difference between the positive electrode terminal and an intermediate-point terminal, and an alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal. The impedance measuring device adjusts an amplitude of the alternating current such that the alternating-current potential difference between the positive electrode terminal and the intermediate-point terminal, and the alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal coincide. The impedance measuring device computes an impedance of the laminated type battery on the basis of the alternating current adjusted and the alternating-current potential difference. On the a phase difference between an alternating-current potential generated at the positive electrode terminal and an alternating-current potential generated at the negative electrode terminal, or a parameter related to the phase difference, the impedance measuring device performs any one process of: a diagnosis process for diagnosing whether or not a measurement state is defective; a cancellation process for discarding a measurement result; and a hold process for fixing the measurement result at a prescribed value.

ABSTRACT

An impedance measuring device outputs an alternating current of a prescribed frequency to a positive electrode terminal and a negative electrode terminal of the laminated type battery. The impedance measuring device detects an alternating-current potential difference between the positive electrode terminal and an intermediate-point terminal, and an alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal. The impedance measuring device adjusts an amplitude of the alternating current such that the alternating-current potential difference between the positive electrode terminal and the intermediate-point terminal, and the alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal coincide. The impedance measuring device computes an impedance of the laminated type battery on the basis of the alternating current adjusted and the alternating-current potential difference. On the a phase difference between an alternating-current potential generated at the positive electrode terminal and an alternating-current potential generated at the negative electrode terminal, or a parameter related to the phase difference, the impedance measuring device performs any one process of: a diagnosis process for diagnosing whether or not a measurement state is defective; a cancellation process for discarding a measurement result; and a hold process for fixing the measurement result at a prescribed value.

DESCRIPTION

**IMPEDANCE MEASURING DEVICE AND
CONTROL METHOD FOR IMPEDANCE MEASURING DEVICE**

TECHNICAL FIELD

[0001] This invention relates to an impedance measuring device for measuring an impedance of a laminated type battery and a control method for impedance measuring device.

BACKGROUND ART

[0002] A device for measuring an internal resistance of a laminated type battery with power supplied to a load from the laminated type battery is proposed in WO2012077450.

[0003] This measuring device outputs the same alternating currents to a positive electrode terminal and a negative electrode terminal of the laminated type battery such that no current leaks to a load side connected to the laminated type battery. Then, an amplitude of the alternating current output to each electrode is adjusted such that an alternating-current potential difference on a positive electrode side obtained by subtracting a potential of an intermediate-point terminal located between the positive electrode terminal and the negative electrode terminal from a potential of the positive electrode terminal of the laminated type battery and an alternating-current potential difference on a negative electrode side obtained by subtracting the potential of the intermediate-point terminal from a potential of the negative electrode terminal coincide. Then, the internal resistance of the laminated type battery is measured on the basis of the adjusted alternating currents and potential differences.

SUMMARY OF INVENTION

[0004] Some of laminated type batteries include capacitance components inside like fuel cell batteries. Capacitance components of a fuel cell battery may vary depending on an operating state of a fuel cell system. In such a case, a difference between a capacitance on a positive electrode side and a capacitance on a negative electrode side becomes large and a phase difference is generated between an alternating-current potential difference on the positive electrode side and an alternating-current potential difference on the negative electrode side.

[0005] In a state where is a phase deviation between the alternating-current potential differences on the positive and negative electrode sides, the alternating current output from the measuring device to the fuel cell battery partly leaks to the load, whereby it may not be possible to ensure impedance measurement accuracy.

[0006] However, since a level of a detection signal does not change even in such a measurement state, there is a problem that the impedance is measured without detecting that the measurement state is defective.

[0007] The present invention is developed focusing on such a problem and aims to provide an impedance measuring device designed to maintain and improve reliability for a measurement result as against a reduction of measurement accuracy due to capacitance components of a laminated type battery.

[0008] According to one aspect of the present invention, an impedance measuring device includes a laminated type battery, a first power supply unit configured to output an alternating current of a prescribed frequency for measuring an impedance of the laminated type battery to a positive electrode terminal of the laminated type battery, and a second power supply unit configured to output an alternating current of the prescribed frequency to a

negative electrode terminal of the laminated type battery. A plurality of battery cells is laminated in the laminated type battery. The impedance measuring device includes a first detection unit configured to detect an alternating-current potential difference between the positive electrode terminal and an intermediate-point terminal of the laminated type battery, and a second detection unit configured to detect an alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal. The impedance measuring device includes an adjustment unit configured to adjust an amplitude of the alternating current output from at least one of the first and second power supply units such that the alternating-current potential difference detected by the first detection unit and the alternating-current potential difference detected by the second detection unit coincide. An impedance measuring device includes a computation unit configured to compute the impedance of the laminated type battery on the basis of the alternating current adjusted by the adjustment unit and the alternating-current potential difference. The impedance measuring device includes a calculation unit configured to calculate a phase difference between an alternating-current potential generated at the positive electrode terminal and an alternating-current potential generated at the negative electrode terminal, or a parameter related to the phase difference. The impedance measuring device includes a processing unit configured to perform, on the basis of the phase difference or the parameter calculated by the calculation unit, any one process of: a diagnosis process for diagnosing whether or not a measurement state is defective; a cancellation process for discarding a measurement result; and a hold process for fixing the measurement result at a prescribed value.

BRIEF DESCRIPTION OF DRAWINGS

[0009] FIG. 1A is an external perspective view showing an example of a laminated type battery to be measured by an impedance measuring device in a first embodiment of the present invention,

FIG. 24 is a diagram showing an impedance measuring device in a seventh embodiment of the present invention,

FIG. 25 is a diagram showing a technique for correcting a measurement error in an eighth embodiment of the present invention, and

FIG. 26 is a flow chart showing a revision correction method for revising an internal resistance.

DESCRIPTION OF EMBODIMENTS

[0010] Hereinafter, embodiments of the present invention are described with reference to the accompanying drawings.

[0011] (First Embodiment)

FIG. 1A is an external perspective view showing an example of a laminated type battery to be measured by an impedance measuring device in a first embodiment of the present invention. In FIG. 1A, a fuel cell stack 1 in which a plurality of battery cells are laminated is shown as an example of the laminated type battery.

[0012] As shown in FIG. 1A, the fuel cell stack 1 includes a plurality of power generation cells 10, current collector plates 20, insulation plates 30, end plates 40 and four tension rods 50.

[0013] The power generation cell 10 is a so-called battery cell and indicates one of a plurality of fuel cells laminated in the fuel cell stack 1. The power generation cell 10 generates, for example, an electromotive voltage of about 1 V (volt). The detailed configuration of the power generation cell 10 is described later with reference to FIG. 1B.

[0014] The current collector plates 20 are respectively arranged at outer sides of the laminated power generation cells 10. The current collector plates 20 are formed of a gas-impermeable conductive material such as dense carbon. The current collector plates 20 include a positive electrode terminal 211 and a

- 7 -

negative electrode terminal 212. Further, an intermediate-point terminal 213 is provided between the positive electrode terminal 211 and the negative electrode terminal 212. The intermediate-point terminal 213 is connected to the power generation cell 10 located in the middle out of the power generation cells 10 laminated from the positive electrode terminal 211 to the negative electrode terminal 212. It should be noted that the intermediate-point terminal 213 may be located at a position deviated from a middle point between the positive electrode terminal 211 and the negative electrode terminal 212. Electrons e^- generated in the power generation cells 10 are extracted from the negative electrode terminal 212 of the fuel cell stack 1.

[0015] The insulation plates 30 are respectively arranged at outer sides of the current collector plates 20. The insulation plates 30 are formed of an insulating material such as rubber.

[0016] The end plates 40 are respectively arranged at outer sides of the insulation plates 30. The end plates 40 are formed of a rigid metal material such as steel.

[0017] One end plate 40 (end plate 40 on a front left side in FIG. 1A) includes an anode supply port 41a, an anode discharge port 41b, a cathode supply port 42a, a cathode discharge port 42b, a cooling water supply port 43a and a cooling water discharge port 43b. In the present embodiment, the anode discharge port 41b, the cooling water discharge port 43b and the cathode supply port 42a are provided on a right side in FIG. 1A. Further, the cathode discharge port 42b, the cooling water supply port 43a and the anode supply port 41a are provided on a left side in FIG. 1A.

[0018] The tension rods 50 are respectively arranged near four corners of the end plate 40. The fuel cell stack 1 is formed with holes (not shown) penetrating inside. The tension rods 50 are inserted into these through holes. The tension rods 50 are formed of a rigid metal material such as steel. An

insulation processing is applied to surfaces of the tension rods 50 to prevent an electrical short circuit between the power generation cells 10. Nuts (not shown by being located on a back side) are threadably engaged with these tension rods 50. The tension rods 50 and the nuts tighten the fuel cell stack 1 in a lamination direction.

[0019] A method for supplying hydrogen as anode gas to the anode supply port 41a is, for example, a method for directly supplying hydrogen gas from a hydrogen storage device, a method for supplying reformed hydrogen-containing gas obtained by reforming hydrogen-containing fuel or the like. It should be noted that the hydrogen storage device is a high-pressure gas tank, a liquefied hydrogen tank, a hydrogen storage alloy tank or the like. The hydrogen-containing fuel is natural gas, methanol, gasoline or the like. Further, air is generally used as cathode gas to be supplied to the cathode supply port 42a.

[0020] FIG. 1B is an exploded view showing the structure of the power generation cell laminated in the fuel cell stack 1.

[0021] As shown in FIG. 1B, the power generation cell 10 is structured such that an anode separator (anode bipolar plate) 12a and a cathode separator (cathode bipolar plate) 12b are arranged on opposite surfaces of a membrane electrode assembly (MEA) 11.

[0022] In the MEA 11, electrode catalyst layers 112 are formed on opposite surfaces of an electrolyte membrane 111 composed of an ion-exchange membrane. Gas diffusion layers (GDLs) 113 are formed on these electrode catalyst layers 112.

[0023] The electrode catalyst layer 112 is, for example, formed of platinum-carrying carbon black particles.

[0024] The GDL 113 is formed of a material having sufficient gas diffusion property and electrical conductivity such as carbon fibers.

[0025] The anode gas supplied from the anode supply port 41a flows in this GDL 113a, reacts with the anode electrode catalyst layer 112 (112a) and is discharged from the anode discharge port 41b.

[0026] The cathode gas supplied from the cathode supply port 42a flows in this GDL 113b, reacts with the cathode electrode catalyst layer 112 (112b) and is discharged from the cathode discharge port 42b.

[0027] The anode separator 12a is laid on one surface (back surface in FIG. 1B) of the MEA 11 via the GDL 113a and a seal 14a. The cathode separator 12b is laid on one surface (front surface in FIG. 1B) of the MEA 11 via the GDL 113b and a seal 14b. The seals 14 (14a, 14b) are rubber-like elastic materials such as silicone rubber, ethylene propylene diene monomer (EPDM) or fluororubber. The anode separator 12a and the cathode separator 12b are, for example, formed by press-molding a separator base made of metal such as stainless steel, forming reaction gas flow passages on one surface and forming cooling water flow passages on an opposite surface such that the reaction gas flow passages and the cooling water flow passages are alternately arranged. As shown in FIG. 1B, the anode separator 12a and the cathode separator 12b are laid together to form the cooling water flow passages.

[0028] The MEA 11, the anode separator 12a and the cathode separator 12b are respectively formed with holes 41a, 41b, 42a, 42b, 43a and 43b, by laying these one next to another, the anode supply port 41a, the anode discharge port 41b, the cathode supply port 42a, the cathode discharge port 42b, the cooling water supply port 43a and the cooling water discharge port 43b are formed.

[0029] FIG. 2 is a diagram showing a basic configuration of an impedance measuring device 5 in the present embodiment.

[0030] The impedance measuring device 5 measures an internal impedance of the fuel cell stack 1, for example, mounted in a vehicle. The fuel cell stack

1 is connected to a load 3 mounted in the vehicle. The load 3 is an electric motor, an auxiliary machine used for power generation of the fuel cell stack 1 or the like. A controller unit (C/U) 6 controls an operating state of the load 3 and operating states of the fuel cell stack 1 such as a power generation state and a wet state on the basis of a measurement result by the impedance measuring device 5.

[0031] The impedance measuring device 5 includes a positive-electrode side direct current shut-off unit 511, a negative-electrode side direct current shut-off unit 512, an intermediate point direct current shut-off unit 513, a positive-electrode side potential difference detection unit 521, a negative-electrode side potential difference detection unit 522, a positive-electrode side power supply unit 531, a negative-electrode side power supply unit 532, an alternating current adjustment unit 540 and a computation unit 550.

[0032] The positive-electrode side direct current shut-off unit 511, the negative-electrode side direct current shut-off unit 512, the intermediate point direct current shut-off unit 513, the positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522 are described in detail with reference to FIG. 3.

[0033] The positive-electrode side direct current shut-off unit 511 is connected to the positive electrode terminal 211 of the fuel cell stack 1. The negative-electrode side direct current shut-off unit 512 is connected to the negative electrode terminal 212 of the fuel cell stack 1. The intermediate point direct current shut-off unit 513 is connected to the intermediate-point terminal 213 of the fuel cell stack 1. The direct-current shut-off units 511 to 513 shut off direct-current signals, but allow alternating-current signals to flow. The direct-current shut-off units 511 to 513 are, for example, capacitors or transformers. It should be noted that the intermediate point

direct current shut-off unit 513 shown by broken line may be omitted.

[0034] The positive-electrode side potential difference detection unit 521 detects a potential difference between an alternating-current potential V_a generated at the positive electrode terminal 211 and an alternating-current potential V_c generated at the intermediate-point terminal 213 (hereinafter, referred to as an “alternating-current potential difference V_1 ”). The positive-electrode side potential difference detection unit 521 outputs a detection signal, whose signal level changes according to the alternating-current potential difference V_1 , to the computation unit 550.

[0035] The negative-electrode side potential difference detection unit 522 detects a potential difference between an alternating-current potential V_b generated at the negative electrode terminal 212 and the alternating-current potential V_c generated at the intermediate-point terminal 213 (hereinafter, referred to as an “alternating-current potential difference V_2 ”). The negative-electrode side potential difference detection unit 522 outputs a detection signal, whose signal level changes according to the alternating-current potential difference V_2 , to the computation unit 550. The positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522 are realized, for example, by differential amplifiers (instrumentation amplifiers).

[0036] The positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 are described in detail with reference to FIG. 4.

[0037] The positive-electrode side power supply unit 531 is a first power supply unit for outputting an alternating current of a reference frequency f_b . The positive-electrode side power supply unit 531 is realized by a voltage-current conversion circuit such as an operational amplifier (OP amplifier). By this voltage-current conversion circuit, a current I_o

proportional to an input voltage V_i is output. It should be noted that $I_o = V_i/R_s$, where R_s denotes a current sensing resistance. This voltage-current conversion circuit is a variable alternating current source capable of adjusting the output current I_o according to the input voltage V_i .

[0038] By using the voltage-current conversion circuit as the positive-electrode side power supply unit 531, the output current I_o can be computed by dividing the input voltage V_i by a proportionality constant R_s even without actually measuring the output current I_o , wherefore the output current I_o can be obtained if the input voltage V_i is detected. Further, since an output of the voltage-current conversion circuit is a current, the alternating current flowing in a laminated cell group and an output current of the positive-electrode side power supply unit 531 are in the same phase even if an element which causes a phase angle such as a capacitor is disposed in a current path. Further, the input voltage V_i is also in the same phase. Thus, it is not necessary to consider a phase deviation of the alternating current in resistance calculation in the subsequent stage and a circuit is simple. Furthermore, even if an impedance of a capacitor in the current path varies, there is no influence of a phase change of the alternating current. From the above, a circuit as shown in FIG. 4 is preferably used as the positive-electrode side power supply unit 531. The negative-electrode side power supply unit 532 is also similarly configured. Specifically, the negative-electrode side power supply unit 532 is a second power supply unit for outputting an alternating current of the reference frequency f_b .

[0039] The alternating current adjustment unit 540 is described in detail with reference to FIG. 5.

[0040] The alternating current adjustment unit 540 adjusts an amplitude of the alternating current output from at least one of the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532

such that the alternating-current potential V_a on the positive electrode side and the alternating-current potential V_b on the negative electrode side coincide.

[0041] In the present embodiment, the alternating current adjustment unit 540 increases and decreases both the amplitude of the alternating current output from the positive-electrode side power supply unit 531 and the amplitude of the alternating current output from the negative-electrode side power supply unit 532 such that both the alternating-current potential difference V_1 on the positive electrode side and the alternating-current potential difference V_2 on the negative electrode side have a prescribed value. The alternating current adjustment unit 540 is realized, for example, by a PI (Proportional Integral) control circuit.

[0042] Further, the alternating current adjustment unit 540 outputs command signals for the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 as alternating currents I_1 and I_2 to be output from the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 to the computation unit 550.

[0043] The alternating current adjustment unit 540 includes a positive-electrode side detector circuit 5411, a positive-electrode side subtractor 5421, a positive-electrode side integration circuit 5431, a positive-electrode side multiplier 5441, a negative-electrode side detector circuit 5412, a negative-electrode side subtractor 5422, a negative-electrode side integration circuit 5432 and a negative-electrode side multiplier 5442.

[0044] The alternating current adjustment unit 540 further includes reference power supplies 545 and alternating-current signal sources 546. The reference power supply 545 outputs a potential difference determined with 0 V (volt) as a reference (hereinafter, referred to as a "reference voltage V_s "). The reference voltage V_s is a value determined in advance to match the

alternating-current potential difference $V1$ on the positive electrode side and the alternating-current potential difference $V2$ on the negative electrode side. The alternating-current signal source 546 is an oscillation source for oscillating an alternating-current signal of the reference frequency f_b . The reference frequency f_b is set at a prescribed frequency suitable to measure the internal impedance of the fuel cell stack 1.

[0045] The positive-electrode side detector circuit 5411 removes an unnecessary signal from the alternating-current potential V_a generated in a signal line connecting between the direct current shut-off unit 511 and the positive-electrode side power supply unit 531 and converts the alternating-current potential V_a into a direct-current signal proportional to an amplitude of the alternating-current potential V_a . For example, the positive-electrode side detector circuit 5411 outputs an average or effective value of the alternating-current potential difference $V1$ as the direct-current signal.

[0046] In the present embodiment, the positive-electrode side detector circuit 5411 is realized by a synchronous detector circuit. The positive-electrode side detector circuit 5411 extracts a real axis component $V1r$ and an imaginary axis component $V1x$ of the alternating-current potential difference $V1$ from the alternating-current potential V_a generated at an output terminal of the positive-electrode side power supply unit 531. Then, the positive-electrode side detector circuit 5411 outputs the real axis component $V1r$ of the alternating-current potential difference $V1$ to the positive-electrode side subtractor 5421. The real axis component $V1r$ is a value equivalent to an average or effective value of the alternating-current potential difference $V1$. As a phase of the alternating-current potential difference $V1$ is retarded with respect to the alternating current $I1$, the value of the real axis component $V1r$ becomes smaller. The detail of the positive-electrode side detector circuit

5411 is described later with reference to FIG. 6.

[0047] The positive-electrode side subtractor 5421 calculates a differential signal indicating a deviation width of the real axis component V_{1r} from the reference voltage V_s by subtracting the reference voltage V_s from the real axis component V_{1r} of the alternating-current potential difference V_1 output from the positive-electrode side detector circuit 5411. For example, as the deviation width from the reference voltage V_s increases, a signal level of the differential signal increases.

[0048] The positive-electrode side integration circuit 5431 averages the differential signal or adjusts the sensitivity of the differential signal by integrating the differential signal output from the positive-electrode side subtractor 5421. Then, the positive-electrode side integration circuit 5431 outputs the integrated differential signal as a positive-electrode side current command value I_{1c} to the positive-electrode side multiplier 5441.

[0049] The positive-electrode side multiplier 5441 outputs a command signal of the alternating current I_1 for converging the alternating-current potential difference V_1 to the reference voltage V_s by multiplying an alternating-current signal of the reference frequency f_b output from the alternating-current signal source 546 by the positive-electrode side current command value I_{1c} . An amplitude of the command signal is increased with an increase of the positive-electrode side current command value I_{1c} by the positive-electrode side multiplier 5441. The positive-electrode side multiplier 5441 outputs its command signal of the alternating current I_1 to the positive-electrode side power supply unit 531. The alternating-current voltage signal V_i input as the command signal of the alternating current I_1 to the positive-electrode side power supply unit 531 is converted into the alternating-current signal I_o by the positive-electrode side power supply unit 531 and output to the positive electrode 211 of the fuel cell stack 1.

[0050] It should be noted the negative-electrode side detector circuit 5412, the negative-electrode side subtractor 5422, the negative-electrode side integration circuit 5432 and the negative-electrode side multiplier 5442 are respectively basically identically configured to the positive-electrode side detector circuit 5411, the positive-electrode side subtractor 5421, the positive-electrode side integration circuit 5431 and the positive-electrode side multiplier 5441.

[0051] FIG. 6 is a diagram showing an example of the configuration of the positive-electrode side detector circuit 5411.

[0052] The positive-electrode side detector circuit 5411 includes an in-phase component extraction unit 710 and an orthogonal component extraction unit 720.

[0053] The in-phase component extraction unit 710 extracts the real axis component V_{lr} of the alternating-current potential difference V_l by multiplying the alternating-current potential V_a from the positive-electrode side power supply unit 531 by an in-phase signal $\sin(0)$ for detecting the same frequency component as the alternating current I_l output from the positive-electrode side power supply unit 531.

[0054] The in-phase signal $\sin(0)$ is an alternating-current signal having the reference frequency f_b and having the same phase as the alternating current output from the positive-electrode side power supply unit 531. The in-phase signal $\sin(0)$ is input to the in-phase component extraction unit 710, for example, from the alternating-current signal source 546.

[0055] The in-phase component extraction unit 710 includes an in-phase multiplier 711 and an in-phase low-pass filter 712.

[0056] The in-phase multiplier 711 multiplies the alternating-current potential V_a on the positive electrode side by the in-phase signal $\sin(0)$. This causes an in-phase alternating-current signal corresponding to a degree of

coincidence of a waveform of the alternating-current potential V_a and that of the in-phase signal $\sin(0)$ to be output from the in-phase multiplier 711. For example, if the alternating-current potential V_a and the in-phase signal $\sin(0)$ perfectly coincide in phase, an in-phase alternating-current signal having a full-wave rectification waveform is output. Further, as the degree of coincidence of the waveforms of the alternating-current potential V_a and the in-phase signal $\sin(0)$ increases, the real axis component V_{1r} increases.

[0057] The in-phase low-pass filter 712 detects a direct-current component of the in-phase alternating-current signal as the real axis component V_{1r} . In the present embodiment, the in-phase low-pass filter 712 is realized by a low-pass filter (LPF) for removing an alternating-current component of the in-phase alternating-current signal, i.e. a high-frequency range component and allowing the passage of a direct-current component of the in-phase alternating-current signal. The in-phase alternating-current signal smoothed by the in-phase low-pass filter 712 is input to the positive-electrode side subtractor 5421 and a phase difference detection unit 561.

[0058] As just described, the in-phase component extraction unit 710 rectifies the alternating-current potential V_a by multiplying the alternating-current potential V_a by the in-phase signal $\sin(0)$ having the same phase as the output current I_1 of the positive-electrode side power supply unit 531. In this way, only the alternating-current signal having the same frequency and phase as the output current I_1 of the positive-electrode side power supply unit 531 can be extracted as the real axis component V_{1r} from the alternating-current potential V_a . Thus, even if the alternating-current potential V_a is buried in noise, the real axis component V_{1r} can be reliably detected.

[0059] The orthogonal component extraction unit 720 is provided to detect a phase difference between the alternating-current potentials V_a and V_b .

[0060] The orthogonal component extraction unit 720 extracts the imaginary axis component V_{1x} of the alternating-current potential difference V_1 by multiplying the alternating-current potential V_a by an orthogonal signal $\sin(90)$ for detecting a component having the same frequency as the alternating current I_1 output from the positive-electrode side power supply unit 531 and having a phase orthogonal to that of the alternating current I_1 .

[0061] The orthogonal signal $\sin(90)$ is an alternating-current signal having the reference frequency f_b , a phase advanced by 90° with respect to the output current of the positive-electrode side power supply unit 531 and the same amplitude as the in-phase signal $\sin(0)$. The orthogonal signal $\sin(90)$ is input to the orthogonal component extraction unit 720 while turning, for example, the phase of the alternating-current signal source 546 by 90° .

[0062] The orthogonal component extraction unit 720 includes an orthogonal multiplier 721 and an orthogonal low-pass filter 722.

[0063] The orthogonal multiplier 721 multiplies the alternating-current potential V_a by the orthogonal signal $\sin(90)$. This causes an orthogonal alternating-current signal corresponding to a degree of coincidence of the waveform of the alternating-current potential V_a and that of the orthogonal signal $\sin(90)$ to be output from the orthogonal multiplier 721.

[0064] The orthogonal low-pass filter 722 detects a direct-current component of the orthogonal alternating-current signal as the imaginary axis component V_{1x} . In the present embodiment, the orthogonal low-pass filter 722 is realized by a low-pass filter (LPF) for removing an alternating-current component of the orthogonal alternating-current signal, i.e. a high-frequency range component and allowing the passage of a direct-current component of the orthogonal alternating-current signal. The orthogonal alternating-current signal smoothed by the orthogonal low-pass filter 722 is input as the imaginary axis component V_{1x} of the detection signal to the phase

difference detection unit 561.

[0065] As just described, the orthogonal component extraction unit 720 rectifies the alternating-current potential difference V_a by multiplying the alternating-current potential V_a by the orthogonal signal $\sin(90^\circ)$. In this way, only the alternating-current signal having the same frequency as the output current of the positive-electrode side power supply unit 531 and having the phase advanced by 90° from that of the output current can be extracted as the imaginary axis component V_{1x} from the alternating-current potential V_a . Thus, even if the alternating-current potential V_a is buried in noise, the imaginary axis component V_{1x} can be reliably detected.

[0066] As described above, the positive-electrode side detector circuit 5411 detects the real axis component V_{1r} and the imaginary axis component V_{1x} of the alternating-current potential difference V_1 on the basis of the alternating-current potential V_a . Then, the positive-electrode side detector circuit 5411 outputs the real axis component V_{1r} to the positive-electrode side subtractor 5421 to feed back the amplitude of the alternating current output from the positive-electrode side power supply unit 531. Further, the positive-electrode side detector circuit 5411 outputs the imaginary axis component V_{1x} of the alternating-current potential difference V_1 to the phase difference detection unit 561 to detect the phase difference between the alternating-current potentials generated at the positive electrode terminal 211 and the negative electrode terminal 212 of the fuel cell stack 1.

[0067] It should be noted that although an example in which the real axis component V_{1r} of the alternating-current potential difference V_1 is output to the positive-electrode side subtractor 5421 has been described in the present embodiment, a vector value V_{1p} of the alternating-current potential difference V_1 may be computed from the alternating-current potential V_a and output to the positive-electrode side subtractor 5421. Specifically, the vector value V_{1p}

is obtained by computing a square root of the sum of a square value of the real axis component $V1r$ and a square value of the imaginary axis component $V1x$ as in the following equation.

[0068] [Equation 1]

$$V1p = \sqrt{V1r^2 \times V1x^2} \quad \dots (1)$$

[0069] Further, an example in which the real axis component $V1r$ and the imaginary axis component $V1x$ of the alternating-current potential difference $V1$ are extracted from the alternating-current potential Va generated at the output terminal of the positive-electrode side power supply unit 531 has been described in the present embodiment. However, the real axis component $V1r$ and the imaginary axis component $V1x$ of the alternating-current potential difference $V1$ may be extracted from an output signal of the positive-electrode side potential difference detection unit 521 instead of from the alternating-current potential Va . For example, the real axis component $V1r$ of the alternating-current potential difference $V1$ can be detected by multiplying a detection signal indicating the alternating-current potential difference $V1$ output from the positive-electrode side potential difference detection unit 521 by the in-phase signal $\sin(0)$.

[0070] As described above, the alternating current adjustment unit 540 adjusts the amplitude of the alternating current output from the positive-electrode side power supply unit 531 such that the real axis component $V1r$ of the alternating-current potential difference $V1$ extracted from the alternating-current potential Va becomes the reference voltage Vs . Similarly, the alternating current adjustment unit 540 adjusts the amplitude of the alternating current output from the negative-electrode side power supply unit 532 such that the real axis component $V2r$ of the alternating-current potential difference $V2$ extracted from the alternating-current potential Vb becomes the reference voltage Vs .

[0071] Since this causes the alternating-current potentials V_a and V_b to be controlled to the same level, the amplitude of the alternating-current potential to be superimposed on the positive electrode terminal 211 and that of the alternating-current potential to be superimposed on the negative electrode terminal 212 become equal to each other. In this way, it can be prevented that the alternating current leaks from the impedance measuring device 5 toward the load 3 via the fuel cell stack 1. It should be noted that a control of the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 such that the alternating-current potentials V_a and V_b become equal to each other is referred to as an “equipotential control” below.

[0072] However, since the power generation cells 10 equivalently have capacitance components besides resistance components, the equipotential control may not properly function due to the capacitance components combined in the fuel cell stack 1. A case where the equipotential control does not properly function is described below.

[0073] An equivalent circuit of the fuel cell stack 1 can be expressed as a circuit in which an internal resistance R_1 on the positive electrode side and an internal resistance R_2 on the negative electrode side, and a capacitance C_1 on the positive electrode side and a capacitance C_2 on the negative electrode side are connected in parallel as shown in FIG. 2. The inventors found out that the capacitances C_1 and C_2 largely changed depending on the operating state of the fuel cell stack 1, the operating state of the load 3 and the like.

[0074] For example, when power required from the load 3 suddenly increases during the power generation of the fuel cell stack 1 and an output current extracted from the fuel cell stack 1 increases, gas concentrations of the anode gas and the cathode gas in the fuel cell stack 1 increase. Associated with this, the capacitances C_1 and C_2 change and a phase difference Φ

between the detection signal indicating the alternating-current potential difference V1 and the detection signal indicating the alternating-current potential difference V2 increases.

[0075] FIG. 7 is a graph showing a phase deviation between the detection signals indicating the alternating-current potential differences V1 and V2.

[0076] FIG. 7 shows a vector 611 indicating the alternating-current potential difference V1, a vector 612 indicating the alternating-current potential difference V2 and a differential vector 613 indicating a potential difference V_e obtained by subtracting the vector 612 from the vector 611. Further, amplitudes of the detection signals are shown by dashed-dotted line.

[0077] It should be noted that a horizontal axis shows the real axis components of the alternating-current potential differences V1 and V2 with the alternating currents I1 and I2 as references and a vertical axis shows the imaginary axis components of the alternating-current potential differences V1 and V2.

[0078] In FIG. 7, the magnitudes of the vectors 611 and 612 are adjusted to the reference voltage V_s and the vectors 611 and 612 when a reactance of the capacitance C2 becomes smaller than that of the capacitance C1 due to the operating state of the fuel cell stack 1 or the load 3 are shown.

[0079] The vector 611 is delayed by a phase angle of θ_1 with respect to the alternating current I1 due to the capacitance C1. The real axis component V_{1r} of the vector 611 is a value obtained by multiplying the alternating current I1 and the internal resistance R1. The imaginary axis component V_{1x} is a value obtained by multiplying the alternating current I1 and a capacitance reactance X_{1c} . It should be noted that the capacitance reactance X_{1c} is an inverse of a value obtained by multiplying an angular velocity ω of the alternating current I1 and the capacitance C1.

[0080] The vector 612 is delayed by a phase angle of θ_2 with respect to the

alternating current I_2 due to the capacitance C_2 . The real axis component V_{2r} of the vector 612 is a value obtained by multiplying the alternating current I_2 and the internal resistance R_2 . The imaginary axis component V_{2x} is a value obtained by multiplying the alternating current I_2 and a capacitance reactance X_{2c} . It should be noted that the capacitance reactance X_{2c} is an inverse of a value obtained by multiplying an angular velocity ω of the alternating current I_2 and the capacitance C_2 .

[0081] Here, a case where the phase angle θ_1 of the vector 611 becomes smaller than the phase angle θ_2 of the vector 612 is described.

[0082] In the fuel cell stack 1, the anode discharge port 41b is provided on the side of the positive electrode terminal 211 as shown in FIG. 1. For example, in a fuel cell system with a purge valve for discharging impurity gas such as nitrogen from the anode discharge port 41b, the impurity gas tends to be accumulated near the anode discharge port 41b, i.e. on the side of the positive electrode terminal 211. Thus, a hydrogen gas concentration of a group of the power generation cells laminated from the positive electrode terminal 211 to the intermediate-point terminal 213 may become lower than that of a group of the power generation cells laminated from the intermediate-point terminal 213 to the negative electrode terminal 212.

[0083] In such a situation, as the hydrogen gas concentration in the fuel cell stack 1 decreases, the capacitance components of the power generation cells 10 with respect to the alternating current become smaller. Thus, the capacitance C_1 becomes smaller than the capacitance C_2 . As a result, as shown in FIG. 7, the phase angle θ_1 of the vector 611 becomes smaller than the phase angle θ_2 of the vector 612 and the phase difference Φ is generated between the detection signal indicating the alternating-current potential difference V_1 and the detection signal indicating the alternating-current potential difference V_2 .

[0084] FIGS. 8 are conceptual charts showing an alternating current leaking to the load 3 when the phase difference Φ is generated between the detection signals indicating the alternating-current potential differences V1 and V2.

[0085] FIG. 8(a) is a chart showing waveforms of the alternating-current potential difference V1 of the vector 611 and the alternating-current potential difference V2 of the vector 612 shown in FIG. 7. FIG. 8(b) is a chart showing a waveform of the alternating-current potential difference Ve of the differential vector 613. A vertical axis represents amplitude and a horizontal axis is a common time axis in both FIGS. 8(a) and 8(b).

[0086] As shown in FIG. 8(a), the phase difference Φ between the phase angle θ_1 of the vector 611 and the phase angle θ_2 of the vector 612 is generated between the alternating-current potential differences V1 and V2. In such a case, as shown in FIG. 8(b), the alternating-current potential difference Ve is generated between the positive electrode terminal 211 and the negative electrode terminal 212 of the fuel cell stack 1.

[0087] Due to the alternating-current potential difference Ve, a part of the alternating current I1 or I2 output from the positive-electrode side power supply unit 531 or the negative-electrode side power supply unit 532 to the fuel cell stack 1 leaks toward the load 3 without flowing in the fuel cell stack 1. Here, a part of the alternating current I2 output from the negative-electrode side power supply unit 532 leaks toward the load 3 from the negative electrode terminal 212 of the fuel cell stack 1.

[0088] When the part of the alternating current I2 leaks to the load 3, an error is created between the current command value I2 used to compute the internal resistance R2 and an actual value of the current actually flowing through the resistance component R2. Thus, an error of the calculated internal resistance R2 becomes large. Since the amount of the current

leaking to the load 3 also increases as the phase difference Φ increases, the measurement accuracy of the internal resistance R2 is reduced.

[0089] Thus, errors included in measurement results of the internal resistances R1 and R2 may be beyond an allowable range in a state where the capacitance C1 or C2 vary depending on the operating state of the fuel cell stack 1 and the phase difference Φ is created between the detection signals of the alternating-current potential differences V1 and V2.

[0090] Even in such a measurement state, the both signal levels of the detection signals output from the positive-electrode side detector circuit 5411 and the negative-electrode side detector circuit 5412 indicate a fixed value by the equipotential control. Thus, the impedance is measured without detecting that the measurement state of the impedance measuring device 5 is defective.

[0091] Accordingly, in the embodiment of the present invention, a phase difference of the alternating-current potentials supplied to both the positive electrode terminal 211 and the negative electrode terminal 212 due to the capacitance components of the fuel cell stack 1 is detected and whether or not the measurement state where the impedance is measured is defective is diagnosed on the basis of that phase difference.

[0092] In the first embodiment, this is realized by the phase difference detection unit 561 and a determination circuit 562 shown in FIG. 5.

[0093] The phase difference detection unit 561 is a circuit for detecting a phase difference between an alternating-current potential generated at the positive electrode terminal 211 and an alternating-current potential generated at the negative electrode terminal 212 of the fuel cell stack 1. The phase difference detection unit 561 calculates the phase difference between the alternating-current potential differences V1 and V2 on the basis of the detection signal of the alternating-current potential difference V1 output from

the positive-electrode side detector circuit 5411 and the detection signal of the alternating-current potential difference V2 output from the negative-electrode side detector circuit 5412.

[0094] Specifically, the phase difference detection unit 561 computes the phase angle $\theta 1$ of the alternating-current potential difference V1 using the real axis component V1r and the imaginary axis component V1x of the alternating-current potential difference V1 output from the positive-electrode side detector circuit 5411 in accordance with the following equation.

[0095] [Equation 2]

$$\theta 1 = \tan^{-1} \left(\frac{V1r}{V1x} \right) \quad \dots (2)$$

[0096] Further, the phase difference detection unit 561 computes the phase angle $\theta 2$ of the alternating-current potential difference V2 using the real axis component V2r and the imaginary axis component V2x of the alternating-current potential difference V2 output from the positive-electrode side detector circuit 5412 in accordance with the following equation.

[0097] [Equation 3]

$$\theta 2 = \tan^{-1} \left(\frac{V2r}{V2x} \right) \quad \dots (3)$$

[0098] Then, the phase difference detection unit 561 calculates a value obtained by subtracting the phase angle $\theta 2$ of the alternating-current potential difference V2 from the phase angle $\theta 1$ of the alternating-current potential difference V1 as the phase difference Φ between the alternating-current potential generated at the positive electrode terminal 211 and the alternating-current potential generated at the negative electrode terminal as in the following equation and outputs it to the determination circuit 562.

[0099] [Equation 4]

$$\Phi = \theta_1 - \theta_2 \quad \dots (4)$$

[0100] The determination circuit 562 compares the phase difference Φ output from the phase difference detection unit 561 and a predetermined allowable value Th1 and diagnoses whether or not the measurement state where the internal resistances R1 and R2 are measured is defective.

[0101] The allowable value Th1 of the phase difference Φ is an upper limit value in a range where an measurement error is allowable, i.e. a threshold value and set by experimental data or the like. It should be noted that a technique for determining the allowable value Th1 is described later with reference to FIG. 10.

[0102] In the present embodiment, the determination circuit 562 judges that the equipotential control is defective due to the phase difference Φ and generates a determination signal of H (High)-level indicating that that the measurement state is defective when the phase difference Φ is larger than the allowable value Th1 or when the phase difference Φ is equal to the allowable value Th1.

[0103] On the other hand, the determination circuit 562 generates a determination signal of L (Low)-level indicating that the measurement state is not defective when the phase difference Φ is smaller than the allowable value Th1. Then, the determination circuit 562 outputs the generated determination signal to the controller unit 6 or the computation unit 550.

[0104] Next, the computation unit 550 is described in detail with reference to FIG. 9.

[0105] The detection signals indicating the alternating-current potential differences V1 and V2 and output from the positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522, and the command signals of the alternating currents I1 and I2 for the positive-electrode side power supply unit 531 and

the negative-electrode side power supply unit 532 are input to the computation unit 550. Specifically, the computation unit 550 obtains the detection values of the alternating currents I1 and I2 and those of the alternating-current potential differences V1 and V2.

[0106] The computation unit 550 computes the internal impedance of the fuel cell stack 1 on the basis of the alternating-current potential differences V1 and V2 and the alternating currents I1 and I2.

[0107] For example, the computation unit 550 computes the real axis component and the imaginary axis component of the alternating-current potential difference V1 on the basis of the detection signal from the positive-electrode side potential difference detection unit 521 and computes the real axis component and the imaginary axis component of the alternating-current potential difference V2 on the basis of the detection signal from the negative-electrode side potential difference detection unit 522.

[0108] In the present embodiment, the computation unit 550 calculates the internal resistance R1 by dividing the real axis component of the alternating-current potential difference V1 by the alternating current I1 and calculates the internal resistance R2 by dividing the real axis component of the alternating-current potential difference V2 by the alternating current I2. It should be noted that the computation unit 550 may calculate the capacitances C1 and C2 using the imaginary axis components of the alternating-current potential differences V1 and V2.

[0109] It should be noted that the computation unit 550 may compute average or effective values of the alternating-current potential differences V1 and V2 on the basis of the detection signals from the positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522 and compute average or effective values of the alternating currents I1 and I2 on the basis of the command signals from

the alternating current adjustment unit 540. Then, the computation unit 550 calculates the internal resistance R_1 by dividing the average or effective value of the alternating-current potential difference V_1 by the average or effective value of the alternating current I_1 and calculates the internal resistance R_2 by dividing the average or effective value of the alternating-current potential difference V_2 by the average or effective value of the alternating current I_2 .

[0110] The computation unit 550 includes an AD (Analog-Digital) converter 551 and a microcomputer chip 552.

[0111] The AD converter 551 converts the command signals (I_1 , I_2) of the alternating currents and the detection signals (V_1 , V_2) of the alternating-current potential differences, which are analog signals, into digital numeric signals and transfers them to the microcomputer chip 552.

[0112] The microcomputer chip 552 stores a program for calculating internal resistances R_n and the internal resistance R of the entire fuel cell stack 1 in advance. The microcomputer chip 552 successively computes at prescribed minute time intervals or outputs a computation result according to a request of the controller unit 6. It should be noted that the internal resistances R_n and the internal resistance R of the entire fuel cell stack 1 are computed by the following equations.

[0113] [Equations 5]

$$\text{Computation equation for resistance } R_n = \frac{V_n}{I_n} (n=1,2,\dots,n) \quad \dots (5-1)$$

$$\text{Overall resistance value } R = \sum R_n \quad \dots (5-2)$$

[0114] The computation unit 550 may be realized by an analog computation circuit using an analog computation IC. According to the analog computation circuit, a temporally continuous change of the resistance value can be output to the controller unit 6.

[0115] The controller unit 6 obtains the internal resistance R output from the computation unit 550 as an impedance measurement result and obtains the determination signal output from the determination circuit 562 as a measurement state determination result. The determination signal is input to the controller unit 6, for example, via the computation unit 550.

[0116] The controller unit 6 controls the operating state of the fuel cell stack 1 according to the measurement result of the internal resistance R . For example, the controller unit 6 judges that the electrolyte membranes of the fuel cell stack 1 are dry and reduces a flow rate of the cathode gas supplied to the fuel cell stack 1 if the internal resistance R is high. In this way, the amount of moisture carried out from the fuel cell stack 1 can be reduced.

[0117] In the present embodiment, the controller unit 6 judges that the measurement state is defective and discards the measurement result of the internal resistance R when a balance between the capacitances $C1$ and $C2$ is lost, the phase difference Φ of the alternating-current potential differences $V1$ and $V2$ increases and the determination signal becomes H-level.

[0118] Then, the controller unit 6 sets the internal resistance R computed by the computation unit 550 before the determination signal is switched from L-level to H-level as the measurement result and fixes the measurement result until the determination signal returns to L-level.

[0119] Specifically, every time the internal resistance R is obtained in a prescribed sampling cycle, the controller unit 6 records that resistance value in time series in an unillustrated memory and holds it in the memory for a specific period. Then, the controller unit 6 calculates a fixed value to be used as the measurement result on the basis of a plurality of resistance values held in the memory when the determination signal is switched from L-level to H-level. For example, an average value of the plurality of resistance values held in the memory, an update value recorded last in the memory out of the

plurality of resistance values or the like is used as the fixed value.

[0120] It should be noted that although an example in which the measurement result of the internal resistance R is discarded if the measurement state of the impedance measuring device 5 is determined to be defective has been described here, measurement data in which a code indicating a measurement failure, the phase difference Φ detected by the phase difference detection unit 561 and the like are attached to the measurement result may be generated without discarding the measurement result. A plurality of control blocks for controlling a cathode gas supply flow rate, an anode gas supply flow rate, a cooling water temperature and the like of the fuel cell stack 1 are present in the controller unit 6 and, if required measurement accuracy of the internal resistance R differs for each control block, how to handle the measurement result can be changed according to the code attached to the measurement data.

[0121] Further, although an example in which the determination circuit 562 is provided in the alternating current adjustment unit 540 has been described in the present embodiment, there is no limitation to this.

[0122] For example, the phase difference Φ detected by the phase difference detection unit 561 may be directly input to the controller unit 6 and the controller unit 6 may diagnose whether or not the measurement state of the impedance measuring device 5 is defective. Alternatively, the phase difference Φ may be input to the computation unit 550 and the computation unit 550 may diagnose the measurement state and may discard the measurement result and output the measurement result before the determination of a measurement failure to the controller unit 6 if the measurement failure is determined.

[0123] Furthermore, although an example in which the phase difference Φ of the alternating-current potential differences $V1$ and $V2$ is computed in the

phase difference detection unit 561 has been described in the present invention, the phase difference Φ may be computed in the computation unit 550.

[0124] Specifically, the real axis component $V1r$ and the imaginary axis component $V1x$ output from the positive-electrode side detector circuit 5411 and the real axis component $V2r$ and the imaginary axis component $V2x$ output from the negative-electrode side detector circuit 5412 are input to the computation unit 550 and the phase difference Φ is computed in accordance with equations (2) to (4) in the computation unit 550.

[0125] Further, although an example in which the phase difference Φ of the alternating-current potential differences $V1$ and $V2$ is used to detect whether or not the measurement state is defective has been described in the present embodiment, a difference ΔVx between the imaginary axis component $V1x$ on the positive electrode side and the imaginary axis component $V2x$ on the negative electrode side may be used.

[0126] The phase difference Φ of the alternating-current potential differences $V1$ and $V2$ is in a proportional relationship with the difference ΔVx obtained by subtracting the imaginary axis component $V2x$ on the negative electrode side from the imaginary axis component $V1x$ on the positive electrode side as shown in the following equation. For example, as the phase difference Φ of the detection signals increases, the difference ΔVx of the imaginary axis components increases.

[0127] [Equation 6]

$$\Phi \propto (V1x - V2x) \quad \dots (6)$$

[0128] Accordingly, by utilizing the relationship of equation (6), the measurement state can be determined to be defective if the difference ΔVx of the imaginary axis components exceeds a prescribed allowable value. It should be noted that the allowable value is an upper limit value in a range

where an impedance measurement error is allowable, and set according to a system design from experimental data or the like.

[0129] Next, a setting technique for setting the allowable value $Th1$ for the phase difference Φ between the alternating-current potentials Va and Vb is described.

[0130] FIG. 10 is a diagram showing an example of the setting technique for setting the allowable value for the phase difference Φ used in the determination circuit 562.

[0131] In FIG. 10, it is assumed that a relationship of a leakage current $I_L(\Phi)$, whose amplitude value changes according to the magnitude of the phase difference Φ , and an impedance measurement error E is linear. In such a case, a transmission function G is computed by modeling a circuit configuration of the impedance measuring device 5.

[0132] As a circuit model of the transmission function G , the alternating currents $I1$ and $I2$ on the positive and negative electrode sides are input to the fuel cell stack 1. Then, the alternating-current potential differences $V1$ and $V2$, the alternating currents $I1$ and $I2$ and the leakage current $I_L(\Phi)$ which is a part of the alternating current $I1$ or $I2$ leaking to the load 3 from one electrode terminal of the fuel cell stack 1 and flowing to the other electrode terminal, are input from the fuel cell stack 1 to the impedance measuring device 5. This causes an measurement error $E(\Phi)$ corresponding to the leakage current $I_L(\Phi)$ to be added to the internal resistance R , and that addition value is output as a measurement result from the impedance measuring device 5.

[0133] Inputs of this transmission function G include the alternating-current potential differences $V1$ and $V2$ on the positive and negative electrode sides when being adjusted to the reference voltage Vs , an alternating current $(I1-I_L)$ on the positive electrode side obtained by subtracting the leakage current I_L from the alternating current $I1$ and an

alternating current ($I_2 + I_L$) on the negative electrode side obtained by adding the leakage current I_L to the alternating current I_2 . An output of the transmission function G in response to these inputs is a value obtained by adding the measurement error $E(\Phi)$ to the internal resistance R (V_s , I_1 , I_2).

[0134] By substituting the allowable value $E(\Phi)$ of the measurement error determined according to the usage of the measurement result into an inverse transmission function G^{-1} of such a transmission function G , the leakage current $I_L(\Phi)$ is calculated and this calculation value is used as a determination value for determining whether or not the measurement state is defective. The allowable value $Th1$ of the phase difference Φ is determined by this determination value.

[0135] It should be noted that although an example in which the allowable value $Th1$ is set by computing the transmission function G has been described here, there is no limitation to this. For example, a relationship between the phase difference Φ detected by the phase difference detection unit 561 and the measurement error $E(\Phi)$ by the impedance measuring device 5 may be obtained in advance by an experiment or the like and the phase difference Φ corresponding to the allowable measurement error $E(\Phi)$ may be set as the allowable value $Th1$.

[0136] Further, although an example in which the allowable value $Th1$ is fixed at a predetermined value has been described in the present embodiment, the allowable value $Th1$ may be appropriately changed in consideration of deterioration causes since characteristics of substances constituting the fuel cell stack 1 are deteriorated as the use time of the fuel cell stack 1 becomes longer.

[0137] For example, a data table or a function expression indicating a relationship of an integrated value of the use time of the fuel cell stack 1 and the allowable value of the phase difference Φ is stored in advance in the

impedance measuring device 5 and the allowable value Th1 is changed such as at the start-up of the impedance measuring device 5 using such a data table or the like. Further, the allowable value Th1 may be set or revised in consideration of a variable element due to a reduction in the oscillation accuracy of the alternating currents of the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 provided in the impedance measuring device 5 besides the integrated use time of the fuel cell stack 1.

[0138] In this way, the allowable value used to determine whether or not the impedance measurement state is defective can be properly set. Thus, whether or not the measurement state is defective can be properly diagnosed and reliability for the measurement result can be enhanced.

[0139] FIG. 11 is a flow chart showing an example of a control method when the equipotential control executed by the alternating current adjustment unit 540 is realized by a controller.

[0140] In Step S1, the controller determines whether or not the positive electrode alternating-current potential V_a is larger than a prescribed value. The controller proceeds to Step S2 if a determination result is negative while proceeding to Step S3 if the determination result is affirmative.

[0141] In Step S2, the controller determines whether or not the positive electrode alternating-current potential V_a is smaller than the prescribed value. The controller proceeds to Step S4 if a determination result is negative while proceeding to Step S5 if the determination result is affirmative.

[0142] In Step S3, the controller reduces the output of the positive-electrode side power supply unit 531. Specifically, the controller reduces the amplitude of the alternating current I1. In this way, the positive electrode alternating-current potential V_a decreases.

[0143] In Step S4, the controller maintains the output of the

positive-electrode side power supply unit 531. In this way, the positive electrode alternating-current potential V_a is maintained.

[0144] In Step S5, the controller increases the output of the positive-electrode side power supply unit 531. In this way, the positive electrode alternating-current potential V_a increases.

[0145] In Step S6, the controller determines whether or not the negative electrode alternating-current potential V_b is larger than the prescribed value. The controller proceeds to Step S7 if a determination result is negative while proceeding to Step S8 if the determination result is affirmative.

[0146] In Step S7, the controller determines whether or not the negative electrode alternating-current potential V_b is smaller than the prescribed value. The controller proceeds to Step S9 if a determination result is negative while proceeding to Step S10 if the determination result is affirmative.

[0147] In Step S8, the controller reduces the output of the negative-electrode side power supply unit 532. In this way, the negative electrode alternating-current potential V_b decreases.

[0148] In Step S9, the controller maintains the output of the negative-electrode side power supply unit 532. In this way, the negative electrode alternating-current potential V_b is maintained.

[0149] In Step S10, the controller increases the output of the negative-electrode side power supply unit 532. In this way, the negative electrode alternating-current potential V_b increases.

[0150] In Step S11, the controller determines whether or not the alternating-current potentials V_a and V_b are the prescribed value. The controller proceeds to Step S12 if a determination result is affirmative while exiting from the process if the determination result is negative.

[0151] In Step S12, the controller computes the internal resistance values in accordance with the aforementioned equations (5-1), (5-2).

[0152] FIGS. 12 are time charts when the impedance measuring device 5 is controlled by the controller. It should be noted that step numbers are also written to make correspondence with the flow chart easily understandable.

[0153] In an initial stage in FIGS. 12, the internal resistance value R_1 on the positive electrode side is higher than the internal resistance value R_2 on the negative electrode side (FIG. 12(A)). The controller starts the control in such a state.

[0154] At time t_0 , neither the positive electrode alternating-current potential V_a nor the negative electrode alternating-current potential V_b has reached a control level (FIG. 12(C)). In this state, the controller repeats Steps $S_1 \rightarrow S_2 \rightarrow S_5 \rightarrow S_6 \rightarrow S_7 \rightarrow S_{10} \rightarrow S_{11}$. This causes the alternating current I_1 on the positive electrode side and the alternating current I_2 on the negative electrode side to increase (FIG. 12(B)).

[0155] When the positive electrode alternating-current potential V_a reaches the control level at time t_1 (FIG. 12(C)), the controller repeats Steps $S_1 \rightarrow S_2 \rightarrow S_4 \rightarrow S_6 \rightarrow S_7 \rightarrow S_{10} \rightarrow S_{11}$. This causes the alternating current I_1 on the positive electrode side to be maintained and the alternating current I_2 on the negative electrode side to increase (FIG. 12(B)).

[0156] When the negative electrode alternating-current potential V_b also reaches the control level to have the same level as the positive electrode alternating-current potential V_a at time t_2 (FIG. 12(C)), the controller repeats Steps $S_1 \rightarrow S_2 \rightarrow S_4 \rightarrow S_6 \rightarrow S_7 \rightarrow S_9 \rightarrow S_{11} \rightarrow S_{12}$. This causes the alternating current I_1 on the positive electrode side and the alternating current I_2 on the negative electrode side to be maintained. Then, the internal resistance value R_1 on the positive electrode side and the internal resistance value R_2 on the negative electrode side are computed in accordance with equation (5-1). Then, the overall internal resistance value R is computed by adding the internal resistance value R_1 on the positive electrode side and the internal resistance

value R2 on the negative electrode side.

[0157] The internal resistance value R2 on the negative electrode side increases due to a change in the wet state of the fuel cell stack or the like at and after time t3 (FIG. 12(A)). In this case, the controller repeats Steps S1→S2→S4→S6→S8→S11→S12. Since the alternating current I2 on the negative electrode side is reduced in accordance with an increase of the internal resistance value R2 on the negative electrode side by processing in this way, the negative electrode alternating-current potential Vb is maintained at the same level as the positive electrode alternating-current potential Va. Thus, the internal resistance R is computed also in this state.

[0158] At and after t4, the internal resistance value R2 on the negative electrode side coincides with the internal resistance value R1 on the positive electrode side (FIG. 12(A)). In this case, the controller repeats Steps S1→S2→S4→S6→S7→S9→S11→S12. The alternating-current potential Va on the positive electrode side and the alternating-current potential Vb on the negative electrode are maintained at the same level (FIG. 12(C)) by processing in this way, and the internal resistance R is computed.

[0159] Next, functions and effects when the measurement state is acceptable due to the equipotential control of the impedance measuring device 5 are described.

[0160] FIG. 13 is a chart illustrating states of the positive electrode potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and the negative electrode potential generated at the negative electrode terminal 212 when the measurement state of the impedance measuring device 5 is acceptable.

[0161] During the output of the fuel cell stack 1, a potential difference V3 is generated between the positive electrode terminal 211 and the negative electrode terminal 212. Before the impedance measuring device 5 is started

(ON), the positive electrode potential and the negative electrode potential are constant and a direct-current voltage is supplied to the load 3. Thereafter, when the impedance measuring device 5 is started and the alternating currents I1 and I2 are output from the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532, the alternating-current potential Va is superimposed on the positive electrode potential and the alternating-current potential Vb is superimposed on the negative electrode potential.

[0162] Then, in accordance with the commands by the alternating current adjustment unit 540, the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 output the alternating currents I1 and I2 while adjusting the amplitudes thereof.

[0163] The alternating current I1 output from the positive-electrode side power supply unit 531 is output to the positive electrode terminal 211 of the fuel cell stack 1 via the positive-electrode side direct current shut-off unit 511 and flows into the positive-electrode side potential difference detection unit 521 via the intermediate-point terminal 213 and the intermediate point direct current shut-off unit 513. At this time, the alternating-current potential difference V1 ($V1 = Va - Vc$) is generated between the positive electrode terminal 211 and the intermediate-point terminal 213 due to an impedance determined by the internal resistance R1 and the capacitance C1 and the alternating current I1. This alternating-current potential difference V1 is detected by the positive-electrode side potential difference detection unit 521.

[0164] On the other hand, the alternating current I2 output from the negative-electrode side power supply unit 532 is output to the negative electrode terminal 212 of the fuel cell stack 1 via the negative-electrode side direct current shut-off unit 512 and flows into the negative-electrode side potential difference detection unit 522 via the intermediate-point terminal 213

and the intermediate point direct current shut-off unit 513. At this time, the alternating-current potential difference V_2 ($V_2 = V_b - V_c$) is generated between the negative electrode terminal 212 and the intermediate-point terminal 213 due to an impedance determined by the internal resistance R_2 and the capacitance C_2 and the alternating current I_2 . This alternating-current potential difference V_2 is detected by the negative-electrode side potential difference detection unit 522.

[0165] The alternating current adjustment unit 540 adjusts the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 such that a difference ($V_1 - V_2$) between the alternating-current potential difference V_1 on the positive electrode side of the fuel cell stack 1 and the alternating-current potential difference V_2 on the negative electrode side, i.e. a difference ($V_a - V_b$) between the alternating-current potentials V_a and V_b is constantly small.

[0166] Thus, the amplitude of the alternating-current component V_a of the positive electrode potential and that of the alternating-current component V_b of the negative electrode potential are adjusted, wherefore the voltage difference V_3 is constant without variation in a state where no phase difference Φ is generated between the alternating-current potentials V_a and V_b .

[0167] Then, the computation unit 550 applies Ohm's law using the alternating-current potential differences V_1 and V_2 output from the positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522 and the alternating currents I_1 and I_2 output from the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532. In this way, the internal resistance R_1 on the positive electrode side and the internal resistance R_2 on the negative electrode side of the fuel cell stack 1 are calculated in the computation unit 550.

[0168] Here, since the alternating-current potentials of the positive electrode terminal 211 and the negative electrode terminal 212 are equal, the leakage of the alternating current to the load device 3 can be suppressed even if the load device 3 such as a travel motor is connected to the positive electrode terminal 211 and the negative electrode terminal 212.

[0169] In this way, the values of the alternating currents I_1 and I_2 flowing into the fuel cell stack 1 whose internal resistance is measured and the values of the alternating currents output from the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 substantially coincide. Thus, the internal resistance values R_1 and R_2 of the fuel cell stack 1 can be precisely computed by the alternating current values output from the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532. Further, without depending on the state of the load 3, the internal resistance R of the entire fuel cell stack 1 can be precisely measured on the basis of the internal resistance values R_1 and R_2 of the fuel cell stack 1 in operation. Further, since the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 are used, the internal resistance R can be measured even while the fuel cell stack 1 is stopped.

[0170] FIG. 14 is a flow chart showing a process procedure example of a failure detection method for detecting whether or not the measurement state of the impedance measuring device 5 is defective.

[0171] In Step S101, the positive-electrode side detector circuit 5411 resolves the alternating-current potential difference V_1 on the positive electrode side into the real axis component V_{1r} and the imaginary axis component V_{1x} and outputs the real axis component V_{1r} and the imaginary axis component V_{1x} to the phase difference detection unit 561.

[0172] In Step S102, the phase difference detection unit 561 computes the

phase angle θ_1 of the alternating-current potential difference V_1 with respect to the alternating current I_1 on the basis of the real axis component V_{1r} and the imaginary axis component V_{1x} of the alternating-current potential difference V_1 in accordance with equation (2).

[0173] In Step S103, the negative-electrode side detector circuit 5412 resolves the alternating-current potential difference V_2 on the negative electrode side into the real axis component V_{2r} and the imaginary axis component V_{2x} and outputs the real axis component V_{2r} and the imaginary axis component V_{2c} to the phase difference detection unit 561.

[0174] In Step S104, the phase difference detection unit 561 computes the phase angle θ_2 of the alternating-current potential difference V_2 with respect to the alternating current I_2 on the basis of the real axis component V_{2r} and the imaginary axis component V_{2x} of the alternating-current potential difference V_2 in accordance with equation (3).

[0175] In Step S105, the phase difference detection unit 561 outputs a value obtained by subtracting the phase angle θ_2 of the alternating-current potential difference V_2 from the phase angle θ_1 of the alternating-current potential difference V_1 in accordance with equation (4) as the phase difference Φ between the alternating-current potential differences V_1 and V_2 to the determination circuit 562.

[0176] In Step S106, the determination circuit 562 judges whether or not the phase difference Φ is smaller than the allowable value Th_1 . Then, the determination circuit 562 determines the measurement state of the internal resistance R_2 to be acceptable if the phase difference Φ is smaller than the allowable value Th_1 . On the other hand, the determination circuit 562 determines the measurement state to be defective if the phase difference Φ is not smaller than the allowable value Th_1 . The determination circuit 562 outputs that determination result to the computation unit 550.

[0177] In Step S107, the computation unit 550 outputs the resistance values computed in Step S12 shown in FIG. 11 as a measurement result to the controller unit 6 if the measurement state of the internal resistance R is determined to be acceptable. It should be noted that the computation unit 550 may generate and output measurement data indicating the resistance values computed in Step S12, the determination result and the phase difference Φ .

[0178] On the other hand, the computation unit 550 performs a measurement result processing associated with a measurement failure in Step S108 if the measurement state of the internal resistance R is determined to be defective.

[0179] In the measurement result processing, the computation unit 550 discards the resistance values computed in Step S12 and outputs the resistance values before the determination of the measurement failure as the measurement result to the controller unit 6, for example, only for a prescribed time. Alternatively, the computation unit 550 may generate and output measurement data indicating the resistance values computed in Step S12 and the determination result.

[0180] When the process is finished in Step S107 or S108, a series of processings of the failure detection method based on the phase difference Φ are finished.

[0181] According to the first embodiment of the present invention, the impedance of the fuel cell stack 1 as an example of a laminated type battery is measured. This impedance measuring device 5 includes the positive-electrode side power supply unit 531 configured to output the alternating current of the prescribed reference frequency f_b to the positive electrode terminal 211 of the fuel cell stack 1 and the negative-electrode side power supply unit 532 configured to output the alternating current of the

reference frequency f_b to the negative electrode terminal 212 of the fuel cell stack 1. Further, the impedance measuring device 5 includes the positive-electrode side potential difference detection unit 521 configured to detect the alternating-current potential difference V_1 between the positive electrode terminal 211 and the intermediate-point terminal 213 and the negative-electrode side potential difference detection unit 522 configured to detect the alternating-current potential difference V_2 between the negative electrode terminal 212 and the intermediate-point terminal 213. The impedance measuring device 5 also includes the alternating current adjustment unit 540 configured to adjust the amplitude of the alternating current output from at least one of the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 such that the alternating-current potential differences V_1 and V_2 coincide, and the computation unit 550 configured to compute the impedance on the basis of the adjusted alternating current and alternating-current potential differences.

[0182] Further, the impedance measuring device 5 includes the phase difference detection unit 561 configured to compute the phase difference Φ between the alternating-current potential generated at the positive electrode terminal 211 and the alternating-current potential generated at the negative electrode terminal 212, or a parameter correlated with the phase difference Φ . Any one of a diagnosis process for diagnosing whether or not the measurement state is defective, a cancellation process for discarding the measurement result and a hold process for fixing the measurement result at a prescribed value having high reliability is performed on the basis of the phase difference Φ or the parameter correlated with the phase difference Φ .

[0183] As just described, the diagnosis process of the measurement state, the cancellation process of the measurement result and the hold process are performed by detecting the phase difference Φ between the alternating-current

potential generated at the positive electrode terminal 211 and the alternating-current potential generated at the negative electrode terminal 212. Thus, reliability for the measurement result can be ensured. Therefore, it is possible to maintain and improve reliability for the measurement result when the measurement accuracy of the impedance measuring device 5 is reduced due to variations of capacitance components of the laminated type battery.

[0184] For example, depending on the operating state of the fuel cell stack 1, the capacitance components of the fuel cell stack 1 may change in response to the alternating-current signal of the reference frequency f_b and a difference between the capacitance C_1 on the positive electrode side and the capacitance C_2 on the negative electrode side may increase. In such a case, the phase difference Φ between the alternating-current potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and the alternating-current potential generated at the negative electrode terminal 212 increases and more alternating current leaks to the load 3 connected to the fuel cell stack 1.

[0185] As a result, both an error between the output current I_1 of the positive-electrode side power supply unit 531 and the current actually flowing through the internal resistance R_1 and an error between the output current I_2 of the negative-electrode side power supply unit 532 and the current actually flowing through the internal resistance R_2 increase. Thus, the measurement accuracy of the internal resistance R is reduced.

[0186] Further, the internal resistance R measured by the impedance measuring device 5 is used, for example, to control a degree of wetness of the fuel cell stack 1 in a fuel cell system. Thus, it is difficult to properly control the degree of wetness of the fuel cell stack 1 with the internal resistance R measured in a state where the measurement accuracy of the internal resistance R is reduced, i.e. a state where the measurement state of the

impedance measuring device 5 is defective.

[0187] As a measure against this, in the present embodiment, the impedance measuring device 5 detects the phase difference Φ or the parameter related to the phase difference Φ and detects a reduction in impedance measurement accuracy due to variations of the capacitances C1 and C2.

[0188] For example, the impedance measuring device 5 outputs a diagnosis result to the effect that the measurement state is defective together with the measurement result if the measurement state is judged to be defective on the basis of the phase difference Φ . In this way, in a system using the measurement result, whether or not to use the internal resistance R can be judged according to the diagnosis result of the measurement state when the usage of the measurement result, measurement accuracy required from the system or the like is different.

[0189] Alternatively, the impedance measuring device 5 may discard the measurement result when the measurement state is determined to be defective. Since this prevents the measurement result with low measurement accuracy and low reliability from being output, only the measurement result with high reliability can be reliably output to the controller unit 6 or the like.

[0190] Further, even when the measurement state is defective, the past measurement result obtained before failure determination may be output. In this way, regardless of the measurement state of the impedance measuring device 5, it is possible to output the measurement result when the measurement state was acceptable, i.e. the measurement result with high measurement accuracy to a system that has to continue a control utilizing that measurement result.

[0191] Normally, in the fuel cell stack 1, the internal resistance R changes mainly depending on a degree of wetness of the power generation cells 10, whereas the capacitance C1 or C2 changes depending on a gaseous state in

the fuel cell stack 1, the operating state of the load 3 and the like. Thus, a correlation between a change of the internal resistance R and a change of the capacitance C is said to be low.

[0192] Accordingly, there is a high possibility that the resistance component R indicates a fixed value even in such a situation where the phase difference Φ increases according to a variation of the capacitance $C1$ or $C2$ and the measurement state is determined to be defective. Thus, when the measurement state is determined to be defective on the basis of the phase difference Φ , reliability for an output result can be improved by outputting the internal resistance value before the failure determination as the measurement result.

[0193] As just described, according to the first embodiment, it is possible to maintain and improve reliability for the measurement result as against a reduction in the measurement accuracy of the impedance measuring device 5 due to the capacitance components of the laminated type battery.

[0194] Further, in the present embodiment, the phase difference detection unit 561 computes the phase difference Φ on the basis of the detection signal indicating the alternating-current potential difference $V1$ output from the positive-electrode side detector circuit 5411 and the detection signal indicating the alternating-current potential difference $V2$ output from the negative-electrode side detector circuit 5412.

[0195] Then, the impedance measuring device 5 determines the measurement state to be defective if the phase difference Φ is not smaller than the prescribed threshold value $Th1$ and determines the measurement state to be acceptable if the phase difference Φ is smaller than the threshold value $Th1$. The threshold value $Th1$ is set on the basis of an allowable range of the measurement accuracy required from the system and the like.

[0196] Thus, even if the phase difference Φ is generated between the

alternating-current potential differences V1 and V2, the impedance measuring device 5 determines the measurement state to be acceptable within the allowable range of the measurement error and determines the measurement state to be defective only when the phase difference Φ is larger than the allowable range. In this way, the measurement state can be easily and properly diagnosed according to the request of the system that uses the measurement result.

[0197] It should be noted that an example in which the detection signals output from the positive-electrode side detector circuit 5411 and the negative-electrode side detector circuit 5412 are used as the respective detection signals of the alternating-current potential differences V1 and V2 has been described in the present embodiment. However, the phase difference Φ may be computed using the detection signals output from the positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522 instead of the detection signals output from the positive-electrode side detector circuit 5411 and the negative-electrode side detector circuit 5412.

[0198] (Second Embodiment)

FIG. 15 is a diagram showing the configurations of an alternating current adjustment unit 540 and a phase difference detection unit 571 in a second embodiment of the present invention.

[0199] In the second embodiment, the phase difference detection unit 571 and a determination circuit 572 are provided instead of the phase difference detection unit 561 and the determination circuit 562 shown in FIG. 5. It should be noted that constituent parts other than the phase difference detection unit 571 and the determination circuit 572 are not described here since being the same as those of the alternating current adjustment unit 540 shown in FIG. 5.

[0200] A positive-electrode side current command value $I1c$ output from a positive-electrode side integration circuit 5431 and a negative-electrode side current command value $I2c$ output from a negative-electrode side integration circuit 5432 are input to the phase difference detection unit 571.

[0201] The phase difference detection unit 571 calculates a difference between a time change amount $\Delta I1c$ of the positive-electrode side current command value $I1c$ and a time change amount $\Delta I2c$ of the negative-electrode side current command value $I2c$. The time change amounts $\Delta I1c$ and $\Delta I2c$ are time change rates and indicate increased or decreased amounts of the positive-electrode side current command value $I1c$ and the negative-electrode side current command value $I2c$ within the same time.

[0202] Generally, when an internal resistance R of a fuel cell stack 1 changes, the positive-electrode side current command value $I1c$ and the negative-electrode side current command value $I2c$ change in the same direction in a state where the difference between the positive-electrode side current command value $I1c$ and the negative-electrode side current command value $I2c$ is substantially constant. For example, both the positive-electrode side current command value $I1c$ and the negative-electrode side current command value $I2c$ increase when the internal resistance R decreases, and both the positive-electrode side current command value $I1c$ and the negative-electrode side current command value $I2c$ decrease when the internal resistance R increases.

[0203] Contrary to this, when an output voltage between a positive-electrode side 211 and a negative-electrode side 212 of the fuel cell stack 1 suddenly changes, the positive-electrode side current command value $I1c$ and the negative-electrode side current command value $I2c$ tend to change in opposite directions. The reason for such changes is that a voltage fluctuation is transmitted to a positive-electrode side power supply unit 531

due to a fluctuation of the output voltage of the fuel cell stack 1 and a phase angle and the like of an alternating-current potential V_a change. As a result, the phase difference Φ increases and the amount of a current leaking to a load 3 increases.

[0204] Accordingly, the phase difference detection unit 571 judges whether or not the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} have changed in opposite directions, using an absolute value of a difference obtained by subtracting the time change amount ΔI_{2c} from the time change amount ΔI_{1c} as a parameter related to the phase difference Φ .

[0205] FIG. 16A is a chart showing a judgment technique for judging whether or not the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} have changed in opposite directions. FIG. 16B is a graph showing a relationship of an absolute difference between the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} and a measurement state.

[0206] In FIG. 16A, the phase difference detection unit 571 obtains the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} in every prescribed determination cycle (S sec) and records the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} together in a memory 5711. Along with this, the phase difference detection unit 571 reads the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} recorded last time from the memory 5711.

[0207] At time n , the phase difference detection unit 571 obtains the positive-electrode side current command value $I_{1c}(n)$ and reads the last positive-electrode side current command value $I_{1c}(n-s)$ obtained S seconds

before time n from the memory 5711. It should be noted that a time at which the current command value was obtained is shown in parentheses here.

[0208] Then, the phase difference detection unit 571 calculates the time change amount $\Delta I1c$ of the positive-electrode side current command value $I1c$ by subtracting the positive-electrode side current command value $I1c(n-s)$ obtained last time from the positive-electrode side current command value $I1c(n)$ obtained this time as in the following equation.

[0209] [Equation 7]

$$\Delta I1c = I1c(n) - I1c(n-s) \quad \dots (7)$$

[0210] Here, since the positive-electrode side current command value $I1c$ has decreased, the time change amount $\Delta I1c$ is a negative (minus) value.

[0211] Further, the phase difference detection unit 571 obtains the negative-electrode side current command value $I2c(n)$ and reads the negative-electrode side current command value $I2c(n-s)$ obtained last time from the memory 5711 at time n . Then, the phase difference detection unit 571 calculates the time change amount $\Delta I2c$ of the negative-electrode side current command value $I2c$ by subtracting the negative-electrode side current command value $I2c(n-s)$ obtained last time from the negative-electrode side current command value $I2c(n)$ obtained this time as in the following equation.

[0212] [Equation 8]

$$\Delta I2c = I2c(n) - I2c(n-s) \quad \dots (8)$$

[0213] Here, since the negative-electrode side current command value $I2c$ has increased, the time change amount $\Delta I2c$ is a positive (plus) value.

[0214] Subsequently, the phase difference detection unit 571 calculates an absolute value of a value obtained by subtracting the time change amount $\Delta I2c$ of the negative-electrode side current command value $I2c$ from the time change amount $\Delta I1c$ of the positive-electrode side current command value $I1c$.

[0215] Since the time change amount $\Delta I1c$ is a negative value and the time

change amount ΔI_{2c} is a positive value at time n , the absolute value of the difference between the time change amounts ΔI_{1c} and ΔI_{2c} is a largest value. As just described, when the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} change in the opposite directions, the absolute value of the difference (absolute difference) between the time change amount ΔI_{1c} of the positive-electrode side current command value I_{1c} and the time change amount ΔI_{2c} of the negative-electrode side current command value I_{2c} increases.

[0216] Thus, as shown in FIG. 16B, the measurement state is determined to be defective when the absolute value ($|\Delta I_{1c} - \Delta I_{2c}|$) of the difference between the time change amounts ΔI_{1c} and ΔI_{2c} becomes larger than a predetermined allowable value Th_2 .

[0217] Therefore, in the present embodiment, the determination circuit 572 judges whether or not the absolute value of the difference between the time change amount ΔI_{1c} of the positive-electrode side current command value I_{1c} and the time change amount ΔI_{2c} of the negative-electrode side current command value I_{2c} is larger than the allowable value Th_2 as in the following equation.

[0218] [Equation 9]

$$|\Delta I_{1c} - \Delta I_{2c}| < Th_2 \quad \dots (9)$$

[0219] Then, as shown in FIG. 16A, the determination circuit 572 judges that the absolute value of the difference between the time change amounts ΔI_{1c} and ΔI_{2c} is larger than the allowable value Th_2 and determines the impedance measurement state to be defective at time n .

[0220] In such a situation, an equipotential control is balanced in a state where alternating currents I_1 and I_2 to be supplied to the fuel cell stack 1 partly leak to the load 3. Thus, a determination result to the effect that the measurement state is defective is output from the impedance measuring

device 5 also after time n.

[0221] It should be noted that an example in which the measurement state is determined using the absolute value of the difference between the time change amounts $\Delta I1c$ and $\Delta I2c$ has been described in the present embodiment, the determination circuit 572 may determine the measurement state using the time change amounts $\Delta I1c$ and $\Delta I2c$ as they are. In this case, both positive (plus) and negative (minus) allowable values are set in the determination circuit 572 and the determination circuit 572 determines the measurement state to be defective when an allowable range from the positive allowable value to the negative allowable value is exceeded.

[0222] FIG. 17 is a flow chart showing a process procedure of a diagnosis method for diagnosing a measurement state on the basis of the difference between the time change amount $\Delta I1c$ of the positive-electrode side current command value $I1c$ and the time change amount $\Delta I2c$ of the negative-electrode side current command value $I2c$. This computation method is performed in every prescribed determination cycle of S seconds.

[0223] In Step S201, the phase difference detection unit 571 waits until the determination cycle of S seconds elapses.

[0224] In Step S202, the phase difference detection unit 571 obtains both the positive-electrode side current command value $I1c(n)$ and the negative-electrode side current command value $I2c(n)$ of time n.

[0225] In Step S203, the phase difference detection unit 571 records both the positive-electrode side current command value $I1c(n)$ and the negative-electrode side current command value $I2c(n)$ obtained this time in the memory 5711 and reads the last positive-electrode side current command value $I1c(n-s)$ and negative-electrode side current command value $I2c(n-s)$ obtained S seconds ago from the memory 5711.

[0226] In Step S204, the phase difference detection unit 571 calculates the

time change amount $\Delta I1c$ of the positive-electrode side current command value $I1c$ by subtracting the positive-electrode side current command value $I1c(n-s)$ obtained last time from the positive-electrode side current command value $I1c(n)$ obtained this time in accordance with equation (7).

[0227] In Step S205, the phase difference detection unit 571 calculates the time change amount $\Delta I2c$ of the negative-electrode terminal current command value $I2c$ by subtracting the negative-electrode terminal current command value $I2c(n-s)$ obtained last time from the negative-electrode terminal current command value $I2c(n)$ obtained this time in accordance with equation (8).

[0228] Then, in Step S206, the phase difference detection unit 571 sets the absolute value of the difference between the time change amounts $\Delta I1c$ and $\Delta I2c$ as the parameter related to the phase difference Φ and outputs it to the determination circuit 572.

[0229] In Step S207, the determination circuit 572 judges in accordance with equation (9) whether or not the absolute value of the difference between the time change amounts $\Delta I1c$ and $\Delta I2c$ is larger than the allowable value $Th2$.

[0230] In Step S208, the determination circuit 572 determines the measurement state to be acceptable if the absolute value of the difference between the time change amounts $\Delta I1c$ and $\Delta I2c$ is not larger than the allowable value $Th2$. Thereafter, a computation unit 550 outputs computed resistance values to the controller unit 6, for example, similarly to the processing of Step S107 shown in FIG. 13.

[0231] In Step S209, the determination circuit 572 determines the measurement state to be defective if the absolute value of the difference between the time change amounts $\Delta I1c$ and $\Delta I2c$ is larger than the allowable value $Th2$. Then, the computation unit 550 outputs the computed resistance values to the controller unit 6 similarly to the processing of Step S107 shown in FIG. 13. Thereafter, the computation unit 550 performs a measurement

result processing, for example, similarly to the processing of Step S108 shown in FIG. 13.

[0232] When the processing of Step S208 or S209 is finished, a series of processings of the diagnosis method based on the difference between the time change amounts $\Delta I1c$ and $\Delta I2c$ are finished.

[0233] According to the second embodiment of the present invention, the alternating current adjustment unit 540 extracts a real axis component $V1r$ of an alternating-current potential difference $V1$ by a positive-electrode side detector circuit 5411 and calculates the positive-electrode side current command value $I1c$ for the positive-electrode side power supply unit 531. Along with this, the alternating current adjustment unit 540 extracts a real axis component $V2r$ of an alternating-current potential difference $V2$ by a positive-electrode side detector circuit 5412 and calculates the negative-electrode terminal current command value $I2c$ for a negative-electrode terminal power supply unit 532.

[0234] Then, the determination circuit 572 determines the measurement state of the impedance measuring device 5 to be defective if one of the positive-electrode side current command value $I1c$ and the negative-electrode terminal current command value $I2c$ increases when the other decreases.

[0235] In this way, it can be detected that the phase difference Φ increases to cause a measurement failure of the impedance measuring device 5 due to a transient change of the output voltage of the fuel cell system 1.

[0236] For example, a situation where a breaker connected between the fuel cell system 1 and the load 3 is switched from a shut-off state to a connected state after a start process of the fuel cell system 1 is completed falls into a situation where the output power of the fuel cell system 1 transiently changes. Since the amount of the current flowing from the fuel cell system 1 to the load 3 transiently largely changes in such a situation, the amount of

anode gas and cathode gas consumed in the fuel cell system 1 transiently increases, a gas concentration changes and the output voltage of the fuel cell system 1 fluctuates. As a result, the phase of the alternating current supplied from the positive-electrode side power supply unit 531 is likely to shift, a balance between a capacitance C1 on the positive electrode side and a capacitance C2 on the negative electrode side is lost and the alternating current I1 or I2 partly leaks to the load 3.

[0237] Alternatively, the amount of a power generation current supplied from the fuel cell system 1 to the load 3 transiently largely changes also when an accelerator operation amount is increased to suddenly accelerate a vehicle in a state where the power generation current is supplied from the fuel cell system 1 to the load 3. Also in such a situation, the output voltage of the fuel cell system 1 suddenly fluctuates as the gas concentration changes in the fuel cell system 1.

[0238] Particularly in such a fuel cell system that power is generated while anode gas is stored in the fuel cell system 1 without being circulated, more impurities are retained on a downstream side than on an upstream side of an anode gas flow passage in the fuel cell system 1. Thus, due to a transient change of the power generation current output from the fuel cell system 1, a variation of the gas concentration becomes large between the positive and negative electrode sides of the fuel cell system 1 and a balance between the capacitance C1 on the positive electrode side and the capacitance C2 on the negative electrode side is largely lost.

[0239] When the output voltage of the fuel cell system 1 transiently changes in this way, the positive-electrode side current command value I1c and the negative-electrode terminal current command value I2c change in opposite directions. Utilizing this property, an increase of the phase difference Φ is detected in the present embodiment. In this way, the

impedance measuring device 5 can detect that the measurement state is defective.

[0240] In the present embodiment, the phase difference detection unit 571 calculates the difference obtained by subtracting the time change amount ΔI_{2c} of the negative-electrode side current command value I_{2c} from the time change amount ΔI_{1c} of the positive-electrode side current command value I_{1c} as the parameter related to the phase difference Φ . The determination circuit 572 determines a measurement failure when that difference is beyond the prescribed allowable range or when the absolute value of the difference between the time change amounts ΔI_{1c} and ΔI_{2c} is larger than the allowable value Th_2 . By using the absolute value of the difference between the time change amounts ΔI_{1c} and ΔI_{2c} , the measurement state can be determined by setting only one allowable value. Thus, the determination circuit 572 can have a simple configuration.

[0241] The positive-electrode side current command value I_{1c} changes according to a change of the phase angle θ_1 of the alternating-current potential difference V_1 and the negative-electrode side current command value I_{2c} changes according to a change of the phase angle θ_2 of the alternating-current potential difference V_2 . Thus, if the magnitude of either one of the capacitances C_1 and C_2 changes, the difference between the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} changes. However, the difference between the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} is also changed by a change of the internal resistance R of the fuel cell stack 1. Thus, a change of the internal resistance R and a change of the phase difference Φ needs to be separated for more precise diagnosis.

[0242] When the phase difference Φ is changed by a change of the state on

the side of the load 3, the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} temporarily change in opposite directions. In contrast, when the magnitude of the internal resistance R changes, both the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} moderately change in the same direction. Thus, by calculating the difference between the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} per unit time, a variation of the phase difference Φ can be accurately detected on the basis of the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} .

[0243] It should be noted that an example in which the phase difference detection unit 571 computes each of the time change amounts of the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} and calculates the absolute value of the difference between these has been described in the present embodiment. However, the positive-electrode side current command value I_{1c} and the negative-electrode side current command value I_{2c} may be input to the computation unit 550 and the absolute value of the difference of the time change amounts may be computed in the computation unit 550.

[0244] (Third Embodiment)

FIG. 18 is a diagram showing the configurations of an alternating current adjustment unit 540 and a phase difference detection unit 581 in a third embodiment of the present invention.

[0245] In the third embodiment, the phase difference detection unit 581 and a determination circuit 582 are provided instead of the phase difference detection unit 561 and the determination circuit 562 shown in FIG. 5. It should be noted that constituent parts other than the phase difference

detection unit 581 and the determination circuit 582 are denoted by the same reference signs and not described here since being the same as those of the alternating current adjustment unit 540 shown in FIG. 5.

[0246] An output terminal of a positive-electrode side power supply unit 531 and an output terminal of a negative-electrode side power supply unit 532 are respectively connected to the phase difference detection unit 581. Then, an alternating-current potential V_a generated at the output terminal of the positive-electrode side power supply unit 531 and an alternating-current potential V_b generated at the output terminal of the negative-electrode side power supply unit 532 are input to the phase difference detection unit 581.

[0247] The phase difference detection unit 581 detects an alternating-current component of a potential difference ($V_a - V_b$) of the alternating-current potentials V_a and V_b . Specifically, the phase difference detection unit 581 detects an alternating-current component of a potential difference V_3 between a positive electrode terminal 211 and a negative electrode terminal 212 of a fuel cell stack 1.

[0248] Normally, a phase difference Φ between an alternating-current potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and an alternating-current potential generated at the negative electrode terminal 212 is designed to be equal to a phase difference between the alternating-current potential V_a generated at the output terminal of the positive-electrode side power supply unit 531 and the alternating-current potential V_b generated at the output terminal of the negative-electrode side power supply unit 532. Thus, a detection signal indicating the potential difference V_3 , which is an output voltage of the fuel cell stack 1, indicates a fixed value by an equipotential control in a state where no phase difference is generated between the alternating-current potentials V_a and V_b . In contrast, the detection signal indicating the potential difference V_3 includes an

alternating-current component in a state where the phase difference Φ is generated between the alternating-current potentials V_a and V_b .

[0249] As the phase difference Φ increases, an amplitude of the alternating-current component of the potential difference ($V_a - V_b$) between the alternating-current potentials V_a and V_b increases. Thus, the potential difference ($V_a - V_b$) can be utilized as a parameter correlated with the phase difference Φ .

[0250] Thus, the phase difference detection unit 581 detects the alternating-current component of the potential difference ($V_a - V_b$) between the alternating-current potentials V_a and V_b as the parameter related to the phase difference Φ .

[0251] FIG. 19 is a circuit diagram showing a detailed configuration of the phase difference detection unit 581.

[0252] The phase difference detection unit 581 includes a differential amplifier 5811, a multiplier 5812 and a low-pass filter 5813.

[0253] The differential amplifier 5811 detects the potential difference ($V_a - V_b$) by subtracting the alternating-current potential V_b from the alternating-current potential V_a and outputs it as a detection signal indicating the potential difference V_3 to the multiplier 5812. The differential amplifier 5811 has the same configuration as the positive-electrode side potential difference detection unit 521 and the negative-electrode side potential difference detection unit 522 shown in FIG. 3.

[0254] The multiplier 5812 multiplies the detection signal output from the differential amplifier 5811 by an in-phase signal $\sin(0)$. In this way, a signal obtained by removing an unnecessary signal from the detection signal and indicating the alternating-current component included in the potential difference V_3 is output from the multiplier 5812.

[0255] It should be noted that the in-phase signal $\sin(0)$ is an

alternating-current signal having the same phase as alternating currents of a reference frequency f_b output from the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532. The in-phase signal $\sin(0)$ is, for example, input to the multiplier 5812 from an alternating-current signal source 546.

[0256] The low-pass filter 5813 is an LPF for smoothing a signal output from the multiplier 5812 and allowing the passage of a direct-current component of the output signal. An amplitude component of the output signal is detected by the low-pass filter 5813. Thus, the direct-current signal smoothed by the low-pass filter 5813 is input as an amplitude value of the alternating-current component included in the potential difference V_3 to the determination circuit 582.

[0257] As just described, the phase difference detection unit 581 detects the amplitude value of the alternating-current component included in the potential difference V_3 between the positive electrode terminal 211 and the negative electrode terminal 212 of the fuel cell stack 1 and outputs it as the parameter related to the phase difference Φ to the determination circuit 582.

[0258] The determination circuit 582 determines a measurement state to be defective and outputs a determination signal of H-level when the amplitude value of the alternating-current component included in the potential difference V_3 is larger than a predetermined allowable value Th_3 . It should be noted that the allowable value Th_3 for the alternating-current component of the potential difference V_3 is set, for example, by experimental data or the like similarly to the allowable value Th_1 of the phase difference Φ .

[0259] According to the third embodiment of the present invention, a signal line connecting between a positive-electrode side direct current shut-off unit 511 and the positive-electrode side power supply unit 531 and a signal line connecting between a negative-electrode side direct current shut-off unit 512

and the negative-electrode side power supply unit 532 are both connected to the phase difference detection unit 581.

[0260] The phase difference detection unit 581 detects the potential difference ($V_a - V_b$) between the alternating-current potentials V_a and V_b as the potential difference V_3 between the alternating-current potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and the alternating-current potential generated at the negative electrode terminal 212. Then, the impedance measuring device 5 calculates the alternating current component included in the potential difference ($V_a - V_b$) as the parameter related to the phase difference Φ and determines the measurement state to be defective when that alternating-current component is larger than the prescribed threshold value.

[0261] In this way, the potential difference ($V_a - V_b$) obtained by subtracting the alternating-current potential V_b generated at the output terminal of the negative-electrode side power supply unit 532 from the alternating-current potential V_a generated at the output terminal of the positive-electrode side power supply unit 531 is detected as an alternating-current potential difference V_e between the positive electrode terminal 211 and the negative electrode terminal 212 of the fuel cell stack 1.

[0262] In this way, the alternating-current component generated in the potential difference V_3 between the alternating-current potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and the alternating-current potential generated at the negative electrode terminal 212 can be more directly detected as compared to the first and second embodiments. Thus, the phase difference Φ generated between the alternating-current potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and the alternating-current potential generated at the negative electrode terminal 212 can be accurately computed. Therefore, a

failure of the measurement state due to the phase difference Φ can be more reliably determined.

[0263] Further, since the alternating-current component generated in the potential difference V_3 can be more directly detected, the detection is less subject to a change in an internal state of the fuel cell stack 1, a change in an operating state of a load 3 and the like and determination accuracy can be improved.

[0264] Furthermore, in the present embodiment, it is not necessary to provide the orthogonal multiplier 721 and the orthogonal low-pass filter 722 on both positive and negative electrode sides as in the first embodiment. Thus, the number of multipliers, LPFs and the like used in the impedance measuring device 5 can be reduced.

[0265] (Fourth Embodiment)

FIG. 20 is a diagram showing the configuration of the impedance measuring device having a phase difference detection unit 591 in a fourth embodiment of the present invention.

[0266] In the fourth embodiment, a current sensor 590, the phase difference detection unit 591 and a determination circuit 592 are provided instead of the phase difference detection unit 561 and the determination circuit 562 shown in FIG. 5. It should be noted that other constituent parts are denoted by the same reference signs and not described here since being the same as those of the alternating current adjustment unit 540 shown in FIG. 5.

[0267] The current sensor 590 is connected between a fuel cell stack 1 and a load 3. In the present embodiment, the current sensor 590 is connected between a positive electrode terminal 211 of the fuel cell stack 1 and a positive electrode terminal of the load 3.

[0268] The current sensor 590 detects a leakage current I_L leaking from the fuel cell stack 1 to the load 3. For example, the current sensor 590 extracts

an alternating-current component from a current flowing from the fuel cell stack 1 to the load 3 and detects an amplitude value of the extracted alternating-current component as the leakage current I_L . The current sensor 590 outputs that detected leakage current I_L to the phase difference detection unit 591.

[0269] As a phase difference Φ between alternating-current potentials V_a and V_b increases, the amplitude value of the alternating current flowing from the fuel cell stack 1 to the load 3, i.e. the leakage current I_L increases. Thus, the leakage current I_L can be utilized as a parameter related to the phase difference Φ .

[0270] The phase difference detection unit 591 outputs a detection signal related to the phase difference Φ to the determination circuit 592 according to the leakage current I_L . In the present embodiment, as the leakage current I_L increases, the phase difference detection unit 591 increases a signal level of the detection signal.

[0271] The determination circuit 592 determines a measurement state to be defective and outputs a determination signal of H-level when the detection signal output from the phase difference detection unit 591 is larger than a predetermined allowable value $Th4$. It should be noted that the allowable value $Th4$ is set by experimental data or the like similarly to the allowable value $Th1$ of the phase difference Φ .

[0272] According to the fourth embodiment, the leakage current I_L of the alternating current detected by the current sensor 590 connected between the fuel cell stack 1 and the load 3 is utilized as the parameter correlated with the phase difference Φ between the alternating-current potentials generated at the positive electrode terminal 211 and the negative electrode terminal 212. Then, the impedance measuring device 5 determines the measurement state to be defective when the leakage current I_L detected by the current sensor 590 is

larger than the prescribed threshold value.

[0273] Thus, the leakage current I_L can be more reliably detected when the alternating currents input to the fuel cell stack 1 by a positive-electrode side power supply unit 531 and a negative-electrode side power supply unit 532 leak to the load 3 due to the phase difference Φ . Accordingly, an impedance measurement error can be precisely estimated on the basis of the magnitude of the leakage current I_L , wherefore a measurement failure can be more accurately detected. Thus, reliability for a measurement result can be maintained and improved.

[0274] (Fifth Embodiment)

An impedance measuring device in a fifth embodiment of the present invention is described. It should be noted that the impedance measuring device of the present embodiment is basically the same in configuration as the impedance measuring device 5 shown in FIG. 5 and described using the same reference signs as in FIG. 5.

[0275] In the present embodiment, an execution period of a failure detection process of detecting on the basis of a phase difference Φ whether or not a measurement state is defective is limited. Since this can reduce a useless diagnosis process, a computational load of the impedance measuring device 5 can be reduced.

[0276] Specifically, the impedance measuring device 5 performs a measurement state diagnosis process in accordance with a command transmitted from a controller unit 6.

[0277] The controller unit 6 controls an operating state of a fuel cell system for causing a fuel cell stack 1 to generate power by supplying anode gas and cathode gas to the fuel cell stack 1. Specifically, the controller unit 6 manages power required to the fuel cell stack 1 from a load 3, a power generation state of the fuel cell stack 1 and the like and controls supply

amounts of the anode gas and the cathode gas to be supplied to the fuel cell stack 1.

[0278] The impedance measuring device 5 performs the measurement state diagnosis process when a prescribed diagnosis condition under which capacitances C1 and C2 of the fuel cell stack 1 are likely to vary holds.

[0279] The start times of a start process performed when the fuel cell stack 1 is started, a purge process performed during a stop process of the fuel cell stack 1, a restart process performed when a vehicle returns from an idle stop state and the like are desirable as the above diagnosis conditions. A difference between the capacitances C1 and C2 is likely to increase while such processes are performed. It should be noted the purge process performed during the stop process is a process of opening a purge valve provided in an anode gas discharge passage until a pressure of anode gas present in the fuel cell stack 1 decreases to a prescribed value.

[0280] In the case of starting the above processes, the controller unit 6 transmits a diagnosis execution command to the impedance measuring device 5. Then, the impedance measuring device 5 judges that the diagnosis condition establishes and performs the measurement state diagnosis process upon receiving the diagnosis execution command.

[0281] Further, even if an abnormal state is avoided and a return is made to a normal process after a measurement value of an internal resistance R exceeds a system predicted value and the fuel cell system is determined to be in the abnormal state, there is also a possibility that the measurement state of the internal resistance R is not recovered to a acceptable state immediately after the return.

[0282] Thus, a recovery process for recovering the abnormal state of the fuel cell stack 1 may be added to the diagnosis condition. In this case, the controller unit 6 transmits a diagnosis execution command to the impedance

measuring device 5 when starting the recovery process. It should be noted that examples of the recovery process include a process for increasing a supply amount of cathode gas, a purge amount or the like, for example, in the event of flooding.

[0283] Further, the diagnosis process may be performed also when an average change rate of a detection signal level of an alternating-current potential difference $V1$ or $V2$, a detection signal level of an alternating current $I1$ or $I2$, a measurement value of an internal resistance R or the like becomes extremely large and exceeds a prescribed threshold value. This is because there is a possibility that the phase difference Φ is large in such a case.

[0284] The execution of a process requiring high reliability for the measurement result of the internal resistance R and the like can be thought as the other diagnosis conditions.

[0285] It should be noted that although an example in which the execution period of the diagnosis process is limited only to the execution period of a specific process has been described in the present embodiment, the diagnosis process may be performed with a determination cycle S extended when the diagnosis condition does not hold and the determination cycle S may be shortened when the diagnosis condition holds. In this way, it is possible to reduce a processing load of the impedance measuring device 5 while suppressing a reduction in reliability for the measurement result.

[0286] Next, there is described a technique for suppressing a reduction in the measurement accuracy of the internal resistance R measured by the impedance measuring device 5 when the phase difference Φ is generated between the alternating-current potential differences $V1$ and $V2$.

[0287] (Sixth Embodiment)

FIG. 21 is a diagram showing the detail of an alternating current adjustment unit 540 in a sixth embodiment of the present invention. The

alternating current adjustment unit 540 includes a phase correction unit 600 instead of the determination circuit 562 shown in FIG. 5.

[0288] The phase correction unit 600 corrects a phase difference (phase deviation) between an alternating current I1 output from a positive-electrode side power supply unit 531 and an alternating current I2 output from a negative-electrode side power supply unit 532 on the basis of a phase difference Φ output from a potential difference detection unit 561.

[0289] The phase correction unit 600 calculates a shift amount for shifting a phase of the alternating current I1 or I2 to reduce the phase difference Φ output from the potential difference detection unit 561 as a correction amount M necessary to correct the phase deviation.

[0290] FIG. 22 is a diagram showing the configuration of an impedance measuring device 5 in the present embodiment.

[0291] Here, a phase variable power supply unit 5311 is provided instead of the positive-electrode side power supply unit 531 shown in FIG. 2.

[0292] The phase variable power supply unit 5311 is an alternating current source capable of outputting an alternating current I1 of a reference frequency f_b and changing a phase of the alternating current I1.

[0293] The phase variable power supply unit 5311 outputs the alternating current I1 of the reference frequency f_b according to a command signal output from the alternating current adjustment unit 540 similarly to the positive-electrode side power supply unit 531. Further, the phase variable power supply unit 5311 shifts the phase of the alternating current I1 according to the correction amount M output from the phase correction unit 600.

[0294] The phase variable power supply unit 5311 is realized, for example, by providing a known phase shift circuit in addition to the voltage-current conversion circuit shown in FIG. 4. A state variable filter constituting an all-pass filter or the like is used as this phase shift circuit. In the present

embodiment, the phase shift circuit is connected between an input terminal of the voltage-current conversion circuit and an output terminal of a positive-electrode side multiplier 5441.

[0295] In such a phase shift circuit, the phase of the alternating current I1 to be output to the voltage-current conversion circuit is shifted by changing a central frequency of a filter. Thus, the phase correction unit 600 is provided with a voltage-controlled oscillation circuit (VCO: voltage-controlled oscillator) and the like and the correction amount M is converted into a frequency by the voltage-controlled oscillation circuit and that frequency is input as the central frequency of the filter to the phase shift circuit.

[0296] FIG. 23 is a chart showing a direction of shifting the phase of the alternating current I1 output from the phase variable power supply unit 5311 according to the correction amount M output from the phase correction unit 600. In this example, the phases of the alternating currents I1 and I2 coincide when the correction amount M is zero.

[0297] In the present embodiment, as a phase of an alternating-current potential difference V1 is shifted in an advancing direction with respect to an alternating-current potential difference V2, the correction amount M output from the phase correction unit 600 becomes a positive (plus) value larger than zero.

[0298] Thus, as shown in FIG. 23, the phase of the alternating current I1 output from the phase variable power supply unit 5311 is shifted in a retarding direction with respect to the alternating current I2 as the correction amount M becomes larger than zero.

[0299] On the other hand, as a phase of the alternating-current potential difference V2 is shifted in the advancing direction with respect to the alternating-current potential difference V1, the correction amount M becomes a negative (minus) value smaller than zero. Thus, the phase of the alternating

current I1 output from the phase variable power supply unit 5311 is shifted in the advancing direction.

[0300] It should be noted that although an example in which the phase variable power supply unit 5311 is provided instead of the positive-electrode side power supply unit 531 has been described in the present embodiment, the negative-electrode side power supply unit 532 may be replaced by the phase variable power supply unit 5311 and the phase of the alternating current I2 may be shifted to reduce the phase difference Φ .

[0301] In such a case, in order to reduce the phase difference Φ , the phase of the alternating current I2 needs to be shifted in a direction opposite to the one in which the phase of the alternating current I1 is shifted. Thus, the phase correction unit 600 is, for example, provided with an inversion circuit for inverting a sign of the phase difference Φ . For example, since the correction amount M becomes smaller than zero as the phase difference Φ becomes larger than zero, the phase of the alternating current I2 output from the phase variable power supply unit 5311 is shifted in the advancing direction with respect to the alternating current I1.

[0302] According to the sixth embodiment of the present invention, the phase of the alternating current I1 or I2 is corrected on the basis of the phase difference Φ between the alternating-current potential differences V1 and V2 by the phase correction unit 600. Since the phase difference Φ is reduced in this way, an error between the alternating current I1 used for the computation of an internal resistance R1 and an actual current actually flowing through the internal resistance R1 and an error between the alternating current I2 used for the computation of an internal resistance R2 and an actual current actually flowing through the internal resistance R2 become smaller. Thus, a reduction in the measurement accuracy of the internal resistance R calculated on the basis of the alternating currents I1 and I2 can be suppressed.

[0303] Thus, in the impedance measuring device 5 for measuring an internal resistance of a fuel cell stack 1, it is possible to suppress a reduction of the measurement accuracy due to variations of capacitance components in the fuel cell stack 1.

[0304] Further, in the present embodiment, the phase correction unit 600 shifts the phase of the alternating current I1 output from the phase shift circuit provided in the phase variable power supply unit 5311 such that the phase difference Φ between the alternating-current potential differences V1 and V2 is reduced.

[0305] This enables the phase of the alternating-current potential difference V1 to approach that of the alternating-current potential difference V2 even if a balance between capacitances C1 and C2 is lost according to a change in an internal state of a fuel cell stack 1 or a state of a load 3. Thus, even if a difference between the capacitances C1 and C2 increases, an increase of the phase difference Φ can be suppressed, wherefore a reduction in the measurement accuracy of the internal resistance R can be suppressed.

[0306] It should be noted that although an example in which the phase shift circuit is provided between the positive-electrode side power supply unit 531 and an alternating-current signal source 546 has been described in the present embodiment, a phase shift circuit may be provided between the positive-electrode side power supply unit 531 and a positive electrode terminal 211 of the fuel cell stack 1.

[0307] It should be noted that although an example in which the phase variable power supply unit 5311 is used as a technique for shifting the phase of the alternating current I1 has been described in the present embodiment, there is no limitation to this. A technique for shifting the phase of the alternating current I1 without using the phase variable power supply unit 5311 is described as another example with reference to FIG. 24.

[0308] (Seventh Embodiment)

FIG. 24 is a diagram showing a configuration example of a phase correction unit 600 in a seventh embodiment of the present invention.

[0309] Here, the positive-electrode side multiplier 5441 shown in FIG. 5 is provided with a phase variable alternating-current signal source 5461 instead of the alternating-current signal source 546 for outputting an alternating-current signal of a reference frequency f_b .

[0310] The phase variable alternating-current signal source 5461 is an alternating current source capable of outputting an alternating current of the reference frequency f_b and changing a phase of the alternating current.

[0311] The phase correction unit 600 includes an integration circuit 601 to correct the phase of an alternating current I1 by a PI control.

[0312] The integration circuit 601 integrates a phase difference Φ output from a phase difference detection unit 561 and outputs an integrated value as a correction amount M to the phase variable alternating-current signal source 5461. Since a noise component included in a detection signal output from the phase difference detection unit 561 is suppressed by the integration circuit 601, the phase of the alternating current I1 can be accurately shifted.

[0313] For example, a phase of an alternating-current signal output from the phase variable alternating-current signal source 5461 is shifted in a retarding direction as the correction amount M output from the integration circuit 601 becomes larger than zero. Associated with this, the phase of the alternating current I1 output from a positive-electrode side power supply unit 531 is also shifted in the retarding direction.

[0314] On the other hand, since the phase of the alternating-current signal output from the phase variable alternating-current signal source 5461 is shifted in an advancing direction as the correction amount M becomes smaller than zero, the phase of the alternating current I1 output from the

positive-electrode side power supply unit 531 is similarly shifted in the advancing direction.

[0315] By providing the phase variable alternating-current signal source 5461 to shift the phase of the alternating-current signal of the reference frequency f_b in this way, the phase of the alternating current I_1 can be shifted to reduce a phase difference Φ between alternating-current potential differences V_1 and V_2 .

[0316] It should be noted that although an example in which the phase variable alternating-current signal source 5461 is provided instead of the alternating-current signal source 546 of the positive-electrode side power supply unit 531 has been described in the present embodiment, the phase variable alternating-current signal source 5461 may be provided instead of the alternating-current signal source 546 of the negative-electrode side power supply unit 532.

[0317] In such a case, the phase correction unit 600 is, for example, provided with an inversion circuit for inverting a sign of the phase difference Φ as described in the sixth embodiment. For example, since the correction amount M becomes smaller than zero as the phase difference Φ becomes larger than zero, the phase of the alternating current I_2 output from the phase variable power supply unit 5311 is shifted in the advancing direction.

[0318] According to the seventh embodiment of the present invention, the phase variable alternating-current signal source 5461 is used instead of the alternating-current signal source 546 and the phase of the alternating-current signal output from the phase variable alternating-current signal source 5461 is corrected by the correction amount M output from the integration circuit 601. Since this causes the phase of the alternating-current potential difference V_1 to approach that of the alternating-current potential difference V_2 and reduces the phase difference Φ , the leakage current I_L leaking from the

fuel cell stack 1 to the load 3 can be reduced. Thus, measurement accuracy for the internal resistance R of the fuel cell stack 1 can be improved.

[0319] Further, by using the phase variable alternating-current signal source 5461, a circuit configuration can be simplified and the phase of the alternating current I_1 can be inexpensively changed as compared to the case where a phase shift adjusting function is added by providing the positive-electrode side power supply unit 531 with a phase shift circuit. Specifically, it is possible to simplify the circuit configuration while suppressing a cost increase.

[0320] (Eighth Embodiment)

It should be noted that although an example in which the phase of the alternating current I_1 or I_2 is corrected has been described in the sixth and seventh embodiments, an error (deviation) of a measurement result to be measured by the impedance measuring device 5 may be corrected. An example of revising the internal resistance R computed by the computation unit 550 shown in FIG. 5 is described below.

[0321] FIG. 25 is a diagram showing a technique for correcting errors of the alternating currents I_1 and I_2 due to a phase difference Φ between alternating-current potential differences V_1 and V_2 .

[0322] FIG. 25 shows an equivalent circuit of a fuel cell stack 1 and paths of the alternating currents I_1 and I_2 flowing through an impedance Z_L of a load 3. Here, a state is assumed where a phase of the alternating-current potential difference V_1 is advanced by the phase difference Φ from that of the alternating-current potential difference V_2 as shown in FIG. 7.

[0323] An amplitude of an alternating-current potential difference V_e between an alternating-current potential difference generated at a positive electrode terminal 211 of the fuel cell stack 1 and an alternating-current potential generated at a negative electrode terminal 212 can be expressed by

the following equation.

[Equation 10]

$$V_e = 2 * V_s * \sin\left(\frac{\Phi}{2}\right) \quad \dots (10)$$

[0324] It should be noted that a reference voltage V_s is a predetermined value to match the amplitudes of the alternating-current potential differences V_1 and V_2 as described with reference to FIG. 5.

[0325] As shown in equation (10), the amplitude of the alternating-current potential difference V_e is proportional to those of the alternating-current potential differences V_1 and V_2 , i.e. the reference voltage V_s and increases according to the phase difference Φ in a range of 0° to 90° .

[0326] A part of the alternating current I_2 output from a negative-electrode side power supply unit 532 to the negative electrode terminal 212 of the fuel cell stack 1 leaks toward the load 3 due to the phase difference Φ between the alternating-current potential differences V_1 and V_2 . This leakage current I_L can be expressed by the following equation.

[0327] [Equation 11]

$$i_L = \frac{\dot{V}_e}{Z} \quad \dots (11)$$

[0328] It should be noted that the impedance Z_L of the load 3 is a value obtained in advance by an experiment or the like and recorded, for example, in the phase correction unit 600 shown in FIG. 21.

[0329] The leakage current I_L flows from the negative electrode terminal 212 of the fuel cell stack 1 to the positive electrode terminal 211 via the load 3. In the positive electrode terminal 211, the leakage current I_L joins the alternating current I_1 and a current $(I_1 + I_L)$ obtained by adding the leakage current I_L to the alternating current I_1 is output to an intermediate-point

terminal 213 through an internal resistance R1.

[0330] On the other hand, in the negative electrode terminal 212, a current ($I_2 - I_L$) obtained by subtracting the leakage current I_L from the alternating current I_2 is output to the intermediate-point terminal 213 through an internal resistance R2.

[0331] Thus, measurement errors of the internal resistances R1 and R2 caused by the leakage current I_L can be expressed as ratios of measurement values R1m and R2m of the internal resistances R1 and R2 computed by a computation unit 550 and actual values R1r and R2r of the internal resistances R1 and R2 as in the following equations.

[0332] [Equations 12]

$$\frac{R1m}{R1r} = \frac{I1 + I_L}{I1} = 1 + \frac{I_L}{I1} \quad \dots (12-1)$$

$$\frac{R2m}{R2r} = \frac{I2 - I_L}{I2} = 1 - \frac{I_L}{I2} \quad \dots (12-2)$$

[0333] That is, ratios of the leakage current I_L to the detection values of the alternating currents I1 and I2 are the measurement errors of the internal resistances R1 and R2. By applying a revision processing of the following equations to the measurement values R1m and R2m computed on the basis of the alternating-current potential differences V1 and V2 indicated by the detection signals and the alternating currents I1 and I2, the measurement errors caused by the leakage current I_L can be corrected.

[0334] [Equations 13]

$$R1r = R1m / \left(1 + \frac{I_L}{I1} \right) \quad \dots (13-1)$$

$$R2r = R2m / \left(1 - \frac{I_L}{I2} \right) \quad \dots (13-2)$$

[0335] The revision processing shown in equations (13) is performed, for example, in the phase correction unit 600 shown in FIG. 21.

[0336] FIG. 26 is a flow chart showing an example of a correction method for correcting the measurement errors associated with the phase difference Φ in the present embodiment. In this example, the internal resistances $R1$ and $R2$ are revised by the phase correction unit 600.

[0337] First, in Step S301, the phase correction unit 600 obtains the phase difference Φ output from a potential difference detection unit 561.

[0338] In Step S302, the phase correction unit 600 computes the amplitude value of the alternating-current potential difference V_e on the basis of the phase difference Φ obtained from the potential difference detection unit 561 and the predetermined reference potential V_s in accordance with equation (10).

[0339] In Step S303, the phase correction unit 600 computes the leakage current I_L leaking to the load 3 on the basis of the alternating-current potential difference V_e and the impedance Z_L of the load 3 in accordance with equation (11).

[0340] In Step S304, the phase correction unit 600 performs the revision processing for revising the internal resistances $R1$ and $R2$.

[0341] Specifically, the phase correction unit 600 revises the internal resistance value $R1m$ to the actual value $R1r$ on the basis of the leakage current I_L and the internal resistance value $R1m$ computed by the computation unit 550 in accordance with equation (13-1). The phase correction unit 600 revises the internal resistance value $R2m$ to the actual value $R2r$ on the basis of the leakage current I_L and the internal resistance value $R2m$ computed by the computation unit 550 in accordance with equation (13-2).

- 78 -

[0342] Then, the phase correction unit 600 outputs the revised internal resistances R_1 and R_2 to the computation unit 550 and finishes a series of processings for the correction method for correcting the measurement errors associated with the phase difference Φ . Thereafter, an internal resistance R of the entire fuel cell stack 1 is computed in Step S12 shown in FIG. 11.

[0343] As just described, in the impedance measuring device 5, a measurement error of the internal resistance R due to the phase difference Φ between the alternating-current potential differences V_1 and V_2 is corrected.

[0344] According to the eighth embodiment of the present invention, the leakage current I_L is computed on the basis of the phase difference Φ between the alternating-current potential differences V_1 and V_2 and phase deviations, which are errors of the alternating currents I_1 and I_2 associated with the phase difference Φ , are corrected on the basis of the leakage current I_L .

[0345] Specifically, the phase correction unit 600 corrects the phase difference between the alternating currents I_1 and I_2 by revising the detection value of the alternating current I_1 output from the positive-electrode side power supply unit 531 and the detection value of the alternating current I_2 output from the negative-electrode side power supply unit 532 according to the leakage current I_L computed on the basis of the phase difference Φ . In this way, the measurement error of the internal resistance R measured by the impedance measuring device 5 can be corrected. Therefore, it is possible to suppress a reduction of impedance measurement accuracy due to capacitance components of the fuel cell stack 1 in the impedance measuring device 5.

[0346] Thus, the measurement error of the internal resistance R can be corrected by a computational processing even if the phase difference Φ between the alternating-current potential differences V_1 and V_2 increases such as when the impedance of the fuel cell stack 1 changes or when a balance between the capacitances C_1 and C_2 is lost. Therefore, the impedance

measuring device 5 can have a simple circuit configuration as compared to the seventh embodiment.

[0347] According to the sixth to eighth embodiments of the present invention described above, the phase difference Φ between the alternating-current potential generated at the positive electrode terminal 211 of the fuel cell stack 1 and the alternating-current potential generated at the negative electrode terminal 212 is detected by the phase correction unit 600. Then, the phase difference of the alternating current output from at least one of the positive-electrode side power supply unit 531 and the negative-electrode side power supply unit 532 is corrected on the basis of the phase difference Φ . In this way, it is possible to suppress a reduction of impedance measurement accuracy due to the leakage current I_L from the impedance measuring device 5 to the load 3.

[0348] It should be noted that although an example in which the phase of the alternating current I_1 or I_2 is corrected by revising the alternating current I_1 or I_2 output from the positive-electrode side power supply unit 531 or the negative-electrode side power supply unit 532 on the basis of the phase difference Φ has been described in the sixth and seventh embodiments, there is no limitation to this. For example, the phase correction unit 600 may compute the leakage current I_L on the basis of the phase difference Φ as in equation (11) and correct the phase difference between the alternating currents I_1 and I_2 by revising the alternating currents I_1 and I_2 according to the leakage current I_L . In this case, a map in which shift amounts for the phases of the alternating currents I_1 and I_2 are related to each leakage current I_L is set in advance in the phase correction unit 600.

[0349] Although the embodiments of the present invention have been described above, the above embodiments are merely some application examples of the present invention and not intended to limit the technical scope

of the present invention to the specific configurations of the above embodiments.

[0350] For example, although an example in which the internal impedance of the fuel cell stack 1 is measured by the impedance measuring device 5 has been described in the above embodiments, a measurement object has only to be a laminated type battery in which a plurality of battery cells are laminated and may be, for example, a laminated type lithium ion battery. Even in a lithium battery, a capacitance C1 on a positive electrode side and a capacitance C2 on a negative electrode side may differ due to individual differences of battery cells and a phase difference Φ may be generated. Even in such a case, effects of the present application can be obtained as in the above embodiments.

[0351] It should be noted that the above embodiments can be combined as appropriate.

- 81 -

The embodiments of the invention in which an exclusive property or privilege is claimed are defined as follows:

1. An impedance measuring device, comprising:

a laminated type battery, a plurality of battery cells being laminated in the laminated type battery;

a first power supply unit configured to output an alternating current of a prescribed frequency for measuring an impedance of the laminated type battery to a positive electrode terminal of the laminated type battery;

a second power supply unit configured to output an alternating current of the prescribed frequency to a negative electrode terminal of the laminated type battery;

a first detection unit configured to detect an alternating-current potential difference between the positive electrode terminal and an intermediate-point terminal of the laminated type battery;

a second detection unit configured to detect an alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal;

an adjustment unit configured to adjust an amplitude of the alternating current output from at least one of the first and second power supply units such that the alternating-current potential difference detected by the first detection unit and the alternating-current potential difference detected by the second detection unit coincide;

a computation unit configured to compute the impedance of the laminated type battery on the basis of the alternating current adjusted by the adjustment unit and the alternating-current potential difference;

a calculation unit configured to calculate a phase difference between

- 82 -

an alternating-current potential generated at the positive electrode terminal and an alternating-current potential generated at the negative electrode terminal, or a parameter related to the phase difference; and

a processing unit configured to perform, on the basis of the phase difference or the parameter calculated by the calculation unit, any one process of: a diagnosis process for diagnosing whether or not a measurement state is defective; a cancellation process for discarding a measurement result; and a hold process for fixing the measurement result at a prescribed value.

2. The impedance measuring device according to claim 1, wherein:
the calculation unit calculates, as the phase difference, a phase difference between a detection signal indicating the alternating-current potential difference between the positive electrode terminal and the intermediate-point terminal and a detection signal indicating the alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal; and

the processing unit determines the measurement state to be defective when the phase difference calculated by the calculation unit is larger than a prescribed threshold value and determines the measurement state to be acceptable when the phase difference is smaller than the prescribed threshold value.

3. The impedance measuring device according to claim 2, wherein:
the adjustment unit calculates a first current command value for the first power supply unit by extracting a real axis component of the

- 83 -

alternating-current potential difference detected by the first detection unit and calculates a second current command value for the second power supply unit by extracting a real axis component of the alternating-current potential difference detected by the second detection unit; and

the processing unit determines the measurement state to be defective when one of the first and second current command values increases when the other value decreases.

4. The impedance measuring device according to claim 3, wherein:
the calculation unit calculates a difference between a time change rate of the first current command value and that of the second current command value as the parameter related to the phase difference; and

the processing unit determines the measurement state to be defective when the difference calculated by the calculation unit is larger than a prescribed threshold value.

5. The impedance measuring device according to claim 1, further comprising a third detection unit configured to detect a potential difference between the positive electrode terminal and the negative electrode terminal of the laminated type battery as the parameter related to the phase difference, wherein:

the processing unit determines the measurement state to be defective when the potential difference detected by the third detection unit is larger than a prescribed threshold value.

- 84 -

6. The impedance measuring device according to claim 1, further comprising a fourth detection unit connected between a load connected to the laminated type battery and the laminated type battery and configured to detect a leakage current flowing from the laminated type battery to the load as the parameter related to the phase difference, wherein:

the processing unit determines the measurement state to be defective when the leakage current detected by the fourth detection unit is larger than a prescribed threshold value.

7. The impedance measuring device according to claim 2, wherein:

the processing unit discards the impedance computed by the computation unit when the measurement state is determined to be defective as the cancellation process.

8. The impedance measuring device according to claim 2, wherein:

the processing unit outputs a measurement value before the measurement state is determined to be defective as the prescribed value when the measurement state is determined to be defective as the hold process.

9. The impedance measuring device according to claim 1, wherein:

the processing unit performs the diagnosis process when a prescribed condition for the variation of a capacitance component of the laminated type battery holds.

- 85 -

10. The impedance measuring device according to claim 9, wherein:
the processing unit judges that the prescribed condition holds when any one process of: a start process of a fuel cell battery as the laminated type battery; a purge process during a stop process of the fuel cell battery; and a restart process when a vehicle mounted with the fuel cell battery returns from an idle stop state is started.

11. The impedance measuring device according to claim 9, wherein:
the processing unit judges that the prescribed condition holds when a recovery process for recovering an abnormal state of a fuel cell system is started.

12. A control method for an impedance measuring device with a laminated type battery, a plurality of battery cells being laminated in the laminated type battery, a first power supply unit for outputting an alternating current of a prescribed frequency for measuring an impedance of the laminated type battery to a positive electrode terminal of the laminated type battery, and a second power supply unit for outputting an alternating current of the prescribed frequency to a negative electrode terminal of the laminated type battery, comprising:

a first detection step of detecting an alternating-current potential difference between the positive electrode terminal and an intermediate-point terminal of the laminated type battery;

a second detection step of detecting an alternating-current potential difference between the negative electrode terminal and the intermediate-point terminal;

- 86 -

an adjustment step of adjusting an amplitude of the alternating current output from at least one of the first and second power supply units such that the alternating-current potential difference detected in the first detection step and the alternating-current potential difference detected in the second detection step coincide;

a computation step of computing the impedance of the laminated type battery on the basis of the alternating current adjusted in the adjustment step and the alternating-current potential difference;

a calculation step of calculating a phase difference between an alternating-current potential generated at the positive electrode terminal and an alternating-current potential generated at the negative electrode terminal, or a parameter related to the phase difference; and

a processing step of performing, on the basis of the phase difference or the parameter calculated in the calculation step, any one process of: a diagnosis process for diagnosing whether or not a measurement state is defective; a cancellation process for discarding a measurement result; and a hold process for fixing the measurement result at a prescribed value.
