(54) Title: THERMAL ICING CONDITIONS DETECTOR

(57) **Abrégé/Abstract:**

A sensor for detecting icing conditions in an airstream includes a flow housing mounted on an aircraft and in which one or more probes are mounted. At least one of the probes subjected to impingement of the airstream and liquid moisture droplets in such airstream. The heat removal, or cooling effect on the probe in the airstream carrying liquid droplets is determined. A temperature signal indicating the airstream temperature is combined with signals from the at least one probe for determining whether or not icing conditions are present.

ABSTRACT OF THE DISCLOSURE

A sensor for detecting icing conditions in an  
5 airstream includes a flow housing mounted on an  
aircraft and in which one or more probes are mounted.  
At least one of the probes subjected to impingement  
of the airstream and liquid moisture droplets in such  
airstream. The heat removal, or cooling effect on the  
10 probe in the airstream carrying liquid droplets is  
determined. A temperature signal indicating the  
airstream temperature is combined with signals from  
the at least one probe for determining whether or not  
icing conditions are present.

## THERMAL ICING CONDITIONS DETECTOR

### BACKGROUND OF THE INVENTION

The present invention relates to icing conditions detectors or sensors that use temperature sensitive probes, which are connected to sensing circuitry and positioned such that measuring voltage or power characteristics provides information for detecting moisture in a fluid flow, and when combined with an ambient temperature measurement serve to detect icing conditions in the atmosphere.

Emerging regulatory requirements for operating aircraft in icing conditions are being interpreted to require more conservative estimates of sensing icing situations than may be provided with existing ice detectors. Application specific Conditions that conventional accretion based detectors may not be able to detect due to Ludlam Limit effects need to be addressed to meet the new requirements. The ability to detect the existence of icing conditions, rather than actual ice accretion, may therefore be required. "Icing conditions" require the presence of liquid moisture in the airflow, and an air temperature below some selected threshold temperature usually specified to be slightly above freezing.

### SUMMARY OF THE INVENTION

In its broadest form, a single temperature sensitive probe is deployed in the airstream, and is a heated sensor. The sensor can be self-heated from the power used to excite the sensing element, or a separate heater integral to the probe. Air data information, from other sources which are sufficient

-2-

to calculate area normalized mass flow rate are needed. The power consumed by the probe to maintain itself at a selected temperature above ambient in dry air is known to have a fixed relationship to mass  
5 flow rate calculated from the other air data sources. The air data information is independent of the presence of moisture, but, moisture in the air will increase the power drawn by the heated probe relative to the dry condition to maintain the selected  
10 temperature. Thus, if the power drawn by the probe deviates from the expected dry air relationship, the presence of moisture is indicated. A measurement of temperature of the ambient air is also needed to determine whether icing conditions are present.

15 This ability to obtain information relating to the power drawn to provide heat to maintain the probe temperature to indicate the presence of icing conditions is also achieved by providing two identical heated temperature sensors or probes at  
20 different locations in substantially the same mass airflow, but where liquid water is removed from the airflow at one location. As shown in Figure 1, a bifurcated flow channel is provided. One branch channel is essentially free of liquid moisture due to  
25 inertial separation, and the other branch channel carries the liquid moisture in the airflow.

As shown, a flow housing similar to that used with some total air temperature sensors may be used to provide inertial separation between flow channel

-3-

branches. A heated or self-heated temperature probe that is in the moisture carrying channel branch will respond differently from a similarly heated temperature probe in the channel that is free of moisture, assuming there is moisture present in the free stream airflow. Assuming the probes are maintained at a fixed temperature, in non-moisture or dry air flow there will be increasing amounts of heat removed from each probe as flow rate increases, but the amount of heat removed from each will be substantially the same.

By connecting the two resistance type probes into a bridge, the bridge output voltage will remain near zero and independent of flow rate or air speed in dry air, but if there is liquid moisture present the heat removed from one of the probes, where removal of heat is enhanced by evaporation and/or blow off of warmed water, will cause a temperature change at that probe and therefore a resistance change if the probe is a resistance type temperature sensor. The offset in voltage would be expected to increase with increasing liquid water content. When an ambient air temperature measurement, that is the temperature of the freestream airflow, is provided from a separate source, a determination of icing conditions can be made. Alternately, a temperature probe may be located in one of the flow channels, preferably that from which moisture has been removed, to approximate the freestream air temperature.

- 4 -

If a resistance temperature probe is used, this approach can be modified by including this probe in a bridge circuit. In this modified approach it is not necessary that mass airflow through each channel be substantially equal. By measuring suitable combinations of voltages, the presence of moisture in the branch carrying liquid moisture from the freestream airflow can be determined because the relationships between the measurements will differ compared to conditions when the free stream flow is dry. Temperature can be determined by measuring the voltage drop across the temperature sensor.

Again, the presence of liquid moisture and an air temperature below a threshold, usually slightly above freezing, is required for icing conditions, and these parameters can be provided by the instrument of the present invention.

According to an aspect of the present invention there is provided a sensor for detecting icing conditions in an airflow caused by presence of liquid moisture in such airflow, the sensor including:

- a flow housing having a channel providing at least one flow path configured to provide a known mass airflow rate therethrough at relative airflow speeds;
- at least one probe mounted in the at least one flow path such that the airflow impinges on the probe;
- a power source for heating the probe; and
- a sensing circuit coupled to the probe for determining changes in a function which is dependent upon the presence of liquid moisture striking the probe, the sensing circuit providing an output indicating changes in the function, wherein said sensing circuit comprises a bridge circuit, and wherein the probe comprises a first

- 4a -

probe and has a known resistance relationship with temperature, a second probe mounted in a second airflow path that is branched from the at least one airflow path and which has airflow that is substantially free of liquid moisture, and wherein the bridge circuit compares temperatures between the first probe and the second probe.

According to another aspect of the present invention there is provided a sensor for sensing icing conditions in an airflow caused by presence of liquid water in such airflow, said sensor including:

a flow housing having a first flow path configured to have known mass flow rates at different airflow speeds;

a first probe mounted in said first airflow path in position to be impinged by the airflow and by liquid droplets in the airflow, said first probe being heatable in response to a power input, the probe indicating temperature by changes in a temperature sensing element in the first probe;

a circuit connected to said first probe to provide heating power to heat the first probe to a selected temperature above ambient temperature; and

a circuit connected to the first probe to determine the amount of heat removed from the first probe above a known value of heat removal in dry air flowing at the same mass airflow rate as the airflow rate through the flow path to determine if moisture in the airflow is causing heat to be removed from the first probe.

According to a further aspect of the present invention there is provided a sensor for sensing icing conditions in an airflow caused by presence of liquid

- 4b -

moisture in such airflow, said sensor including:

a flow housing having a flow path that is configured to provide airflow in a substantially straight line, the flow housing having a laterally facing outlet opening  
5 leading from the flow path to a passage, the flow path including a first branch flow path downstream of the laterally facing opening, and said passage comprising a second branch flow path;

a first temperature sensor probe mounted in said  
10 first branch flow path;

a second temperature sensing probe mounted in said second branch flow path, the laterally facing opening being positioned such that airflow passing through the laterally facing opening is substantially free of liquid  
15 moisture; and

a bridge circuit connected to resistances in said first and second probes to compare differentials in temperature between temperature sensed by said first and second probes, respectively.

20 BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a schematic side sectional view through a flow housing that can be mounted onto an aircraft and provides an inlet leading to two branch flow channels, one of which has liquid moisture  
25 removed by inertial separation, and illustrating a first form of the invention;

Figure 2 is a schematic bridge circuit illustrating the operation of the first form of the invention;

-5-

Figure 3 is a sectional view through a flow housing having branched flow channels showing probes of a second alternative form of the invention;

Figure 4 is a schematic bridge circuit utilizing the probe arrangement shown in Figure 3;

Figure 5 is a sectional view of a flow housing mounting a single probe directly in the liquid moisture carrying airflow;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

10 In Figure 1, an aircraft skin 10 supports a flow housing 12 that as shown, has a hollow strut 14 and a fore and aft facing flow tube 16 mounted onto the strut 14. The flow tube 16 can have any desired cross-sectional shape, and is generally rectilinear  
15 or shaped like a flattened circle, and has an inlet end flow channel 18 through which freestream air flow indicated by the arrow 20 is introduced. The flow through the flow tube 16 is controlled by having an outlet orifice 22 at the aft end of the flow tube.  
20 There is an opening 24 between the flow channel 18 and an aft branch flow channel 27 which opens to the hollow strut, which forms a branch flow channel 26.

Liquid water is represented by the dashed lines 28, and the flow housing 12 provides inertial  
25 separation of the liquid moisture so that little of the liquid water passes into the branch flow channel

-6-

26. The branch flow channel 26 has an exhaust opening  
30 at its rear or downstream side. This type of a  
flow housing is used in various temperature sensors,  
and for example is of the type shown in United States  
5 Patent No. 2,970,475 for a gas temperature probe.

In the present invention, the flow housing 12  
mounts temperature sensing probes for determining  
presence of icing conditions, and in this form of the  
invention, a probe indicated at 34 is mounted in the  
10 branch flow channel 27 of flow tube 16, so that the  
freestream liquid moisture laden air impinges on the  
probe 34. Any liquid moisture impinging on the probe  
34 will affect the power needed for heating or self-  
heating the probe, assuming it is desired to maintain  
15 the probe at constant temperature.

A second temperature sensing probe 38 is mounted  
in the branch flow channel 26, the flow in which  
branch channel is essentially free of liquid water,  
so the airflow across probe 38 is and remains  
20 substantially the same as dry, non-liquid water  
carrying air.

Since the detector must operate in icing  
environments the detector housing is provided with  
heaters 35, preferably electrical, to prevent ice  
25 build-up. Heaters 35, for example, may be routed  
internally within the walls of the housing 12 or  
applied as a mat in a fashion similar to that  
currently done with many devices that must be ice

-7-

protected such as temperature probes, pressure probes and antennae.

To prevent deicing heat from significantly influencing the probes within the housing 12, the  
5 flow tube, 16, is provided with a number of small holes or perforations 36, to bleed off the heated boundary layer that forms at the inside walls. This technique is currently used in some aircraft total temperature sensors for the same purpose.

10 A baffle or heat shield 37, is positioned in flow channel 26, to further minimize the influence of deicing heaters located in the forward walls of strut 14, or probe(s) located within flow channel 26. An orifice, 39, provides venting between the baffle 37  
15 and the inner surface of the forward wall of the strut to prevent excessive temperature rise of the baffle wall.

As shown in Figure 2, where in the schematic diagram the resistances of probe 34 indicated as P1,  
20 and probe 38, indicated as P2, are coupled into legs of a bridge circuit 40. Resistors R1, also indicated at 42, and R2, also indicated at 43, are coupled into the bridge and when the air in both of the branch flow channels 26 and 27 is essentially dry, and  
25 balanced to be substantially equal flow rates, the resistances of probes P1 and P2 (34 and 38) will react substantially the same and the bridge will remain balanced. This is indicated by the ratio  $P1/P2 = R1/R2$ .

-8-

The voltage source 46, designated  $V_{\text{supply}}$ , excites the bridge. The output of the bridge is across the opposite terminals from the input, and is designated  $V_b$  in Figure 2. This output signal is  
5 provided to an air data computer 50. It should also be noted that bridge resistors R1 and R2 are selected to be substantially greater than the resistances of P1 and P2 to minimize heating of R1 and R2. The computer 50 is provided with an air temperature  
10 signal from a temperature sensor or source indicated at 54 and this air temperature signal source can be a separate sensor mounted on the aircraft, or as will be explained in connection with Figures 3 and 4, can be an additional probe mounted in the flow housing  
15 12. The sensor or source 54 provides freestream of ambient temperature.

When moisture is such as that indicated by the lines 28 in flow channels 18 and 27 in Figure 1, is present in the freestream air flow, the probe 34  
20 (P1) will experience liquid moisture impingement, whereas little or no liquid moisture will impinge on probe 38 (P2). Probes 34 and 38 are electrically self-heated to a temperature in the range of 50 degrees to 100 degrees C above ambient.

25 As an alternative to self-heating, separate heater elements integral with, or in close proximity to, the temperature sensing elements in the probes 34 and 38 can be used. The mass flow rate of flow stream in the branch channels 26 and 27 is controlled by

-9-

regulating the size of outlets 22 and 30, as well as the size of opening 24 so that the mass flow is substantially the same over each of the probes 34 and 38.

5           In a non-moisture situation, there will be more heat removed from each probe as the flow rate increases, but the amount of heat removed from each will be substantially the same. The bridge 40 will remain substantially balanced. Thus, the output  
10 voltage designated  $V_b$  is independent of the flow rate or air speed.

          If, however, there is liquid moisture present in the freestream airflow in branch channel 27, the heat removed from the probe 34 (P1) is enhanced by  
15 evaporation and/or blow-off of warmed water since the probes are maintained at a temperature significantly above ambient. This results in a probe temperature change at probe 34 and a resistance change in the probe, and consequently an offset or change in output  
20 signal voltage  $V_b$ . The offset in  $V_b$  increases with increasing liquid water content at the same mass flow of air. There is sensitivity to frozen precipitation such as snow and ice crystals but this sensitivity will be relatively low, and will appear in the form  
25 of output voltage spikes that can be filtered by signal conditioning prior to providing the output signal to computer 50, or filtering can be done in the computer 50.

-10-

The temperature measurement from the temperature sensor or signal source 54 is combined with the output of the bridge 40, so that the computer provides an output that indicates icing conditions.

5 Icing conditions are indicated when the temperature T is slightly above freezing or less, and when a voltage output from the bridge circuit 40, is caused by liquid moisture being present in branch channel 27 and impinging on probe 34.

10 In Figures 3 and 4, an alternative form of the invention is shown. Probes 34 (P1) and 38 (P2), are positioned the same as in Figure 1, but an optional temperature sensing probe 60 is provided in the branch flow channel 26. Probe 60 preferably is  
15 positioned upstream of the probe 38 (P2) to avoid heating influences from the probe 38, which as stated is held above ambient temperature. The resistance of probe 60 (P3) and a resistor 62 that is shown  
20 connected into an alternative bridge circuit 64 are chosen to be at least an order of magnitude greater than the resistances of probes 34 and 38 (P1 and P2). This selection of resistances will significantly limit self-heating effects.

25 The resistance element in probe P3 is in the leg of a bridge circuit 64 that is shared by heated probes P1 and P2, as shown in Figure 4. This bridge arrangement affords two bridge voltage outputs, designated  $V_1$  and  $V_2$  in Figure 4. The output  $V_1$  indicates the change in resistance that occurs in

-11-

moisture laden or water laden air in branch flow channel 27, and  $V_2$  is an output that is indicative of the resistance of the probe in the branch flow channel 26, where moisture has been separated.

5       The arrangement of Figures 3 and 4 reduces the dependency of determining mass flow rate, or making the mass flow rates equal over the probes 34 and 38 as shown in Figure 1, because there is an independent measurement of heat loss from probes located in flow  
10 branch channels 27 and 26. There is a known relationship between  $V_1$  and  $V_2$  as a function of dry airflow rate. Furthermore, dry air mass flow rate can be discerned from voltage  $V_4$  across the heated probe 38 in the dry air channel, 26, and  $V_3$ , the voltage  
15 drop across the temperature sensing probe 60, also in dry air channel 26. With moisture laden air in the channel 18, the relationship between  $V_1$  and  $V_2$  will be different because of additional heat losses at probe 34 (P1) from evaporation and/or blow-off since  
20 the branch channel 27 carries the liquid moisture, while branch channel 26 carries air with little or no liquid moisture. Therefore, if the voltage relationship between  $V_1$  and  $V_2$  changes, from the expected relationship with dry air in both branch  
25 flow channels, the presence of liquid moisture in branch flow channel 27 is indicated.

Voltage source  $V_{\text{supply}}$  and voltage  $V_3$  shown in Figure 4, can be measured and provided to a computer 70, to determine the ambient air temperature.

-12-

Temperature and moisture information is thus available to determine the presence of icing conditions as an output 72 from the computer 70. The computer is provided with a set point signal so that  
5 when liquid moisture is sensed to be present and the measured air temperature is below the set point, icing conditions are indicated.

It is to be noted that any type of inertial separation flow path can be utilized, and the  
10 structure shown herein is merely an example of the type that could be used. The change in direction of a flow can be caused by baffles, obstructions such as posts that cause diversion of particles, and various other shapes and forms of channels that have flow  
15 paths branching at a sufficient angle such that the heavier particles will continue in their flow direction under inertial forces and the branch path or bleed path will carry airflow that is substantially free of any liquid moisture particles.

20 The ability to provide orifices or other flow controls such as the outlets 22 and 30 in Figure 1 for exhaust of fluids, is a way of ensuring that the mass flow rates in the separated channels are substantially the same, and yet inertial separation  
25 will keep the liquid particles moving in the same direction along in the straight flow path through branch channel 27.

In Figure 4, the quantity  $R1/P1$  approximately equal to  $R3/P3$  and is approximately equal to  $R2/P2$ .

-13-

Also  $R_3$  is substantially greater than  $R_1$ , and  $R_1$  is substantially equal to  $R_2$  in order to have the bridge perform satisfactorily.

In Figure 5, a flow housing 80 is illustrated, and is of substantially the same form as the flow housing 12 and strut 14, but in this instance, the flow tube 81 forms a flow channel directly from a flow inlet 84 and through a control orifice 86 at the outlet. A strut 88 is used for supporting the flow housing 80 relative to an aircraft skin 90, and in this instance, the strut opening does not carry flow and is a hollow pipe that has no flow outlet for exiting air. The strut could be solid, in other words, in this form of the invention.

A probe indicated at 92 and which can be represented as  $P_4$  is a heated, or self-heated temperature sensitive probe that is deployed in the airstream, and there is no special ducting required. A flow housing for providing ducting is preferred particularly to control airflow over the probe, to minimize probe operating power and to protect the probe, although the probe can protrude directly into an airstream so long as the liquid water is not separated from the airstream in which the probe is mounted.

In this form of icing conditions detector, the operation of the probe 92 is based upon the well known fact that power consumed by a heated body maintained at a constant temperature above ambient of

-14-

the airstream is a function of the mass flow rate. It is desired to maintain the body, in this case the probe 92, at a fixed temperature above ambient. Power consumed in a dry environment will have a fixed  
5 relationship to the mass flow rate calculated from the air data information available from another source.

Probe 92, which again is self-heated or with a separate heater that is shown schematically at 92H in  
10 Figure 5, is connected to a computer 96 with a controlled power source, and the computer provides power to the heater or the self heating resistor along a line 98, and through a "power consumed" indicator 100, which essentially is the power input  
15 to the probe 92. The computer will measure the power that is drawn to maintain the temperature of the probe 92. This power consumed signal provided along a line 102 back to the computer 96 and is maintained at a desired level.

20 In order to provide the data or information necessary to determine the mass flow rate, a pitot (total) pressure input 104, a total air temperature input 106, and a static pressure input 108 can be used to calculate the mass flow rate, and provide the  
25 known parameters to the computer 96 for determining the power that would be consumed at the existing mass flow rate if the probe 92 is in dry air. Then, using the actual power consumed from the indicator 100, the computer provides an indication when moisture is

-15-

present in the airflow. The amount of moisture can also be determined by empirical tests, or calculations that are related to the particular probe 92, and what power this probe consumes or requires to maintain a selected temperature in airflow having liquid moisture conditions at different mass flow measurement rates.

Again, to assess icing conditions, a measurement of temperature from a temperature sensor 106, providing a temperature parameter to a computer system is necessary. Temperature sensing is well known in aircraft, and air data sensors.

The effect of water vapor, that is, humidity, in the airflow will have little influence on performance of the detector of the present invention. The detectors are very sensitive, however, to the presence of water droplets, that is liquid water in the air. It is also recognized that the heat transfer capability of air is not only a function of mass flow rate, but also temperature. Compensating for temperature, if necessary, can be done by suitable analytical techniques that would provide information to a control computer, or direct compensation in the circuitry by having temperature dependent circuit elements. The ability to provide these compensation techniques are presently done in existing mass flow measurement products.

Although the present invention has been described with reference to preferred embodiments,

-16-

workers skilled in the art will recognize that changes may be made in form and detail without departing from the spirit and scope of the invention.

- 17 -

The embodiments of the invention in which an exclusive property or privilege is claimed are defined as follows:

1. A sensor for detecting icing conditions in an airflow caused by presence of liquid moisture in such airflow, the sensor including:

a flow housing having a channel providing at least one flow path configured to provide a known mass airflow rate therethrough at relative airflow speeds;

at least one probe mounted in the at least one flow path such that the airflow impinges on the probe;

a power source for heating the probe; and

a sensing circuit coupled to the probe for determining changes in a function which is dependent upon the presence of liquid moisture striking the probe, the sensing circuit providing an output indicating changes in the function, wherein said sensing circuit comprises a bridge circuit, and wherein the probe comprises a first probe and has a known resistance relationship with temperature, a second probe mounted in a second airflow path that is branched from the at least one airflow path and which has airflow that is substantially free of liquid moisture, and wherein the bridge circuit compares temperatures between the first probe and the second probe.

2. The sensor of claim 1, wherein the sensing circuit comprises a power measurement circuit to indicate power required to maintain the probe at a selected temperature.

3. The sensor of claim 2, wherein the sensing circuit comprises a computer having inputs indicating speed of airflow past the probe, and temperature of the airflow for providing an output based upon power consumed.

- 18 -

4. The sensor of claim 1, wherein the sensing circuit comprises a computer, said computer sensing the output dependent upon the presence of liquid moisture striking the probe, and an air temperature sensor input to the computer, the computer providing an output indicative of icing conditions when liquid moisture is sensed to be present on the probe, and the air temperature is near freezing.

5. The sensor of any one of claims 1 to 4, wherein said flow housing is provided with heaters positioned to heat a wall of the housing and prevent ice build-up on the flow housing.

6. The sensor of any one of claims 1 to 5, further including a third probe mounted in the second airflow path, said third probe comprising a temperature sensor for determining temperature of air flowing across both the first and second probes.

7. The sensor of any one of claims 1 to 6, wherein said at least one airflow path and said second airflow path are defined in a single airflow housing, said second airflow path having an inlet opening that is lateral of the path of movement of air in the at least one airflow path such that the heavier particles in the at least one airflow path are carried past the inlet opening of the second airflow path.

8. A sensor for sensing icing conditions in an airflow caused by presence of liquid water in such airflow, said sensor including:

a flow housing having a first flow path configured to have known mass flow rates at different airflow speeds;

- 19 -

a first probe mounted in said first airflow path in position to be impinged by the airflow and by liquid droplets in the airflow, said first probe being heatable in response to a power input, the probe indicating temperature by changes in a temperature sensing element in the first probe;

a circuit connected to said first probe to provide heating power to heat the first probe to a selected temperature above ambient temperature; and

a circuit connected to the first probe to determine the amount of heat removed from the first probe above a known value of heat removal in dry air flowing at the same mass airflow rate as the airflow rate through the flow path to determine if moisture in the airflow is causing heat to be removed from the first probe.

9. The sensor of claim 8, wherein said flow housing has a branch flow path positioned relative to the flow direction through the first flow path such that the liquid water is inertially separated and maintained in the first flow path, and airflow through the branch flow path being substantially free of liquid moisture, a second probe in the branch flow path, and wherein the circuit includes components to compare the changes in relative heat removal between the first and second probes.

10. The sensor of claim 9, wherein said circuit further comprises a computer receiving signals that indicate when liquid moisture is present in the air flow, and receiving a temperature signal indicating ambient temperature, the computer providing an output signal indicating the presence of icing conditions when the ambient temperature is below a

- 20 -

selected level and liquid moisture is indicated as being present.

11. The sensor of claim 10, wherein the computer receives a set point signal, and compares the set point signal to the ambient temperature, the computer providing the output indicating icing conditions when a signal indicating liquid moisture is present and the ambient temperature is below the set point signal.

12. The sensor of claim 9, wherein the branch flow path is defined in a portion of the housing having a forwardly facing wall, a heater for heating the wall for deicing the forwardly facing wall of the flow housing, and a baffle in the branch flow path between the forwardly facing wall and the second probe to reduce the influence of heaters in the forwardly facing wall.

13. The sensor of any one of claims 8 to 12, wherein the signal from the circuit carries as a function of the quantity of liquid moisture present as a function the amount of heat removed from the first probe.

14. The sensor of claim 9, wherein a third probe for sensing temperature is mounted in the branch flow path, and is included in the circuit to provide a temperature signal for determining the presence of liquid moisture in the first flow path.

15. The sensor of claim 14, wherein the third probe is positioned upstream from the second probe in the branch flow path.

- 21 -

16. The sensor of claim 14, wherein the circuit is a resistance bridge circuit, and wherein the temperature signal is provided at terminals of the bridge.

17. A sensor for sensing icing conditions in an airflow caused by presence of liquid moisture in such airflow, said sensor including:

a flow housing having a flow path that is configured to provide airflow in a substantially straight line, the flow housing having a laterally facing outlet opening leading from the flow path to a passage, the flow path including a first branch flow path downstream of the laterally facing opening, and said passage comprising a second branch flow path;

a first temperature sensor probe mounted in said first branch flow path;

a second temperature sensing probe mounted in said second branch flow path, the laterally facing opening being positioned such that airflow passing through the laterally facing opening is substantially free of liquid moisture; and

a bridge circuit connected to resistances in said first and second probes to compare differentials in temperature between temperature sensed by said first and second probes, respectively.

18. The sensor of claim 17, wherein said first and second branch flow paths are controlled to have substantially the same mass flow rates carried therein.

19. The sensor of claim 18, further including a temperature sensing probe in said second branch flow path positioned to be impinged by air flow in said second branch

- 22 -

flow path prior to the air flow in said second branch flow path impinging on the second probe.

20. The sensor of claim 19, wherein said third probe is a resistance temperature sensing probe, and is connected in the bridge circuit to provide an indication of temperature at selected terminals of the bridge circuit.

21. The sensor of any one of claims 17 to 20, wherein said first and second probes are heated, and are maintained at temperatures substantially above ambient temperature of the air flow.

22. The sensor of any one of claims 17 to 21, wherein the flow housing has boundary layer control orifices through a wall of the flow housing defining the flow path.

23. The sensor of any one of claims 17 to 22, further including a baffle plate in the first branch flow path between a leading edge of the flow housing defining the first branch flow path and the first temperature sensor probe.

24. The sensor of any one of claims 17 to 20, further including a computer connected to the bridge circuit to receive signals indicating differentials between temperatures sensed by said first and second probes, the computer having an input indicating ambient temperature, and providing an output indicating icing conditions when liquid moisture is indicated by the differential in temperatures between the first and second probes, and the ambient temperatures is below a selected level near freezing.

- 23 -

25. The sensor of claim 24, wherein the computer receives a set point signal, the computer providing the output indicating icing conditions when the ambient temperature signal is below the set point signal.

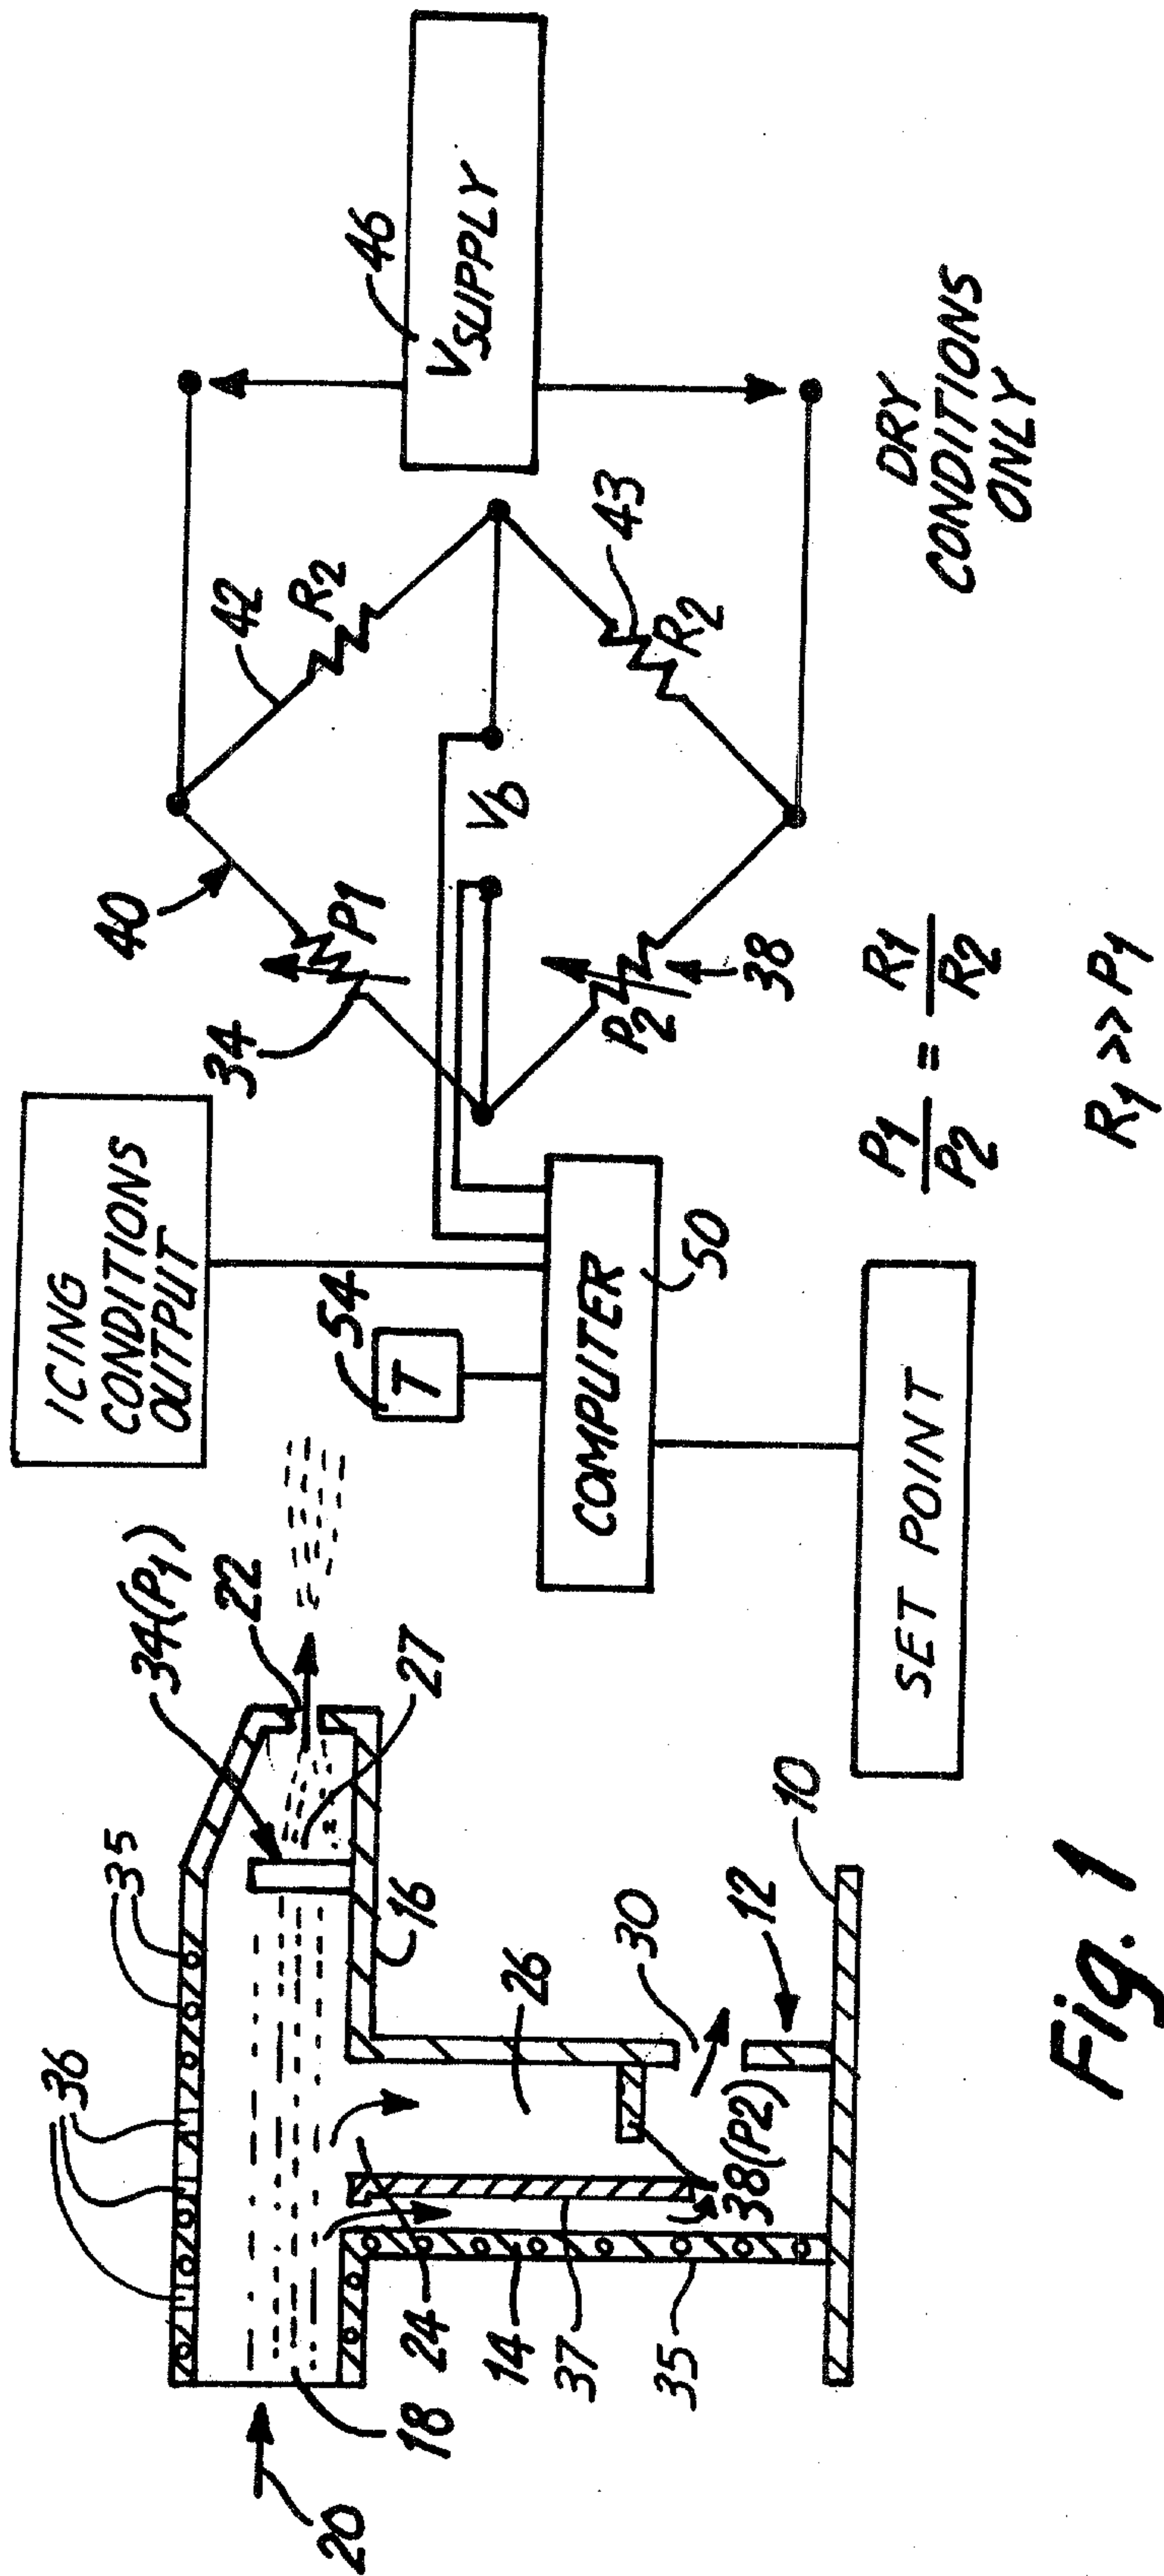

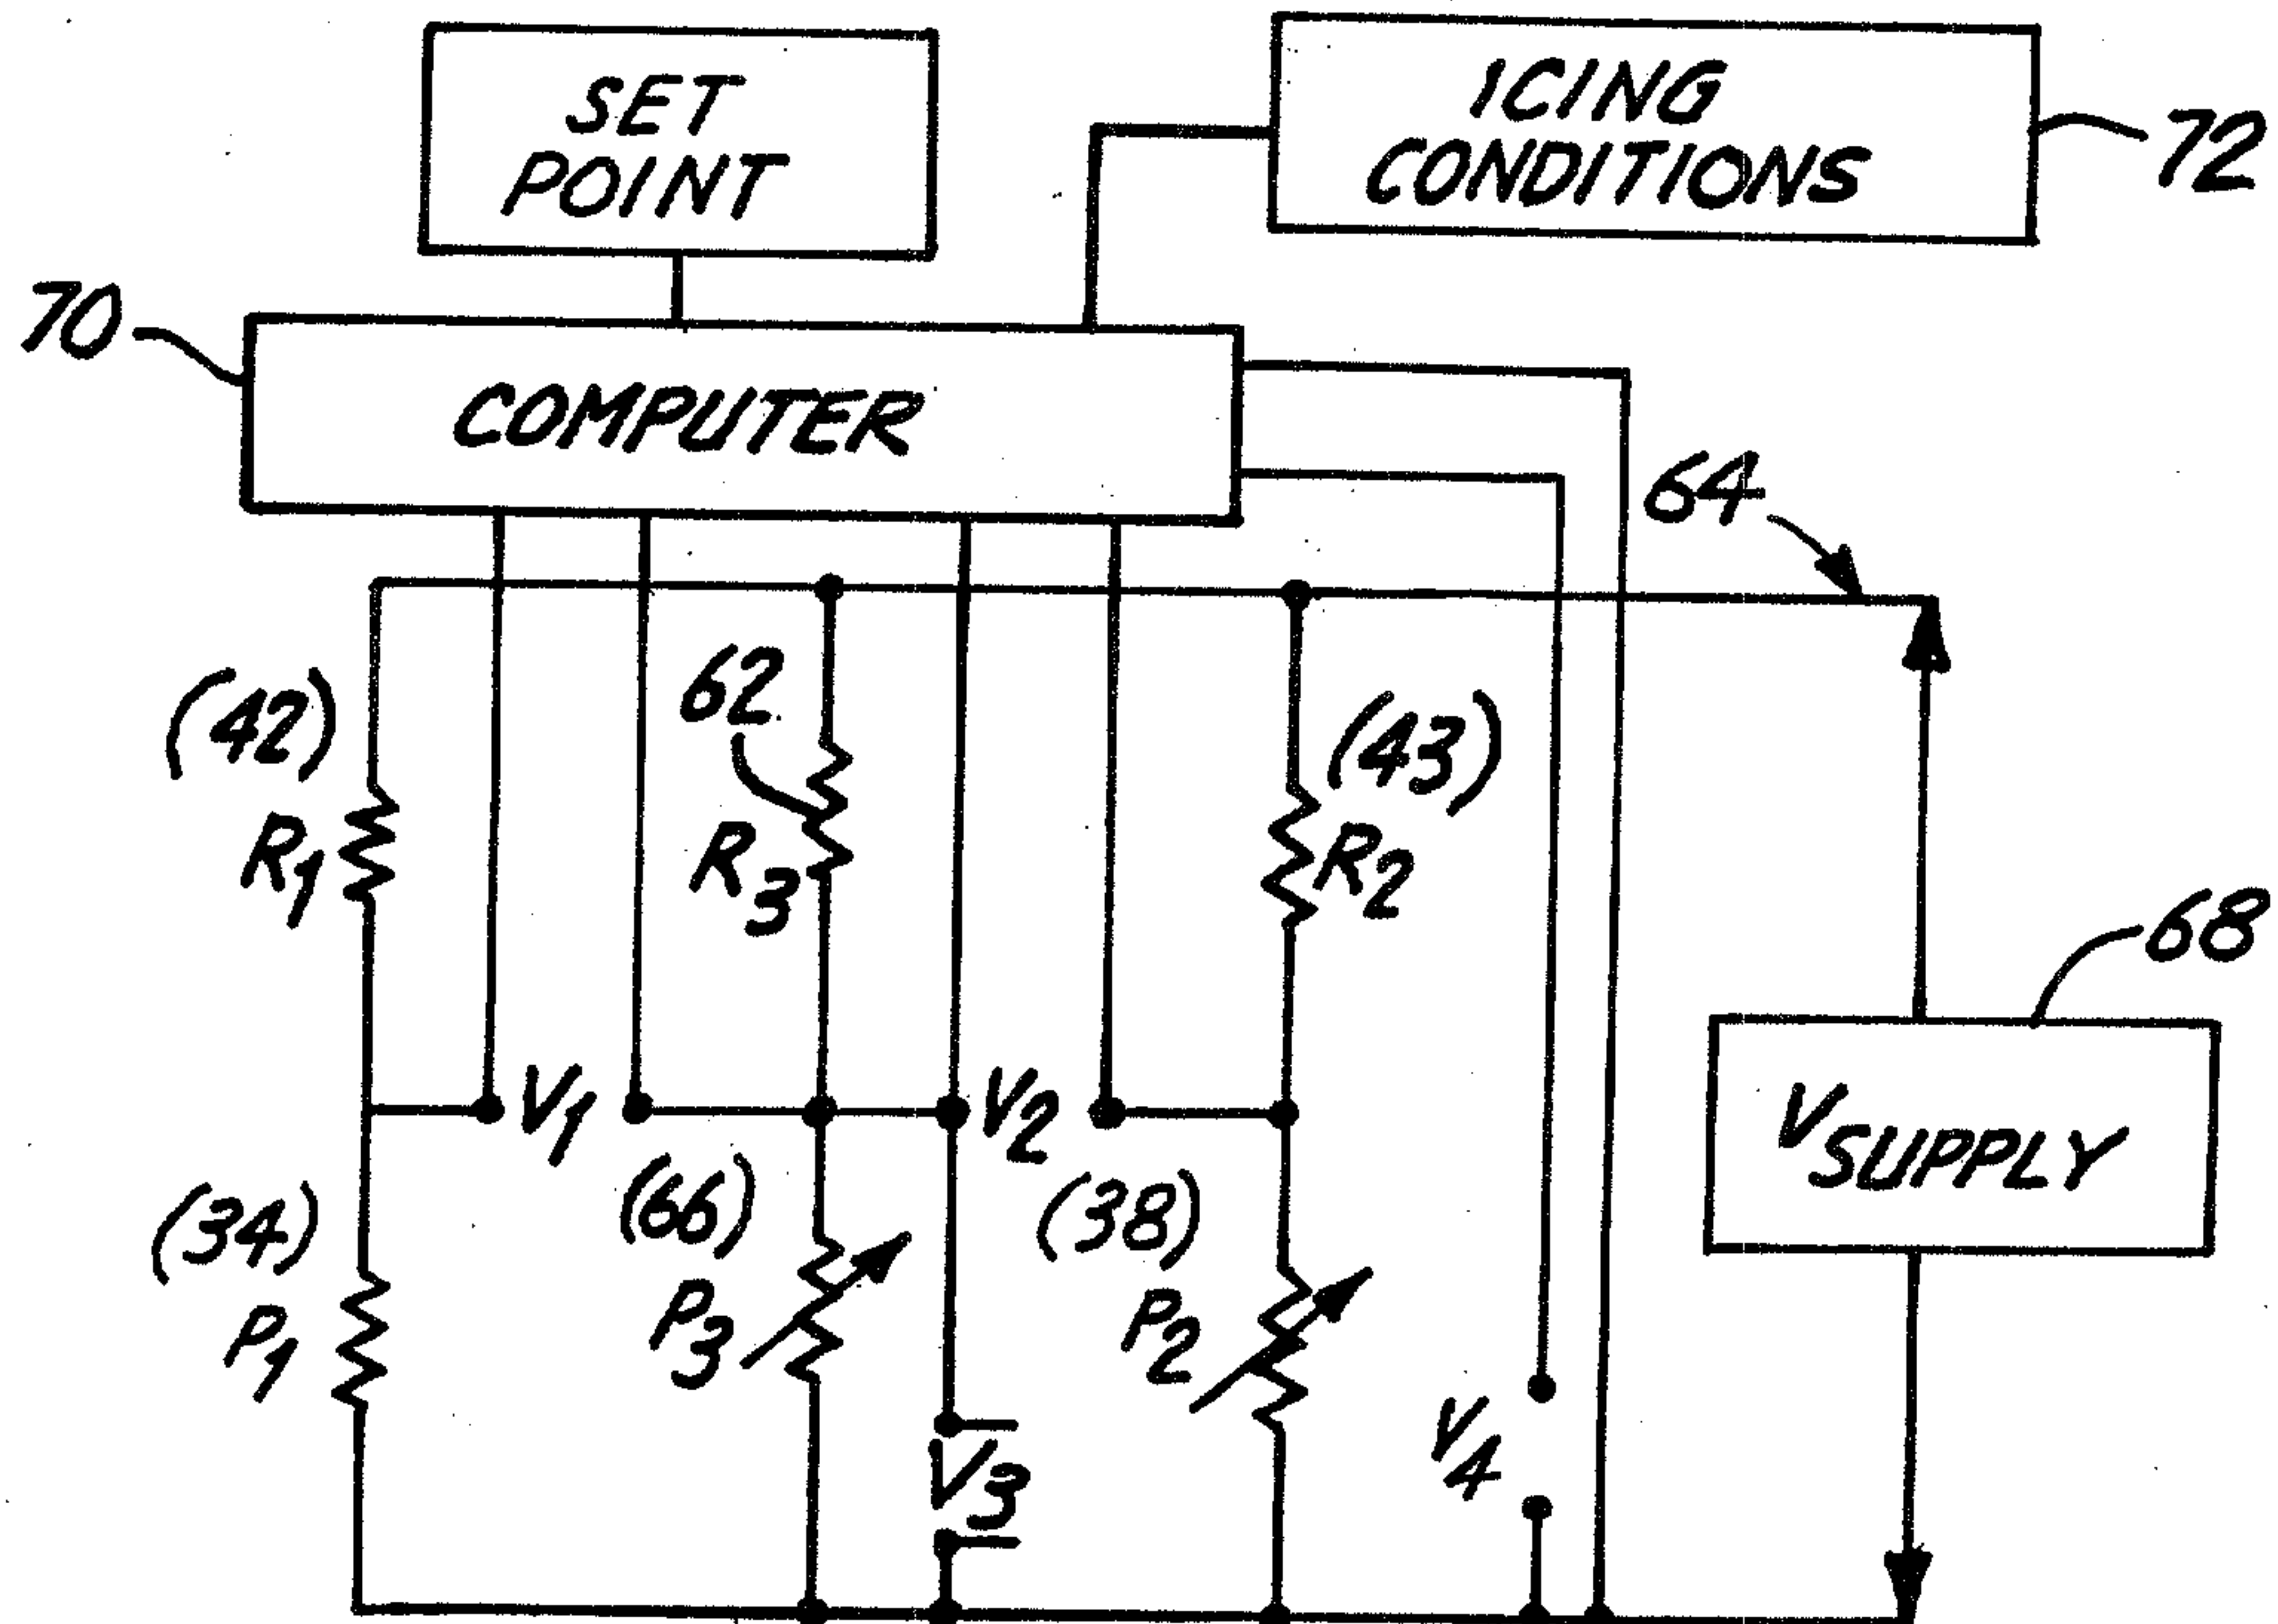

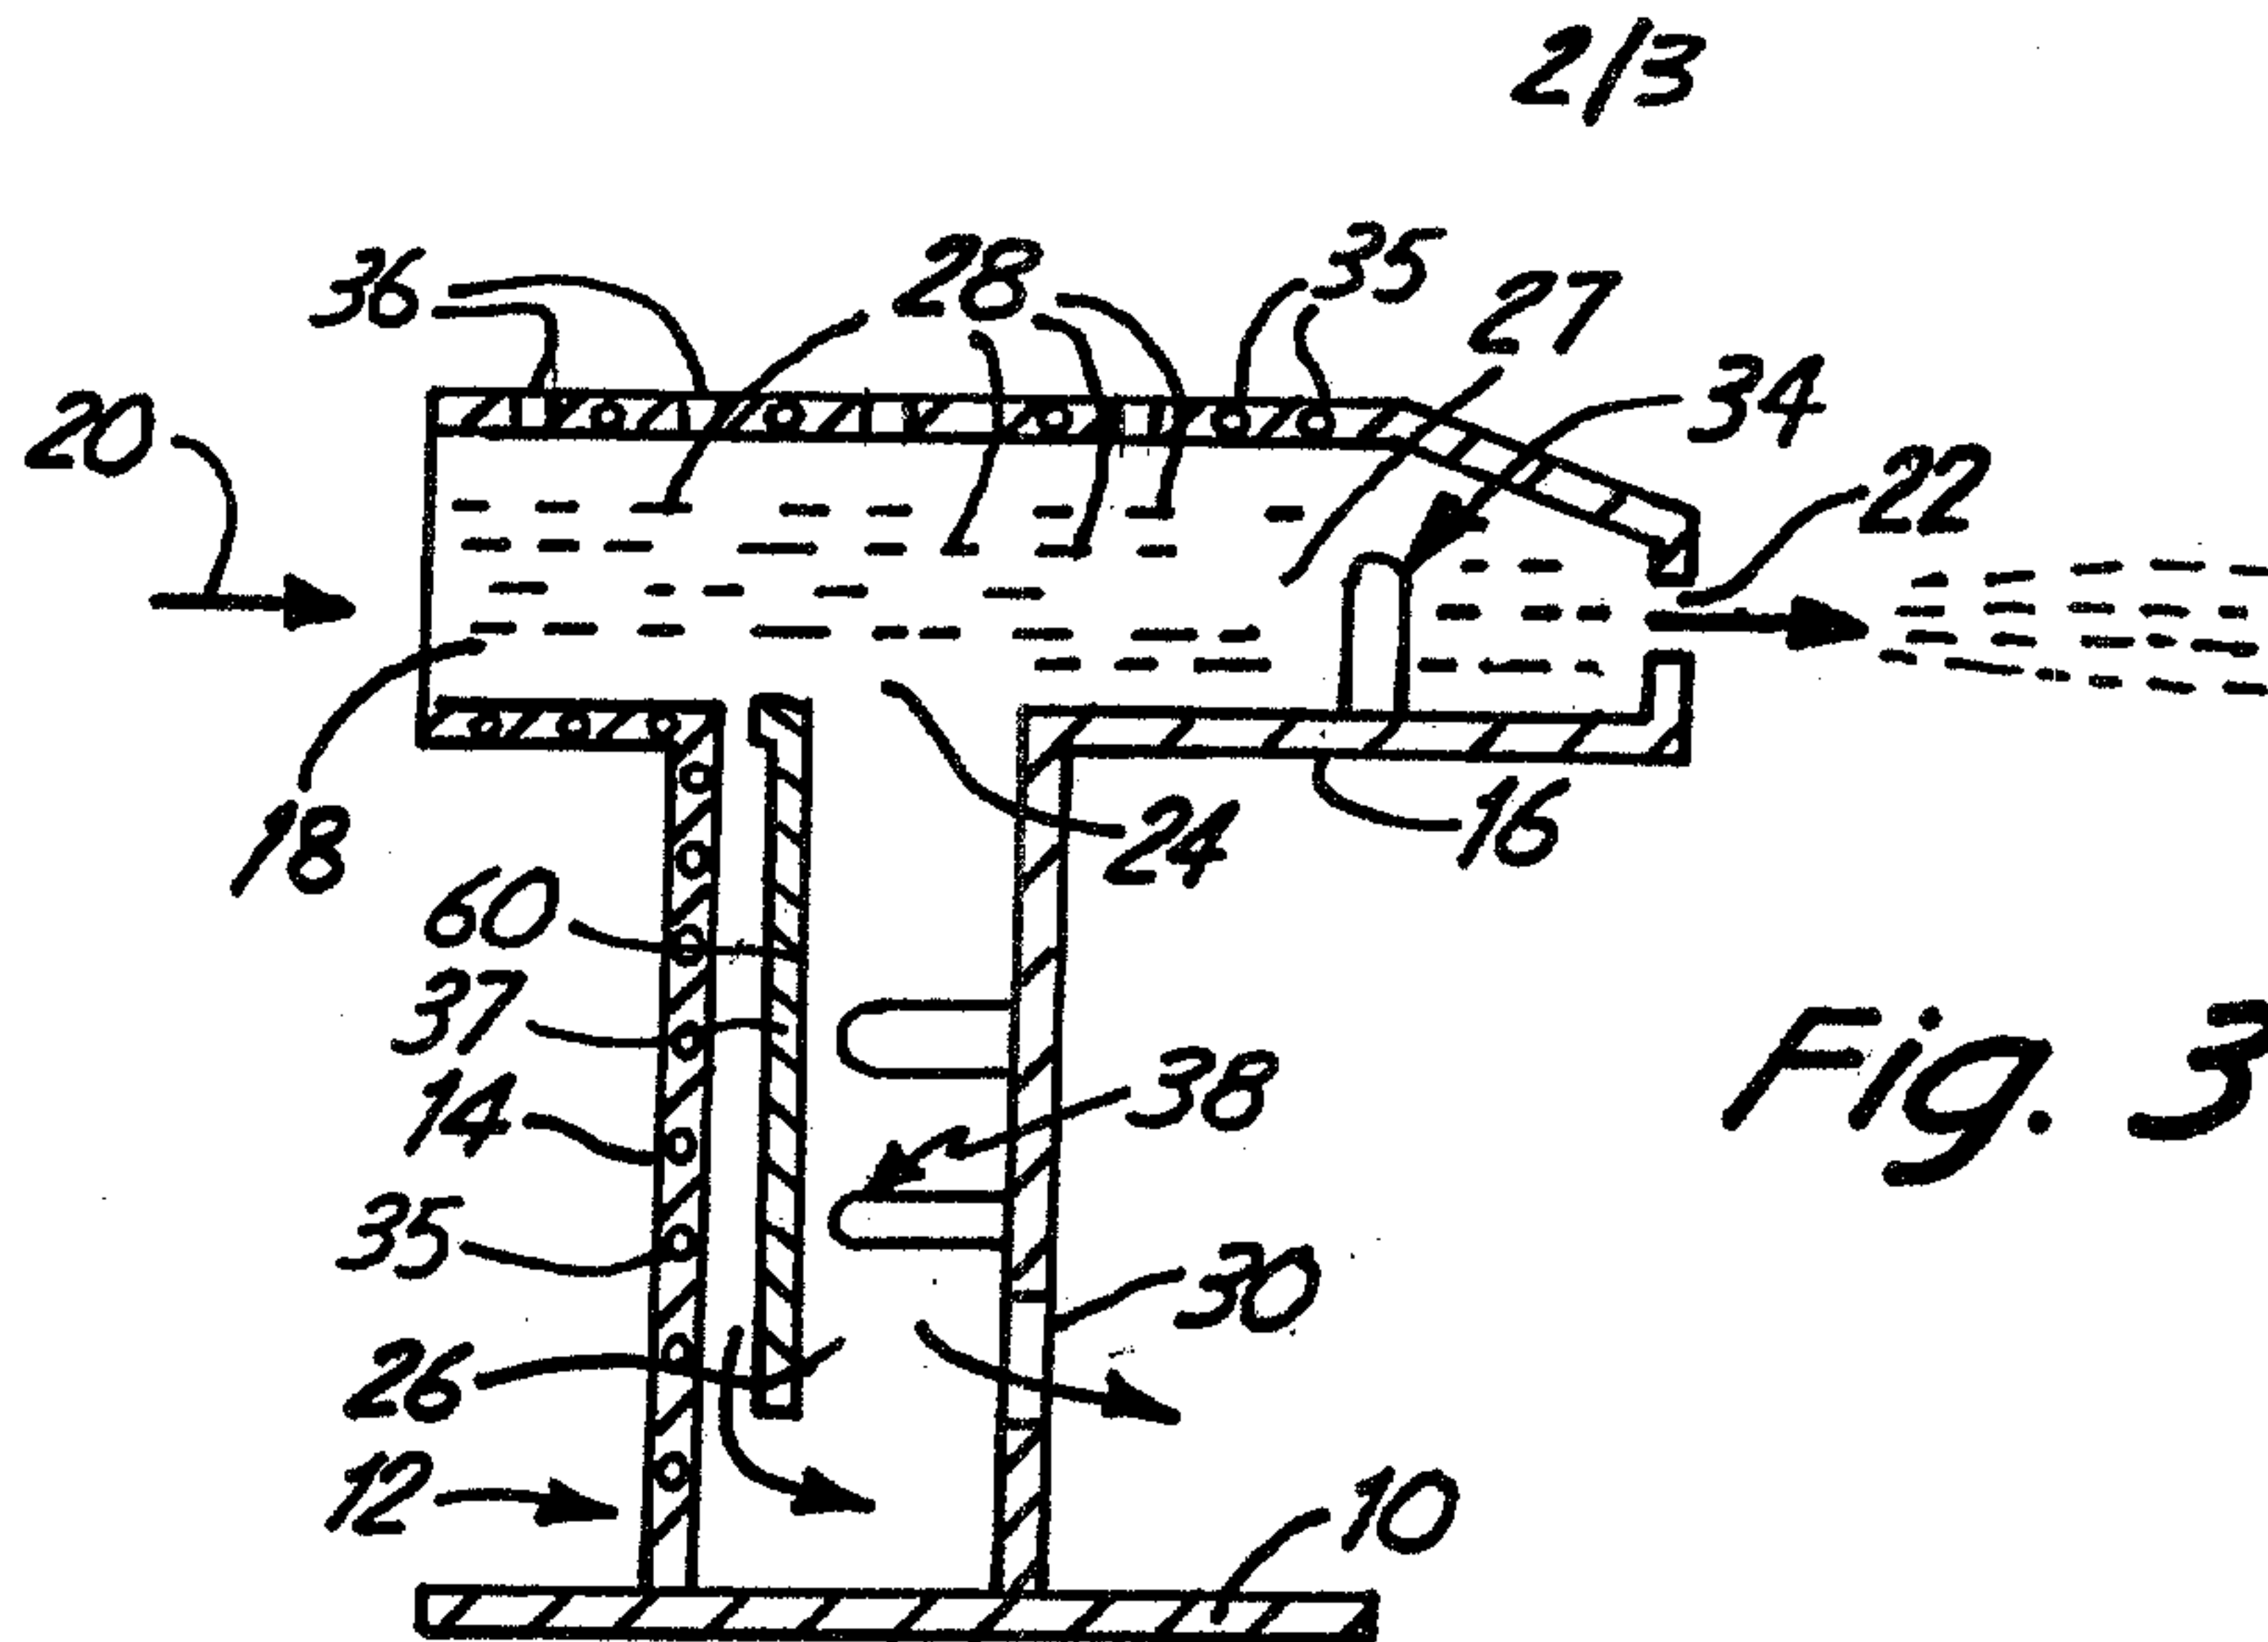

Fig. 2

$$\frac{P_1}{P_2} = \frac{R_1}{R_2}$$

$$R_1 \gg P_1$$

DRY  
CONDITIONS  
ONLY

$$\frac{R_1}{P_1} \approx \frac{R_3}{P_3} \approx \frac{R_2}{P_2}$$

$$R_3 \gg R_1 \quad R_1 \approx R_2$$
