(54) Titre : APPAREIL ET TECHNIQUE DE FORAGE DIRECTIONNEL AVEC SERPENTIN

(54) Title: APPARATUS AND METHOD FOR DIRECTIONAL DRILLING WITH COILED TUBING

(57) **Abrégé/Abstract:**

An improved coiled tubing directional drilling method comprises: providing a bent housing which is rotatably coupled to the coiled tubing, rotating the drill bit, and rotating the bent housing. Apparatus for achieving the method comprises: a rotary connection between the coiled tubing and the bent housing and means for rotating the bent housing relative to the coiled tubing and to the drill bit. A fluid pressure-operated clutch enables alternate rotation and locking of the bent housing. Preferably, a first downhole motor rotates the drill bit and a second downhole motor rotates the bent housing through the clutch or alternately a speed reducer permits the bent housing to contra-rotate slowly under reactive torque developed by the rotating drilling bit.

3
4 FIELD OF THE INVENTION

5 The present invention relates to directional drilling with coiled
6 tubing. More particularly, bottom hole assembly apparatus including an orienting
7 tool driven through a clutch and mud motor, a bent housing and a mud motor
8 driving a drill bit.

9
10 BACKGROUND OF THE INVENTION

11 In conventional jointed tubing directional drilling, a drilling assembly,
12 bent housing and motor are located at the downhole end of a rotary drill string.
13 Additionally, a measurements-while-drilling (MWD) tool is used to signal drilling
14 orientation and direction. Directional drilling is accomplished with an alternating
15 combination of two drilling operations; a relatively short duration of steering or
16 sliding; and a longer period of rotating. The result is a relatively continuous and
17 curved borehole from the kick off point to the end of the curve.

18 More specifically, during the sliding operation, the drill string is
19 slowly rotated to orient the bent housing in the desired direction. The mud motor
20 is then energized so as to drill a curved path in the oriented direction. The non-
21 rotating drill string slides along the borehole as the mud motor drills the curved
22 path. The sliding phase is necessary for adjusting or setting the direction of the
23 borehole path, however this phase is somewhat inefficient due to factors
24 including: the indirect angular path, the drag of the sliding drill string, and the sole
25 use of the mud motor. Once the desired borehole inclination is established, a
26 rotating operation commences which uses a combination of simultaneously

1 rotating the mud motor/drill bit and the drill string (which continuously rotates the
2 bent housing) and which favorably results in both a higher rate of penetration
3 (ROP) and a substantially linear path.

4 In conventional coiled tubing directional drilling, the coiled tubing
5 cannot be rotated and thus is unable to implement the higher efficiency rotating
6 operation available with jointed tubing drilling. A sliding-only operation is
7 achieved using a bottom hole assembly (BHA) mounted at the downhole end of
8 the coiled tubing. The BHA comprises a MWD tool, a mud motor, an orientor, a
9 bent housing and a drill bit. The flow of mud through the coiled tubing and mud
10 motor rotates the drill bit.

11 In coiled tubing directional drilling, the driller sets the build-up rate,
12 which is a measure of increasing borehole inclination from vertical, by setting the
13 angle of the bent housing at the surface. The angle of the bent housing, typically
14 $\frac{1}{2}$ to 3° from the axis of the tubing, sets the drill bit toolface angle. The bent
15 housing angles are typically invariant, and once downhole, the angle is generally
16 fixed until such time as the string is tripped-out and the angle of bent housing is
17 changed at the surface. The orientor can be incrementally rotated while
18 downhole to redirect the bent housing. The orientor is actuated remotely through
19 a cycling of the pressure of the mud in the coiled tubing. Accordingly, the
20 conventional coiled tubing directional drilling mode available to the applicant is a
21 serpentine or tortuous path resulting from successive implementation of sliding
22 operations; first drilling an arcuate path one direction (build) and, when so
23 indicated by the MWD, an arcuate path in an opposing (drop) direction.

24 In patent application WO 97/16622 to Rigden et al., a system is
25 disclosed which uses an upper motor which, through a pivot, rotatably drives a

1 section of drill pipe having a bend sub and second mud motor and drill bit. The
2 upper motor is supported from the coiled tubing. A coupling device is positioned
3 between the upper motor and the lower drill pipe. Coupled, the upper motor
4 rotates the lower drill pipe, bent housing and drill head resulting in straight drilling.
5 Un-coupled, the drill head drills in the last orientation. The preferred coupling
6 device is a flow rate controlled device positioned uphole from the upper motor. A
7 fixed sleeve has a first port exposed to the drilling mud directed to the drill head.
8 A second outer sleeve has a piston exposed to the mud and a resisting spring.
9 At low mud flow rates, the force of the piston cannot overcome the spring and
10 100 % of the mud flows to the drill head for directional drilling. At higher mud
11 rates, the force of the piston overcomes the spring and the outer sleeve slides
12 over the first sleeve, aligning a second port in the second sleeve with the port in
13 the first sleeve. A portion of the mud flow is redirected into an annular passage
14 for driving the upper motor. The speed of rotation of the drill pipe is wholly
15 controlled by mud flow, the response of the spring constant, and the variable
16 sleeve movement. When directional drilling, reactive torque in the drill pipe is
17 presumably fed back in to the upper motor.

18 In WO 93/10326 to Hallundbaek, referred to in WO 97/16622, a
19 system using reactive torque is utilized. No upper motor is employed. Drill bit
20 and toolface interaction results in reactive torque being transmitted along the bent
21 sub. A pivot between the bent sub and the coiled tubing permits contra-rotation.
22 The speed of rotation is controlled using a brake comprising a complex
23 arrangement of a plurality of hydraulic pump devices stacked in the annulus of
24 the swivel. Each hydraulic pump assembly comprises a radial array of small
25 hydraulic pistons and cylinders, the pistons normally driving a circumferential cam

1 in pump mode. In reverse, relative rotation drives the pistons and a hydraulic
2 throttle valve restricts the hydraulic flow, braking rotation therebetween. A mud
3 flow restriction is provided through the swivel for actuating a lock across the
4 swivel. At higher flow rates, increased pressure drop causes the swivel to lock
5 and enable a change of drill pipe direction. As long as flow rates are high the
6 swivel is locked and the bent sub rotates. When the flow reduces, the lock
7 disengages and contra-rotation and straight drilling resumes.

8 To date, prior art coiled tubing directional drilling apparatus and
9 methodology are associated with certain disadvantages. In the more
10 conventional single motor case, operations are restricted to a series of sliding-
11 only operations, and the disadvantages associated with the resulting and typically
12 tortuous borehole path include: reduced rate-of-penetration (ROP); toolface angle
13 drift as a result of the reactive torque; increased borehole length; reduced weight-
14 on-bit (WOB), further reductions in ROP, and increased likelihood of a stuck
15 tubing string, caused by increased frictional drag. In known dual motor
16 implementations, the variable coupling between upper motor and drill head is
17 dependent upon maintaining specified mud flow rates. Further, the means for
18 alternating between straight and sliding operations are either variably flow
19 dependent or are mechanically complex, which may result in uncertain drill pipe
20 rotation rates.

21

22

SUMMARY OF THE INVENTION

The present invention is an improved directional drilling apparatus and method for use with coiled tubing. The principle implements a BHA connected to the coiled tubing and comprises a rotary bit and a bent housing which can be rotated substantially continuously, and at will, for enabling both sliding and rotating operations, heretofore not available with coiled tubing.

In a broad aspect, a method is provided for directional drilling of non-tortuous boreholes with a coiled tubing BHA having a bent housing and a rotary drill bit, the bent housing being alternately coupled using a clutch to the coiled tubing for alternately implementing sliding operation and then rotating or straight operation by rotating the drill bit while simultaneously rotating the bent housing. The coupling comprises operation of a clutch between first and second positions, the first position for rotation of the bent housing under direct driven or reactive torque contra-rotation for straight drilling, and the second position for locking the rotation of the bent housing so as to prevent reactive rotation during sliding. Mud flow is cycled to shift the clutch between first and second positions. Subsequently, mud flow is cycled again to shift the clutch between the second and first positions. One shifted between positions, variable flow rates thereafter can be used to vary drilling characteristics in either the first or second positions without affecting the sliding or straight drilling operations. Preferably, in straight drilling, a flowmeter is also employed for providing feedback enabling monitoring of the bent housing rotation rate during straight drilling.

In a broad apparatus aspect for implementing the novel method, the apparatus comprises: a rotary connection between the coiled tubing and the bent housing. A fluid pressure-actuated clutch alternatively permits the bent housing

1 to rotate or be locked to the coiled tubing. In one embodiment, a first downhole
2 motor rotates the drill bit and a second downhole motor rotates the bent housing
3 through the clutch. In another embodiment, the first downhole motor is not
4 required, a high reduction speed reducer being positioned between the coiled
5 tubing and bent housing so as to permit the bent housing to contra-rotate slowly
6 under reactive torque developed by the rotating drilling bit. Preferably, an energy
7 dissipating device or flowmeter provides control of the rate of contra-rotation.

8

9

BRIEF DESCRIPTION OF THE DRAWINGS

10 Figure 1a is a schematic of a relatively linear borehole formed using
11 the prior art sliding and rotation operations of conventional jointed tubing
12 directional drilling;

13 Figure 1b is a schematic of a borehole having a rather tortuous
14 path formed using the prior art sliding operation of conventional coiled tubing
15 directional drilling;

16 Figure 1c is a schematic of a borehole formed using the present
17 invention with coiled tubing and being far less tortuous than that shown in Fig. 1b;

18 Figures 2 – 2ii illustrate in greater detail the apparatus and
19 operations according to the prior art of Fig. 1a; Fig. 2 illustrates the borehole
20 path; Fig. 2i illustrates the non-rotating tubing and sliding operation; and Fig. 2ii
21 illustrates the operation of rotating the tubing to drill a relatively straight borehole;

22 Figures 3 – 3ii illustrate in greater detail the apparatus and
23 operations according to the prior art of Fig. 1b; Fig. 3 illustrates the borehole
24 path; Fig. 3i illustrates the non-rotating tubing and sliding operation for build; and
25 Fig. 3ii for drop;

1 Figures 4 – 4ii illustrate in more detail implementation of an
2 embodiment of the invention which results in the borehole path of Fig. 1c; Fig. 4
3 illustrates the borehole path; Fig. 4i illustrates the non-rotating tubing, non-
4 rotating lower sub and sliding operation; and Fig. 4ii illustrates the operation of
5 rotating the lower sub to drill a relatively straight borehole;

6 Figure 5a is a simplified side view of a BHA according to the
7 present invention;

8 Figure 5b is a schematic partial view of the BHA of Fig. 5a where
9 the clutch is engaged and the lower sub rotates;

10 Figure 5c is a schematic partial view of the BHA of Fig. 5a where
11 the clutch is disengaged and the lower sub is locked against rotation;

12 Figures 6a – 8c are end-to-end detailed cross-sectional views of the
13 BHA of Fig. 5a, specifically from the second mud motor to which the coiled tubing
14 is connected and down to the connection to the lower sub, the lower sub being
15 conventional and not being detailed. More specifically:

16 Figure 6a is a cross-sectional view of the second mud motor;

17 Figure 6b is a cross-sectional view of the output driveshaft from the
18 second mud motor;

19 Figure 7a is a cross-sectional view of the pressure-balancing piston;

20 Figure 7b is a cross-sectional view of the clutch;

21 Figure 8a is a cross-sectional view of a generic planetary speed
22 reducer (not detailed);

23 Figure 8b is a cross-sectional view of the pressure-reduction piston;

24 Figure 8c is a cross-sectional view of the bearing pack and lower
25 sub connection;

1 Figure 9 is a cross-sectional view of the upper and lower hollow
2 shafts and the clutch in sliding operation, with the mandrel disengaged, at full
3 drilling fluid pressure;

4 Figure 10 is a cross-sectional view of the upper and lower hollow
5 shafts and the clutch, with the mandrel disengaged, and where the drilling fluid
6 pressure is reduced such that the barrel cam is being indexed to rotational
7 operation;

8 Figure 11 is a cross-sectional view of the upper and lower hollow
9 shafts and the clutch in rotational operation, with the mandrel engaged, at full
10 drilling fluid pressure;

11 Figure 12a is a cross-sectional view of a high reduction speed
12 reducer according to the second embodiment of the invention; and

13 Figure 12b is a cross-sectional view of the housing according to Fig.
14 6b, less the driveshaft and including a flowmeter according to the second
15 embodiment of the invention.

16

17

1 DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

2 Having reference to Figs. 1a, 2, 2i and 2ii, a schematic of a
3 relatively continuous and gradual borehole is illustrated having been formed
4 using a prior art, combined sliding (dotted lines) and rotating (continuous lines)
5 operation of conventional jointed tubing and a mud motor. As shown in the
6 schematic of Fig. 2i, the steering or sliding operation is characterized by a non-
7 rotating tubing, non-rotating bent housing and a rotating bit. As shown in Fig. 2ii,
8 the straight or rotating operation is characterized by a rotating tubing, a rotating
9 bent housing and a rotating bit.

10 In contrast to Fig. 1a, Figs. 1b, 3, 3i and 3ii illustrate an alternate,
11 tortuous and inferior borehole formed using the prior art coiled tubing and single
12 mud motor arrangement. Once again, as shown in Fig. 3i, the steering or sliding
13 operation is characterized by a non-rotating tubing, a non-rotating bent housing
14 and a rotating bit. As stated earlier, in conventional coiled tubing however, as
15 shown in Fig. 3ii, there is no rotating operation.

16 Turning to the present invention, and having reference to Figs.
17 1c,4,4i and 4ii, a relatively continuous and gradual borehole 10 can also be
18 achieved. A fanciful illustration of an embodiment of the apparatus is illustrated
19 in Figs 4-4ii. As shown, in Fig. 4i, a sliding operation is characterized by non-
20 rotating coiled tubing 11, a non-rotating bent housing 33 and a rotating bit 34. In
21 the present invention shown in Fig. 4ii, in contradistinction to the prior art, rotating
22 operation is now possible and is characterized by non-rotating coiled tubing 11, a
23 rotating bent housing 33 and a rotating bit 34.

24 Depending upon the particular embodiment either, or both of, the
25 drill bit 34 or the bent housing 33 can be rotationally driven with a motor. This

1 description uses the term motor to include an electric motor or any drilling-fluid
2 actuated motor or mud motor, examples of which are a positive displacement
3 screw motor or a turbine. In the case of a turbine, which are often coupled with
4 higher speed-capable PDC drill bits, the output rpm is generally higher than that
5 provided by a screw-type motor. Accordingly, it is understood in this specification
6 that a turbine-type of motor may be specified to be additionally coupled with a
7 gear-reducer so as to obtain a slower rpm for rotation of either the bent housing
8 or the drill bit.

9 For rotating operation, and if both the first and second motors are
10 mud motors, then drilling fluid is used to rotate both the bent housing and the drill
11 bit simultaneously.

12 More particularly and having reference also to Fig. 5a, a bottom
13 hole assembly (BHA) 19 is connected to the bottom of coiled tubing 11 which
14 extends downhole through the borehole 10. The BHA 19 comprises an upper
15 non-rotating sub 20 and a lower rotatable sub 30.

16 From the downhole end, the lower sub 30 comprises a bit 34, a
17 bent housing 33 and a first motor 32. The type and rotational speed (rpm) of the
18 first motor 32 is matched to the drill bit 34, be it a roller or a PDC type. A MWD
19 tool 31 is also fitted to the lower sub 30 for determining the BHA's orientation.
20 The lower sub 30 components can be of known and conventional configuration.

21 The novel upper sub 20 comprises a plurality of components
22 including, from its uphole end, a coiled tubing connector 21 (typically including
23 release and recovery components – not shown), a pressure-balancing sub 22, an
24 upper bearing sub 23, a clutch assembly 24, a planetary speed reducer 25, a
25 pressure reducing sub 26 and a lower bearing sub 27.

1 In a first embodiment, and having reference to Figs. 5a, 6a-8c, the
2 upper sub also includes a second motor 28 which, through the clutch assembly
3 24, is alternately disengaged or engaged for rotatably driving the lower sub 30.
4 The type and rpm of the second motor 28 can be matched for achieving bent
5 housing rotational speeds such as those typically used in conventional jointed
6 tubing directional drilling.

7 When assembled, the components of the upper sub 20 form a
8 continuous outer housing 40 and a contiguous bore 41. The contiguous bore 41
9 extends through to the lower sub 30 for conducting drilling fluids therethrough
10 and to the drill bit 34.

11 Turning to the detail drawings, as shown in Fig. 6a, the illustrated
12 second motor is, for this embodiment, a positive displacement, screw-type motor
13 28 comprising a stator 42, forming a portion of the outer housing 40, and a rotor
14 43.

15 A driveshaft 44 extends from the rotor 43 and downhole through the
16 bore 41 of the outer housing 40 for forming a drilling fluid annulus 41b
17 therebetween. The driveshaft 44 is connected to an upper hollow shaft 45. The
18 driveshaft is fitted with constant velocity joints 44a at each end, to transmit the
19 eccentric rotational action of the rotor to the centralized upper hollow shaft 45.
20 Drilling fluid flows through annulus 41b and through crossover ports 46 and into
21 the bore 41c of the upper hollow shaft 45.

22 Referring to Fig. 7a, a seal annulus 47 is formed between the outer
23 housing 40 and the upper hollow shaft 45. An annular pressure-balancing piston
24 48 is located in the seal annulus 47. The balancing piston 48 separates drilling
25 fluid in the uphole annulus 41b from clean lubricating oil downhole of the seal

1 annulus 47. The lubricating fluid is distributed along the seal annulus 47,
2 including through the clutch 24 and lower bearings 27. The upper hollow shaft 45
3 passes through upper radial thrust bearings 49. Upsets or shoulders 50 on the
4 upper hollow shaft 45 bear against the bearings 49 which are supported at
5 shoulders 51 formed on the outer housing 40. The bearings 49 center the upper
6 hollow shaft 45 and resist thrust including downhole thrust from the second mud
7 motor 28 and uphole thrust from weight on the drilling bit 34.

8 As shown in Fig. 7b, the lower end of the upper hollow shaft 45
9 terminates at an upper end of a lower input hollow shaft 52a. The upper and
10 lower input hollow shafts 45,52a can be rotationally coupled through the clutch
11 assembly 24. The clutch assembly 24 is described in greater detail in Figs 9 - 11.

12 As shown in Figs 8a-8c, the lower input hollow shaft 52a, extending
13 downhole through the outer housing 40, is decoupled through the speed reducer
14 25 and continues through a slower-rotating lower output hollow shaft 52b which
15 passes through radial bearings 53 and then continues through to the lower
16 bearing sub 27 and to a lower sub connector 54. The speed reducer 25 is of
17 conventional planetary gear design. In Fig. 8b, a pressure-reducing piston 55
18 equalizes the pressure of the lubricating fluids in the annulus 47. In Fig. 8c,
19 radial thrust bearings 53 support the lower sub connector 54 as it extends
20 through the outer housing 40.

21 Returning to Figs. 5a-5c, but not detailed herein, the lower sub 30 is
22 suspended from the lower sub connector 54. Accordingly, when the clutch 24 is
23 engaged, the upper and lower hollow shafts 45,52a,52b co-rotate and rotate the
24 lower bearing sub 30. Simply, when the lower sub 30 rotates, it emulates the
25 rotating operation achieved with conventional jointed tubing directional drilling.

1 The bent housing 33 rotates while the first motor 32 simultaneously continues to
2 rotate the drill bit 34, providing rotating operation and thus achieving high ROP
3 and a substantially linear borehole 10.

4 The ability to select sliding or rotating operation is achieved in part
5 through the selectable rotation or locking of the lower sub 30 from the coiled
6 tubing 11, the selection achieved through the clutch 24. The clutch 24 is located
7 in the upper sub 20 in this embodiment.

8 In greater detail and having reference to Figs. 7b and 9 - 11, the
9 clutch assembly 24 comprises an annular clutch collar 100 which is axially
10 movable on a spline 101 and which normally resides on the lower hollow shaft
11 52b when disengaged for sliding operation. The clutch 24 alternately engages
12 and disengages the upper and lower hollow shafts 45,52a. At a lower end 102 of
13 the upper hollow shaft 45 is a first transverse, toothed and co-rotating clutch face
14 103. A reciprocating and actuating mandrel 104, having an indexing barrel cam
15 105, uses differential fluid pressures between the pressure P2 of the fluid in the
16 borehole 10 outside the outer housing 40 and the pressure P1 of the drilling fluid
17 in the hollow shafts 45,52a, to actuate the clutch collar 100 between two axial
18 positions. The barrel cam 105 is of conventional construction and has three
19 positions. Two alternating axial uphole positions M3, M1 are enabled which
20 respectively represent an engaged and disengaged clutch. An intermediate third
21 position M2 represents the indexed cam shifting of the barrel cam 105 between
22 the two other positions M3,M1. The basic structure of the barrel cam 105 is
23 known to those of ordinary skill in the art, one example of which is provided in US
24 Patent 5,311,952 to Eddison et al., the entire disclosure of which is incorporated
25 herein by reference, (Eddison's Figs.2b,3) and thus detail is not provided. One

1 approach to achieving both M1 and M3 positions is to add an uphole stop to
2 alternating incremental cam paths (not shown).

3 The clutch collar 100 is fitted to a spline 101 at an upper end 107 of
4 the lower hollow shaft 52a. The spline 107 enables axial movement of the collar
5 100 as it co-rotates with the lower hollow shaft 52a. A second transverse,
6 toothed clutch face 108 is formed at the uphole end of the clutch collar 100 which
7 is compatible with the first toothed clutch face 103. When engaged, the first and
8 second toothed clutch faces 103,108 rotatably couple the upper and lower hollow
9 shafts 45,52a for co-rotation.

10 At the lower end of the collar 100 is formed a third transverse
11 toothed clutch face 109. A fourth transverse toothed clutch face 110 is formed at
12 a shoulder 111 formed on the outer housing 40. The fourth toothed clutch face
13 110 is compatible for coupling with the third toothed clutch face 109.

14 When the first and second clutch faces 103,108 are disengaged,
15 the third and fourth clutch faces 109,110 are engaged for locking the lower sub
16 30 from reactive torque rotation so as to enable direction steering or sliding
17 operation. Alternatively, when the first and second clutch faces 103,108 are
18 engaged, the third and fourth clutch faces 109,110 are disengaged.

19 A mandrel annulus 112 is formed between the mandrel 104 and the
20 outer housing 40 and is sealed from the lubrication fluids in the seal annulus 47
21 by a pair of upper and lower spaced mandrel seals 113a,113b. An annular
22 mandrel spring 114 bears against an upper shoulder 115 and against a lower
23 shoulder 116 on the mandrel 104 for biasing the mandrel 104 downhole. The
24 seal annulus 47 bore is constricted forming the upper shoulder 115. The upper
25 mandrel seal 113a separates the mandrel annulus 112 from the seal annulus 47

1 forming a small uphole piston face 117. The seal annulus 47 is enlarged and
2 sealed with the lower seal 113b at the lower mandrel shoulder 116 to form a large
3 downhole piston face 118. A pressure equalizing port 119 is formed between the
4 mandrel annulus 112 and the borehole 10. The indexing barrel cam 105 is fitted
5 to the lower end of the mandrel 104 and downhole from the lower seal 113b.
6 One or more lugs 120 extend radially inwardly from the outer housing 40 to
7 engage the barrel cam 105. As the mandrel 104 reciprocates axially up and
8 down, the lugs 120 and barrel cam 105 cause an indexed and incremental
9 angular rotation of the mandrel 104. At each indexed rotation, the mandrel is
10 positioned between alternating axial uphole positions M3,M1. The mandrel 104
11 itself is not freely-rotating.

12 Axial movement of the mandrel 104 is effected through a
13 combination of pressure differential P2,P1 and spring biasing.

14 The clutch collar 100 is axially manipulated between an uphole-
15 located coiled collar spring 121 and the downhole-located actuating mandrel
16 104. The collar spring 121 biases the collar 100 downhole so as to disengage
17 the first and second clutch faces 103,108 and to engage the third and fourth
18 clutch faces 109,110.

19 The collar 100 and the mandrel 104 are alternately positioned in
20 either an uphole or a downhole position. Further, the mandrel 104 has an
21 intermediate standby position.

22 The operation of the clutch is illustrated in Figs. 9-11. Sliding
23 operation is show in Fig. 9. Rotating operation is shown in Fig. 11. Pressure
24 shifting between sliding-to-rotating and between rotating-to-sliding operations is
25 shown in Fig. 10.

1 Turning first to Fig. 9, in sliding operation, the barrel cam 105 is
2 positioned low on the lugs 120 and the mandrel 104 is correspondingly in its
3 downhole position M1, without supporting the collar at face 117. Un-contested,
4 the collar spring 121 thrusts the collar 100 downhole and the third and fourth
5 clutch faces 109,110 engage, locking the lower hollow shaft 52a and the lower
6 sub 30 against rotation. Each of the collar 100, the lower hollow shaft 52a and
7 the lower sub 30 assume a non-rotating attitude with the outer housing 40.

8 Referring to Fig. 10, the barrel cam 105 is shifted to axially move
9 the mandrel 104 for rotating operation from the sliding operation of Fig. 9. The
10 shifting operation is detailed later.

11 Having reference to Fig. 11, for rotating operation, when the
12 mandrel 104 is in its uphole position M3, the uphole piston face 117 engages the
13 collar 100, thrusting it uphole and overcoming the resistance of the collar spring
14 121. The first and second clutch faces 103,108 engage and rotationally couple.
15 A thrust bearing 130 positioned between the mandrel's non-rotating uphole piston
16 face 117 and rotating collar 110 enables wear-free relative rotation therebetween.
17 Similarly, a thrust bearing 131 positioned between the non-rotating collar spring
18 121 and rotating collar 100 provides wear-free relative rotation therebetween.

19 The axial shifting of the mandrel 104 between an uphole position
20 M3 to a downhole position M1 and back again is achieved through pressure
21 cycling. Having reference to Fig. 10, the mandrel 100 is shifted between uphole
22 and downhole positions M3,M1 through cycling of the drilling fluid pressure P1;
23 an actuating pressure threshold being sensitive to the spring constant of the
24 annular mandrel spring 114. The mandrel operation is in accordance with the
25 known principle that when the small uphole piston face 117 and the large

1 downhole piston face 118 are subjected to the same pressure, the larger
2 downhole piston exerts a greater net uphole force on the mandrel 104. This net
3 uphole force is not resisted by an opposing pressure on the face of the large
4 shoulder 116 due to the communication of the mandrel annulus 112 with the
5 borehole pressure P2 through port 119.

6 Referring to Fig. 10, when the drilling fluid pressure P1 is greater
7 than the borehole pressure P2, the balancing piston 48 (Fig. 7a) is driven
8 downhole, pressurizing the lubrication fluid in the seal annulus 47 to balance the
9 drilling fluid pressure P1. The lubrication fluid communicates with the clutch 24
10 and the uphole side of the small uphole piston face 117. The lubrication
11 communicates with the clutch 24 through fluid passageways extending along the
12 annular space 47 between the outer housing 40 and the first and second hollow
13 shafts 52a,52b. The lubrication fluid further communicates with a downhole end
14 of the mandrel 104 through an annular space 132 formed between the mandrel
15 104 and the lower hollow shaft 52a.

16 The mandrel annulus 112 communicates with the borehole 10
17 through port 119. Thus, when the drilling fluid pressure P1 is less than the
18 borehole pressure P2, the pressure P2 in the mandrel annulus 112 is greater
19 than the pressure P1 of the drilling fluid and thus also that of the lubrication fluid.
20 Hence, the net force on the face 116 of the large downhole piston is downward,
21 driving the mandrel 104 downhole.

22 Note that the clutch 24 is actuated through a pressure cycle, but the
23 uphole or downhole status is dependent upon the incremental and serial
24 positioning of the three-position M1,M2,M3 barrel cam 105. For instance, if a
25 sliding operation was ongoing (Fig. 9) the mandrel's barrel cam 105 is normally

1 positioned at M1 on the lugs 120, the mandrel 104 is in a neutral position, and the
2 clutch collar 100 is disengaged. Upon a decrease of the drilling fluid pressure
3 P1, the mandrel 104 is driven further downhole to M2 by the shifted differential
4 pressure and the annular mandrel spring 114, and the barrel cam 105
5 incrementally rotates. Upon a re-pressurization of the drilling fluid P1, the
6 mandrel 104 is driven uphole to M3 to engage the collar 100, overcoming the
7 collar spring 121 and engaging the clutch 24 for rotation of the lower sub 30 by
8 the second mud motor 28.

9 Upon a subsequent decrease of the drilling fluid pressure P1, the
10 mandrel 104 is again driven further downhole to M2 by the pressure differential
11 and the mandrel spring 114. The barrel cam 105 incrementally rotates the
12 mandrel 104 to the sliding operation mode. Upon a re-pressurization of the
13 drilling fluid P1, the mandrel 104 is again driven uphole to M1 where the barrel
14 cam 105 engages a stop (not shown) which limits the uphole travel, short of
15 engaging the collar 100. Thus, the collar 100 is disengaged from the second
16 motor 28 and becomes engaged with the outer housing 40 so as to lock the lower
17 sub 30 from free-rotation.

18 In a second embodiment, one can omit the second motor 28 and
19 driveshaft 29,44. The upper hollow shaft 45 and speed reducer 25 are retained.
20 Accordingly, for rotating operation, the clutch 24 is engaged and the drill bit 34 is
21 rotated to engage the borehole 10, wherein a reactive torque is transferred to the
22 lower sub 30 through the connection of the first motor 32 to the lower sub 30.
23 The lower sub 30 rotates in the opposite direction to the drill bit 34. The lower
24 sub rotates the lower sub connector 54. To avoid transferring all the first motor
25 torque into rotation of the lower sub 30 and thus defeat the drilling process, a

1 high ratio speed reducer 25 is chosen. The speed reducer 25 is located between
2 the non-rotating upper sub 20 and the rotating lower sub 30. The rotating lower
3 sub connector 54, being connected to the low speed output shaft (such as
4 through the lower output hollow shaft 52b) attempts to rotate the high speed input
5 shaft (such as the lower input hollow shaft 52a and upper hollow shaft 45) at high
6 speed, effectively transferring the majority of the torque into the drill bit 34, with
7 only some torque being expended to rotate the lower sub 30, for rotating
8 operation.

9 The speed reducer's high speed input, such as hollow shafts
10 52a,45 can be coupled to an energy dissipation device 300 for controlling the
11 torque distribution (Fig. 12b). For returning to sliding operation, the clutch 24 is
12 disengaged, locking the lower sub 30 to the upper sub 20. In Figs. 5a-5c, the
13 illustrated first embodiment can represent the second embodiment by
14 replacement of the motor 28 and driveshaft 29 with the energy dissipation device
15 300.

16 In Fig. 12a, one form of speed reducer 25 is illustrated which is
17 well-suited to implementation in the second embodiment. The principles of such
18 a reducer are disclosed in US 4,760,759 to Blake, the entirety of which is
19 incorporated herein by reference. The speed reducer 25 is an in-line gear
20 reducer capable of high reduction rates, in the order of 100:1.

21 Specifically, the speed reducer 25 comprises an input shaft 200, a
22 floating pinion 201, a supporting tubular housing 202, and an output shaft 203.
23 The input and output shafts 200,203 co-rotate at different speeds.
24 Conventionally, the input shaft 200 is the high speed shaft and the output shaft
25 203 is the low speed shaft. The input shaft 200 is concentrically and rotatably

1 supported in the tubular housing 202. The input shaft 200 has an eccentric outer
2 shaft portion 205. The floating pinion 201 has an inner bore 206 fitted with
3 needle bearings for rotation about the eccentric outer shaft portion 205. The
4 pinion 201 therefore rotates eccentrically about the axis of the tubular housing
5 202. The pinion 201 has a large end 207 axially spaced from a small end 208.
6 Each end 207,208 is fitted with a gear face 209,210. The pinion's large end gear
7 face 209 engages a corresponding ring gear 211 in the tubular housing 202. The
8 housing's ring gear 211 has a larger pitch diameter than the pinion's gear face
9 209. As the input shaft 200 rotates, the pinion's large end gear face 209 meshes
10 with the housing gear face 211, causing the pinion 201 to contra-rotate about the
11 input shaft 200.

12 The output shaft 203 is concentrically and rotatably supported in the
13 tubular housing 202. Bearings 215 are fitted into an annulus 216 between the
14 output shaft 203 and the tubular housing 202. The annulus 216 is small and
15 needle bearings 215 are fitted therein. The output shaft 203 has an eccentric
16 bore portion 217 fitted with a small ring gear 212 which axially engages the
17 pinion's eccentric outer small end gear face 210. The eccentric rotation of the
18 pinion 201 causes the output shaft 203 to contra-rotate relative to the pinion 201
19 and rotate in the same direction as the input shaft 200. The difference in the
20 number of teeth in each gear set 209,211 and 210,212 determines the amount of
21 reduction that can be achieved.

22 High reduction rates (100:1) can be achieved in a small tubular
23 assembly with the added advantage of the output shaft 203 turning in the same
24 direction as the input shaft 201. An advantage of positioning the clutch assembly
25 24 on the high speed side of the speed reducer 25 is a reduced torque duty.

1 As stated above, the rotating lower sub connector 54 is connected
2 to the low speed output shaft 203 through lower hollow output shaft 52b, so that
3 the lower sub 30 is capable of only slowly contra-rotating as the drill bit 34
4 rotates.

5 The energy dissipation device 300 is driven by the input shaft 200
6 of the speed reducer 25, preferably at the upper shaft 45. One such device 300
7 includes a viscous drag device such as a flow counter or flowmeter having some
8 form of turbine rotor 301. The flowmeter has known revolutions per unit flow of
9 mud pumped therethrough, such as 1 revolution per US gal of mud. Accordingly,
10 rotation of the high speed input shaft 200 is substantially limited by the mud flow
11 rate therethrough, enabling control of the lower sub's contra-rotation merely by
12 varying the rate of mud flow. The turbine rotor 301 of a flowmeter can be driven
13 by the high speed input shaft to provide the appropriate drag.

14 Performance of a flowmeter can be sensed remotely, whether by
15 electronic or fluid pulse, which enables remote monitoring and manipulation of
16 the rotating operations. A variety of suitable flowmeters are known including
17 those disclosed in US Patents 5,831,177 and 5,636,178, both to Halliburton of
18 Houston Texas.

19 The advantages of the present invention include the ability to
20 practice both rotating and sliding operations in coiled tubing directional drilling
21 while being able to monitor and control the speed of contra-rotation of the bend
22 sub.

23

24

1 THE EMBODIMENTS OF THE INVENTION IN WHICH AN
2 EXCLUSIVE PROPERTY OR PRIVILEGE IS CLAIMED ARE DEFINED AS
3 FOLLOWS:
4

5 1. Apparatus for directional drilling with coiled tubing:

6 (a) an uphole sub connected to the coiled tubing;

7 (b) a downhole sub having a bent housing and a drill bit, rotation of
8 the drill bit forming a borehole;

9 (c) a rotary connection between the uphole sub and the downhole
10 sub for enabling rotation therebetween; and

11 (d) a clutch positioned between the rotary connection and the
12 uphole sub and operable between engaged and disengaged positions using fluid
13 cycles applied alternately to engage the clutch and to disengage the clutch, a
14 fluid cycle comprising a substantial change in pressure of the drilling fluid, so that,

15 i. when the clutch is disengaged, the bent housing is
16 locked against rotation, and

17 ii. when the clutch is engaged, the bent housing is
18 rotatable.
19
20

1 2. The apparatus of claim 1 further comprising:
2 (a) a first motor for rotating the drill bit to form the borehole; and
3 (b) a second motor; so that
4 i. when the clutch is disengaged, the second motor is
5 disengaged from the bent housing, and
6 ii. when the clutch is engaged, the second motor rotates
7 the bent housing.

8
9 3. The apparatus of claim 2 wherein the clutch further comprises:
10 (a) an input shaft and co-rotating first clutch face;
11 (b) an output shaft and co-rotating second clutch face, the output
12 shaft being connected for co-rotation with the lower sub; and
13 (c) means for engaging and disengaging the first and second clutch
14 faces so that, when engaged, the input shaft and the output shaft co-rotate for
15 rotating the lower sub.

16
17 4. The apparatus of claim 3 wherein the clutch further comprises
18 means for locking rotation between the output shaft and the uphole sub when the
19 clutch is disengaged.

20
21

1 5. The apparatus of claim 4 wherein means for axially reciprocating
2 the collar between the first and second positions comprises:

3 (a) an axially reciprocating mandrel, one end of which alternately
4 engages and disengages the collar;

5 (b) means for reciprocating the mandrel in response to pressure
6 changes in the drilling fluid; and

7 (c) a barrel cam formed on the mandrel which indexes the mandrel
8 between its first and second positions.

9

10 6. The apparatus of claim 2 wherein the clutch further comprises:

11 (a) an input shaft and co-rotating first clutch face;

12 (b) an output shaft and co-rotating second clutch face, the output
13 shaft being connected for co-rotation with the lower sub; and

14 (c) a piston for engaging and disengaging the first and second
15 clutch faces so that, when engaged, the input shaft and the output shaft co-rotate
16 for rotating the lower sub.

17

18

1 7. The apparatus of claim 4 wherein the second clutch face is
2 formed on a collar which reciprocates axially on the second shaft further
3 comprising:

4 (a) a third clutch face formed on the collar; and

5 (b) a fourth clutch face formed on the uphole sub so that

6 i. when the clutch is disengaged, the collar is
7 reciprocated axially to a first position to disengage the first and
8 second clutch faces and engage the third and fourth clutch faces for
9 locking rotation between the output shaft and the uphole sub, and

10 ii. when the clutch is engaged, the collar is reciprocated
11 axially to a second position to engage the first and second clutch
12 faces and disengage the third and fourth clutch faces.

13

14 8. The apparatus of claim 2 further comprising a contiguous bore
15 for conducting drilling fluids from the coiled tubing to the drill bit and wherein both
16 of the first and second motors are driven by drilling fluids.

17

18 9. The apparatus of claim 1 further comprising:

19 (a) a speed reducer between the rotary connection and the uphole
20 sub and having a low speed output connected to the rotary connection; and

21 (b) a first motor mounted in the downhole sub and which rotates the
22 drill bit, reactive torque from the drill bit being transmitted into the downhole sub
23 so that when the clutch is engaged, the reactive torque causes the downhole sub
24 and bent housing to rotate opposite to the drill bit and the speed reducer
25 dissipates torque so as to retard free rotation of the downhole sub.

1 10. The apparatus of claim 9 further comprising means driven by the
2 high speed input for dissipating torque at the speed reducer.

3

4 11. The apparatus of claim 9 further comprising a flowmeter driven
5 by the high speed input for dissipating torque at the speed reducer.

6

7 12. The apparatus of claim 9 wherein the clutch further comprises:

8 (a) an input shaft and co-rotating first clutch face;

9 (b) an output shaft and co-rotating second clutch face, the output
10 shaft being connected for co-rotation with the lower sub; and

11 (c) means for engaging and disengaging the first and second clutch
12 faces so that, when engaged, the input shaft and the output shaft co-rotate for
13 rotating the lower sub.

14

15 13. The apparatus of claim 12 wherein the clutch further comprises
16 means for locking rotation between the output shaft and the uphole sub when the
17 clutch is disengaged.

18

19

1 14. The apparatus of claim 13 wherein means for axially
2 reciprocating the collar between the first and second positions comprises:

3 (a) an axially reciprocating mandrel, one end of which alternately
4 engages and disengages the collar;

5 (b) means for reciprocating the mandrel in response to pressure
6 changes in the drilling fluid; and

7 (c) a barrel cam formed on the mandrel which indexes the mandrel
8 between its first and second positions.

9

10 15. The apparatus of claim 14 wherein the clutch further comprises:

11 (a) an input shaft and co-rotating first clutch face;

12 (b) an output shaft and co-rotating second clutch face, the output
13 shaft being connected for co-rotation with the lower sub; and

14 (c) a piston for engaging and disengaging the first and second
15 clutch faces so that when engaged, the input shaft and the output shaft co-rotate
16 for rotating the lower sub.

17

18 16. The apparatus of claim 15 wherein the second clutch face is
19 formed on a collar which reciprocates axially on the second shaft further
20 comprising:

21 (a) a third clutch face formed on the collar; and

22 (b) a fourth clutch face formed on the uphole sub so that

23 i. when the clutch is disengaged, the collar is
24 reciprocated axially to a first position to disengage the first and

1 second clutch faces and engage the third and fourth clutch faces for
2 locking rotation between the output shaft and the uphole sub, and

3 ii. when the clutch is engaged, the collar is reciprocated
4 axially to a second position to engage the first and second clutch
5 faces and disengage the third and fourth clutch faces.

6

7 17. Apparatus for directional drilling with coiled tubing:

8 (a) an uphole sub connected to the coiled tubing;

9 (b) a downhole sub having a bent housing and a drill bit, rotation of
10 the drill bit forming a borehole;

11 (c) a rotary connection between the uphole sub and the downhole
12 sub for enabling continuous rotation;

13 (d) a clutch positioned between the rotary connection and the
14 uphole sub for alternately locking the bent housing against rotation and freeing
15 the bent housing for rotation; and

16 (e) a speed reducer positioned between the coiled tubing and the
17 bent housing and having a high speed shaft and a low speed shaft, the low speed
18 shaft being connected to the bent housing so that when the bent housing is free
19 for rotation, reactive torque from the rotary drill bit causes the bent housing to
20 contra-rotate at a speed less than that of the rotary drill bit.

21

22 18. The apparatus of claim 17 further comprising means driven by
23 the high speed shaft for dissipating torque at the speed reducer.

24

1 19. The apparatus of claim 17 further comprising a flowmeter driven
2 by the high speed shaft for dissipating torque at the speed reducer.

3

4 20. The apparatus of claim 17 wherein the high speed shaft is fluidly
5 coupled to the drilling fluid for resisting rotation.

6

7 21. A method for directional drilling in a borehole with coiled tubing
8 having a bent housing and rotary drill bit connected thereto, the method
9 comprising the steps of:

10 ▪ providing a speed reducer having a low speed output
11 connected to an upper end of a clutch and a rotary connection between a lower
12 end of the clutch and the bent housing, the clutch operable between engaged
13 and disengaged positions through cycling of drilling fluid flow through the coiled
14 tubing;

15 ▪ orienting the bent sub by
16 engaging the clutch for coupling of the speed reducer to the
17 rotating connection,

18 orienting the bent sub in the borehole by rotating the drill bit,
19 reactive torque causing bent sub and rotating connection to contra-rotate
20 and drive the speed reducer through the clutch;

21 ▪ drilling a borehole in a sliding operation by disengaging the
22 clutch for decoupling the speed reducer from the rotating connection and for
23 locking the rotating connection to the coiled tubing, then drilling with the drill bit;

24 ▪ drilling a borehole in a rotating operation by engaging the
25 clutch for coupling of the speed reducer to the rotating connection and releasing

1 the rotating connection from the coiled tubing, then drilling with the drill bit
2 wherein reactive torque causes the bent sub and rotating connection to contra-
3 rotate simultaneously.

4

5 22. The method of claim 21 further comprising the step of
6 dissipating torque at the speed reducer by driving an energy dissipating device.

7

8 23. The method of claim 22 wherein torque is dissipated by driving a
9 viscous device.

10

11 24. The method of claim 22 wherein torque is dissipated by driving a
12 flowmeter.

13

14 25. A method for directional drilling in a borehole with coiled tubing
15 having a bent housing and rotary drill bit connected thereto, the method
16 comprising the steps of:

17 ▪ in a sliding operation, orienting a bent housing by engaging a
18 clutch to couple the bent housing to a motor, rotating the bent housing to orient it
19 in the borehole, disengaging the clutch for disengaging the motor and for locking
20 the bent housing against relative rotation to the coiled tubing, and then drilling
21 with the rotary bit; and

22 ▪ in a rotating operation, engaging the clutch to unlock the bent
23 housing from the coiled tubing and for coupling the bent housing to the motor,
24 and then simultaneously rotating the bent housing and drilling with the rotary drill
25 bit.

1 26. The method of claim 16 further comprising the step of actuating
2 the clutch between the engaged and disengaged positions and between the
3 disengaged and engaged positions by cycling a flow of drilling fluid in the coiled
4 tubing.

5

6 27. A method for directional drilling in a borehole with coiled tubing
7 having a bent housing and rotary drill bit connected thereto, the method
8 comprising the steps of:

9 ▪ in a sliding operation, orienting a bent housing by engaging a
10 clutch to couple the bent housing through a rotary connection at the coiled tubing
11 to a speed reducer, drilling with the rotary bit wherein reactive torque causes the
12 bent sub to contra-rotate at the rotary connection, and once oriented,
13 disengaging the clutch for disengaging the speed reducer and for locking the bent
14 housing against relative rotation to the coiled tubing, and drilling with the rotary
15 bit; and

16 ▪ in a rotating operation, engaging the clutch to unlock the bent
17 housing from the coiled tubing and for coupling the bent housing to the speed
18 reducer, and then drilling with the rotary drill bit wherein reactive torque causes
19 the bent sub to contra-rotate.

20

21 28. The method of claim 27 further comprising dissipating torque at
22 the speed reducer by driving an energy dissipating device.

23

24 29. The method of claim 28 wherein torque is dissipated by driving a
25 viscous device.

1 30. The method of claim 28 wherein torque is dissipated by driving a
2 flowmeter.

3

4 31. The method of claim 30 further comprising the step of controlling
5 the speed of contra-rotation of the bent sub by adjusting the flow of drilling fluid
6 through the flowmeter.

7

8 32. A method of directional drilling with coiled tubing comprising the
9 steps of:

10 ▪ providing a bottom hole assembly at a downhole end of the
11 non-rotating coiled tubing, the bottom hole assembly comprising an uphole sub
12 having a clutch and a rotating connection, and a downhole sub connected to the
13 upper sub's rotating connection, the downhole sub having a bent housing and a
14 rotary drill bit;

15 ▪ orienting the bent housing by engaging the clutch for
16 unlocking the rotating connection for rotation of the downhole sub to the desired
17 orientation;

18 ▪ performing sliding drilling operation by disengaging the clutch
19 for locking the rotating connection and drilling a curved borehole with the rotary
20 bit; and

21 ▪ performing rotating drilling operation by engaging the clutch
22 for unlocking the rotating connection for rotation of the downhole sub drilling with
23 the rotary bit while the downhole sub rotates at the rotating connection for drilling
24 a substantially straight borehole.

25

1 33. The method of claim 23 wherein engaging of the clutch couples
2 a motor with the downhole sub.

3

4 34. The method of claim 23 wherein engaging of the clutch couples
5 a speed reducer with the downhole sub.

6

7 35. The method of claim 34 further comprising dissipating torque at
8 the speed reducer by driving an energy dissipating device.

9

10 36. The method of claim 35 wherein torque is dissipated by driving a
11 viscous device.

12

13 37. The method of claim 35 wherein torque is dissipated by driving a
14 flowmeter.

15

16 38. Apparatus for directional drilling with a BHA suspended from
17 coiled tubing, the BHA having a drill bit, a bent housing and a first motor for
18 driving the drill bit, the apparatus comprising:

19 (a) a second motor positioned between the coiled tubing and the
20 bent housing;

21 (b) a rotary connection between the coiled tubing and the bent
22 housing; and

23 (c) a clutch between the second motor and bent housing and
24 operable between engaged and disengaged positions using fluid cycles applied

1 alternately to engage the clutch and to disengage the clutch, a fluid cycle
2 comprising a substantial change in pressure of the drilling fluid, so that,

3 i. when the clutch is engaged, the bent housing is
4 rotatable by the second mud motor, and

5 ii. when the clutch is disengaged, the bent housing is
6 non-rotating.

7

8 39. The apparatus of claim 38 wherein the clutch comprises:

9 (a) a first clutch member rotatably connected to second motor;

10 (b) a drive member extending between the clutch and the bent
11 housing;

12 (c) a second clutch member rotatably connected to the drive
13 member and axially movable between engaging and disengaging the first clutch
14 member;

15 (d) a mandrel axially movable on the shaft and operable between
16 two axial positions to actuate the second clutch member between engaging and
17 disengaging the first clutch member; and

18 (e) a differential pressure system operable on the mandrel to
19 operate the mandrel between the two axial positions.
