic dispensing cap such that squeezing the container results in the automatic dispensing cap moving from a closed position to an open position, liquid dispensing from the container through the dispensing hole, the automatic dispensing cap moving back from an open position to a closed position, and air venting past the sealing lip into the container.
