(54) Title: DEVICE AND METHOD FOR DETECTING OPENING OF PASSAGE IN BODILY CAVITY

(57) Abstract: The invention relates to a device for detecting opening of a passage in a bodily cavity I comprising an electric signal source; a first transducer for converting an electric signal from the electric signal source into an acoustic signal; a second transducer for reception of the acoustic signal; and where the first and the second transducer are placed on respective sides of the obstruction in the cavity. The invention further relates to a method for measuring opening of a passage in a bodily cavity; the method comprising supplying an acoustic signal at one side of the obstruction and receiving the acoustic signal at the other side of the obstruction, when the passage is open.
Device and method for detecting opening of passage in bodily cavity

FIELD OF THE INVENTION

The invention relates to the field of medicine where bodily cavities are examined and where restrictions or obstructions are diagnosed or identified. Such restrictions may when present form open or closed passages dependent on the pressure on either side of the passage and dependent on the activity of the patient in question. One example of such bodily cavity is the respiratory passage. The tongue and the soft palate may often form an obstruction when these relax during sleep. The condition is called obstructive sleep apnea (OSA) and is characterized by that the patient is not breathing for a longer or shorter period of time. Obviously this inflicts a significant risk for the patient’s health and in severe cases for the patient’s life. Other bodily cavities may contain an obstruction and hence require examination of these.

Although the invention is in the following only explained in connection with its use in the respiratory passage, it should be appreciated that the invention finds use in connection with other bodily cavities as well.

BACKGROUND OF THE INVENTION

In order to remedy some of the risk of the sleep apnea an apparatus has been developed, which applies air under pressure to the patient's respiratory system during sleep. These apparatuses are often designated CPAP machines after the therapy, which is called Continuous Positive Airflow Pressure therapy. Other products designations are used for apparatuses having a similar function. VPAP and DIPAP are examples of such. This pressure helps maintaining open or helps opening any restrictions in the patients respiratory passages and does in this manner help the patient in breathing. The patient may by use of such device reduce the risk of suffocating and can at the same time obtain the necessary rest or sleep. The pressurized air is supplied through a mask, which the patient wears over the mouth and/or nose. Many patients may be helped by means of this therapy and the related
apparatuses as an alternative to surgical treatment. In order to fit the apparatus correctly to
the individual patient the pressure necessary for performing the opening of one or more the
restrictions in passage must be identified and the apparatus must be adjusted to supply the
necessary pressure within a given upper and lower limit. The fitting of the apparatus with
the correct pressure, which is individual for each patient, is very important as an incorrect
too high pressure may lead to nasal dryness, discomfort and swallowing of air. It is obvious
that it is desirable to keep the airflow as low as possible. On the other hand a too low pressure
will not provide the necessary help to the patient. Moreover it is well known that the requi-
red pressure for each patient may change over time as the physiological demands changes.
This does require frequently follow up on the adjustment in order to have the optimal level
of pressure delivered. Hitherto this pressure adjustment has been carried out during a sleep
study and has been carried out by a trained person who adjusts the pressure until it is as high
as required for abolishing apnea, hypoapnea and snoring. In other words the pressure is
adjusted according to some symptoms of the closed passage and not necessarily according
to the actual desired condition, namely the opening of the passage. It is obvious that the
previously used method may lead to an adjustment of the pressure, which is either too low or
too high, where the latter is more often the case, with the consequences described above.

Another method used comprises observation of the counter pressure in the system. When
the counter pressure decreases this is taken as an indication of opening of the passage. This
method has a degree of uncertainty in respect of correct detection of the opening in the
bodily cavity.

Obviously since this previously known apparatus and the related fitting methods for the
apparatus leaves some drawbacks due to a significant uncertainty about the pressure
determination and as the previously known method is rather time consuming, there is a need
for improving the previously known method and apparatus.

A further situation where an obstruction may be diagnosed is in the examining equipment as
disclosed in us 5823965. This previously known apparatus is adapted for examination of the
cross section of a bodily cavity.
It is therefore one objective of the invention is to provide an apparatus, which facilitates the determination of the opening of a passage in a bodily cavity by making a more accurate determination possible in a less time consuming process. It is a further objective of invention is to provide a method, which facilitates the determination of the opening of a closed passage in a bodily cavity by making a more accurate determination possible in a less time consuming process.

**SUMMARY OF THE INVENTION**

According to the invention the first objective is achieved by an apparatus, which comprises an electric signal source; a first transducer for converting an electric signal from the electric signal source into an acoustic signal; a second transducer for reception of the acoustic signal; and where the first and the second transducer are adapted to be placed on respective sides of the obstruction.

By means of the apparatus according to the invention the opening can be determined very accurately as the reception signal is sampled and as the opening of the passage gives rise to a significant and unambiguous change in the received signal. The apparatus according to the invention may also be used in connection with the method and apparatus disclose in us 5823965 in order hereby to detect an obstruction in the bodily cavity. It is obvious that an erroneous diagnose can be avoided by this combination.

In a preferred embodiment the device comprises a hose to be introduced into the bodily cavity beyond the obstruction and where the hose has at least in a zone for placing at the passage an outer wall of a soft or elastomeric material. Hereby the electrical signal means are controllable in a reliable manner and the soft or flexible hose has little or no impact on the measuring accuracy.

In a further preferred embodiment the hose is closed at the distal end. This facilitates the introduction of the hose by means of as guide wire.
In a still further preferred embodiment the apparatus comprises means for supplying a pressurized medium into the cavity. Hereby a necessary opening pressure can be supplied simultaneously with the measuring and the necessary opening pressure may be determined.

In a preferred embodiment the hose has a separate cavity for supplying the pressurized medium beyond a restriction in the bodily cavity.

In a preferred embodiment the first, the second or both transducers are integrated in the hose. This provides for a safe handling of the apparatus and minimizes the risk of breaking the equipment and making erroneous connections of the signal emitting and receiving devices. This is further improved when the electrical connections to the transducers are integrated in the hose.

According to the invention the second objective is achieved by a method comprising supplying an acoustic signal at one side of the passage; receiving the acoustic signal at the other side of the passage, when the passage is open.

By the method according to the invention the opening can be determined very accurately as the reception signal is sampled and as the opening of the passage gives rise to a significant and unambiguous change in the received signal. The apparatus according to the invention may also be used in connection with the method and apparatus disclose in US 5823965 in order hereby to detect an obstruction in the bodily cavity. It is obvious that an erroneous diagnose can be avoided by this combination.

The invention will be described more detailed in the following with reference to the drawing showing a preferred embodiment of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a schematic view of an apparatus according to the invention; FIG. 2 is a perspective view of a tube part of the apparatus of FIG. 1; FIG. 3 is a schematic view of the apparatus of FIG. 1 in a state of use where an obstruction is indicated;
FIG. 4 is a further schematic view of the apparatus of FIG. 1 in a state of use where the obstruction shown in FIG. 3 has been eliminated.

DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to FIG. 1 the apparatus according to the invention comprises a signal generating unit 2 and a signal processing unit 4, a hose or catheter 1 and two transducers 3, 5, i.e. a first emitting transducer 3, e.g. a speaker, and a second receiving transducer 5, e.g. a microphone. The transducers 3, 5 are placed at respective ends, proximal end A and distal end B, of the hose 1 and are connected to the signal generating and processing units. The signal-processing unit is connected to a display 7 and a keyboard 6 for showing the measuring results and controlling the apparatus, respectively. Referring to FIG. 2 a measuring zone G of the hose 1 shown in Fig. 1 appears. It is clear that the wall material 9 allows movement in a radial direction F of the hose, hereby allowing the restriction to compress the hose and hence this will not have an erroneous impact on the measuring results. Referring to FIG. 3 the apparatus of FIG. 1 is shown in a mounted state where the hose or catheter 1 with the transducers 3, 5 has been introduced into a bodily cavity, the respiratory passage, of a patient. The apparatus function in the following manner: a signal is generated in the signal-generating unit and is supplied to the first transducer, which emits an acoustic signal. When the passage is closed as shown in FIG. 3 at the rear part of the tongue at D and at the soft palate at E, the acoustic signal will not reach the second transducer or will only reach the second transducer as a weak signal. Once the passage is opened as shown in FIG. 4 the acoustic signal will immediately give rise to an increase in the level of the signal received by the second transducer. This is an unambiguous indication of the opening of the passage. The opening of the passage may be performed by supplying a pressure to the respiratory passage. This is not shown in FIG. 3 and FIG. 4. When supplying a pressure, which is gradually increased, e.g. in steps or continuously and when sampling the values for the pressure supplied and the opening state at the same time the relevant pressure for performing the opening may be determined very accurately. The signal generator 2 generates a characteristic signal, which is supplied to the transducer and to the signal processor. The signal received by the second transducer is compared with this in the signal-processing unit 4. Hereby erroneous measurements can be avoided, as only the receipt of the correct characteristic signal will result in a detection of an open passage.
CLAIMS

1. A device for detecting opening of a passage in a bodily cavity having an obstruction, comprising:
   - an electric signal source;
   - a signal processing means,
   - first transducer for converting an electric signal from the electric signal source into an acoustic signal;
   - a second transducer for reception of the acoustic signal and for supplying this to the signal processing means;
   - where the first and the second transducer are adapted to be placed on respective sides of the obstruction, when inserted in the bodily cavity..

2. A device according to claim 1, where the first and the second transducer are placed on or in an elongate carrier element with a mutual distance allowing for placement of the first and the second transducer on respective sides of an obstruction in a bodily cavity when inserted in the bodily cavity.

3. A device according to claim 1 or 2, where the device comprises a hose to be introduced into the bodily cavity beyond the obstruction and where the hose has at least in a zone for placing at the passage an outer wall of a soft or elastomeric material.

4. A device according to claim 3, where the hose is closed at the distal end.

5. A device according to claim 1 further comprising means for supplying a pressurized medium into the cavity.

6. A device according to claim 2 or 3, where the first, the second or both transducers are integrated in the carrier or the hose.

7. A device according to claim 2 or 3, where the electrical connections to the transducers are integrated in the carrier or the hose.
8. A device according to claim 5, where the hose has a separate cavity for supplying the pressurized medium beyond a restriction in the bodily cavity.

9. A method for measuring opening of a passage in a bodily cavity, the method comprising:
   - inserting a first transducer in the bodily cavity to a point beyond an obstruction,
   - supplying an acoustic signal through the first transducer at one side of the obstruction;
   - receiving the acoustic signal at the other side of the obstruction, when the passage is open.

10. A method according to claim 9, where a pressure is applied to the bodily cavity and where the opening detection of the passage is related to the pressure applied in a signal processing means.

11. A method according to claim 10, where the pressure is increased during the measurement and the opening detection is carried out continuously.

12. A method according to claim 10, where atmospheric pressure is present on one side of a restriction and an increased pressure established on the other side of a restriction.
