(54) Title: SYSTEM AND METHOD FOR NAVIGATING USING TWO-WAY ULTRASONIC POSITIONING

(57) Abstract: A two-way ultrasonic positioning and navigation system and method involve a plurality of objects each capable of transmitting and receiving ultrasonic signals. A first object transmits an initiating ultrasonic signal and identifies a second object for responding to the initiating ultrasonic signal. The second object transmits a responding ultrasonic signal after a predetermined time delay from receiving the initiating ultrasonic signal. The first object receives the responding ultrasonic signal, and determines a distance between the first object and the second object based on a time period starting at the transmission of the initiating ultrasonic signal and ending at the reception of the responding ultrasonic signal, and on knowledge about the predetermined time delay and other known in advance time delays.

WO 03/062850 A2

SYSTEM AND METHOD FOR NAVIGATION USING TWO-WAY ULTRASONIC POSITIONING

The present invention relates generally to systems and methods for navigating mobile platforms, and particularly to a beacon-based positioning or navigation system utilizing two-way ultrasonic ranging.

5 BACKGROUND OF THE INVENTION

The use of ultrasonic ranging in air to position or navigate a mobile object with respect to a set of fixed beacons is widespread nowadays. Many of these systems use time-of-flight measurements of an ultrasonic signal from a transmitter to a receiver. The transmitter can either be located at the mobile object to be positioned,
10 with receivers on beacons placed strategically in the environment, or conversely, transmitters can be placed on the beacons with a receiver located on the mobile object. In some systems, the ultrasonic signal is accompanied by a radio frequency signal, mainly for the purpose of time-synchronization between the transmitter and the receiver. In some other systems, the difference in flight times of an ultrasonic signal
15 and one other signal such as a radio frequency signal is used to determine the distance between the mobile object and each of the beacons. In situations where the mobile object is moving with a significant speed with respect to the beacons, signal frequency Doppler shift of the transmitted ultrasonic signal may be used to aid in the determination of the velocity and position of the mobile object.

20 In these conventional systems, the distance-measuring accuracy is dependent on the correct determination of the speed of propagation of the ultrasonic signal, i.e., the speed of sound in air. The sound speed in air is dependent on many factors, such as atmospheric temperature, humidity, and wind effect. The use of currently available thermometers and hygrometers makes it very difficult to measure the temperature and
25 humidity along the entire wave path and hence predict the speed of sound along the entire path of an ultrasonic signal. Further, in the presence of a wind current, existing systems are subject to large errors in the calculation of distance and hence large

positioning errors. The present invention overcomes these problems of prior art ultrasonic ranging systems.

5 Additionally, most conventional navigation systems require that the system installer survey the locations of the beacons manually and input the locations into the system. See E. LeMaster and S. Rock, *Self-Calibration of Pseudolite Arrays Using Self-Differencing Transceivers*, Institute of Navigation GPS-99 Conference, Nashville, Tennessee, September 1999. Some systems have been classified as self-calibrating, but still require the user to perform certain precise distance measurements. See Mahajan, A. and Figueroa, F., *An Automatic Self Installation & Calibration*
10 *Method for a 3-D Position Sensing System using Ultrasonics*, Japan-USA Symposium on Flexible Automation, Boston, July 7-10, 1996, pp. 453-460. The present invention also avoids the beacon surveying requirements of prior art systems.

SUMMARY OF THE INVENTION

15 The system and method of the present invention overcome the aforementioned problems with two-way ultrasonic positioning and navigation that mitigates wind-induced changes in speed of sound. Moreover, the two-way ultrasonic ranging technique obviates the need for time synchronization between platforms. In one embodiment of the present invention, an autonomous or semi-autonomous apparatus,
20 or a mobile platform, is positioned or navigated with respect to a few beacons having fixed positions. Positioning applications involve the localization of the mobile platform using two-way ultrasonic time-of-flight measurements. Navigation applications involve tracking the mobile platform using augmenting sensors based on the position of the mobile platform determined through the two-way ultrasonic time-
25 of-flight measurements.

The method for a two-way ultrasonic measurement, according to one embodiment of the present invention, comprises transmitting an initiating ultrasonic signal from an initiator, the initiating ultrasonic signal identifying an intended recipient, receiving the initiating ultrasonic signal at the intended recipient,
30 transmitting a responding ultrasonic signal from the recipient after a predetermined time delay from the reception of the initiating ultrasonic signal, receiving the

responding ultrasonic signal at the initiator, and determining a distance between the initiator and the respondent based on a time period starting at the transmission of the initiating ultrasonic signal and ending at the reception of the responding ultrasonic signal, and on knowledge about the predetermined time delay and the length(s) of the initiating and responding ultrasonic signals. The initiator may be associated with the mobile platform and the respondent with one of the beacons, or vice versa, or the originator and recipient may both be beacons.

A system according to one embodiment of the present invention includes a first set of modules preferably placed on the mobile platform and a second set of modules preferably placed on each of the beacons. The two sets of modules are communicatively coupled through ultrasonic signals and in some embodiments by RF signals also. Each set of modules includes an ultrasonic array coupled to a digital signal processor through an analog/digital converter. The ultrasonic array further includes at least one ultrasonic transceiver or transducer pair for transmitting and receiving ultrasonic signals. The digital signal processor controls the transmission and reception of the ultrasonic signals, including calculating signal arrival time and a figure-of-merit on the quality of a received ultrasonic signal. The first set of modules further includes a central processing unit coupled to the digital signal processor for implementing a position algorithm for determining the position of the mobile platform based on the two-way ultrasonic time-of-flight measurements.

The system can be self-calibrating to eliminate the need for manual survey equipment for determining the positions of the beacons. A method for self-calibrating the locations of the plurality of beacons comprises the steps of: (1) determining a set of inter-beacon distances using inter-beacon ultrasonic measurements; (2) setting a first beacon at an origin of a coordinate system; (3) setting a second beacon on one axis of the coordinate system and determining the coordinates of the second beacon based on the distance between the first beacon and the second beacon; (4) determining the coordinates of a third beacon based on the distances between the first beacon and the second beacon, between the second beacon and the third beacon, and between the third beacon and the first beacon, and based on a predetermined constraint on the

location of the third beacon; and (5) iteratively improving the determined locations of the plurality of beacons.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

5 Figure 1 is block diagram of an overview of a two-way ultrasonic positioning and navigation system 100 in accordance with one embodiment of the present invention. The system 100 includes a mobile platform P, and a number of beacons B_0 , B_1 , ..., and B_{N-1} , where N is an integer larger than one (i.e., at least two), and is preferably greater than two. The beacons B_0 , B_1 , ..., and B_{N-1} may be placed at
10 surveyed locations. Alternately, the beacons can be placed at arbitrary positions, which are automatically determined without user input during an initial system self-calibration procedure, described in more detail below. The system 100 performs two-way ultrasonic time-of-flight measurements to position or track the mobile platform P within a predetermined geographical range or service volume 101.

15 The number N of beacons B_0 , B_1 , ..., and B_{N-1} should be adequate to provide accurate positioning of the mobile platform P throughout the geographical range 101. In a two-dimensional (2D) implementation, assuming the ultrasonic signal propagation speed is known, the minimum number of beacons necessary for the positioning or navigation of the mobile platform P is two. However, this may result in
20 an ambiguity that is difficult to resolve. Hence, typically, the minimum number of beacons for a two-dimensional implementation is three when the beacons are placed in a non-collinear fashion. This idea is illustrated in Figure 7. Similarly, for a three-dimensional (3D) positioning or navigation system, the minimum number of beacons necessary is three, again with a geometric ambiguity that may be difficult to resolved
25 without additional knowledge or the use of a fourth (non-coplanar) beacon. In cases where the propagation speed of sound is not known precisely and is solved by using platform-to-beacon measurement results, the minimum number of beacons is four for 2D positioning/navigation systems, and is five for 3D positioning/navigation systems, respectively. In one embodiment of the present invention, beason-to-beacon
30 measurements (as explained in more detail below) are used to calculate the speed of sound. The beacons are preferably at fixed locations so that changes in the inter-becon

measurements are a consequence of the changes in the speed of sound in air. This measurements can be performed periodically (e.g. every 5 minutes) to update the speed of sound used by the positioning or navigation system.

5 Additionally, as a practical matter, in order to provide good accuracy one needs to ensure that the beacons are positioned to provide good geometry to facilitate an accurate position solution, increasing the requirements on the number of beacons. See Ray, P. K. and Mahajan, A., "Genetic Algorithms to obtain Optimal Location of Receivers in an Ultrasonic Position Estimation System," Submitted to *Robotics and Autonomous Systems*, January 2001. Also, additional beacons may be included on top
10 of the number deemed necessary for accuracy in order to provide system integrity and robustness against erroneous measurements or faulty equipment. If any of the beacons are not visible throughout the entire environment 101, more must be added to ensure that positioning accuracy is not degraded in any portions of the service volume 101.

15 Figure 1A is a block diagram illustrating a first set of modules 110 of the system 100 in accordance with an embodiment of the present invention. The first set of modules 110 is preferably placed on the mobile platform ("platform") P, and includes an ultrasonic array ("array") 111 for transmitting and receiving ultrasonic signals. The first set of modules 110 also preferably includes an analog to digital
20 signal converter (ADC) 112 coupled to the ultrasonic array 111 having one or more acoustic transducers or transceivers, a digital signal processor 113 coupled to the analog to digital converter 112, and a central processing unit (CPU) 114 coupled to the digital signal processor 113. The first set of modules further includes a memory unit 115 coupled to the CPU 114, and a user interface 116 also coupled to the CPU
25 114. When the system 100 is used to navigate the platform P, the first set of modules 110 further includes a vehicle odometry control and feedback sensor 117a, and a field programmable gate array (or DSP) 118 coupled between the sensor 117a and the CPU 114. The first set of modules 110 may further comprise a radio frequency data communication link 119 coupled to the digital signal processor 113 for
30 communicating with the beacons using radio frequency signals, as explained in more detail below. The first set of modules 110 may further include augmentation

navigation sensors 117b, such as one or more gyroscopes and accelerometers, for obtaining information in order to accurately model the movement of the mobil platform P.

Figure 1B is a block diagram illustrating a second set of modules 120 of the system 100 in accordance with an embodiment of the present invention. The second set of modules 120 is preferably placed on each of the N beacons $B_0, B_1, \dots,$ and B_{N-1} , and includes an ultrasonic array 121 having one or more acoustic transducers or transceivers for transmitting and receiving ultrasonic signals. The acoustic transducers or transceivers of the ultrasonic array 121 are coupled to a digital signal processor (DSP) 123 by an analog signal conditioning circuit 122. In an embodiment of the present invention where the speed of sound in air is determined by the system 100, as explained in more detail below, the second set of modules 120 further includes a temperature and/or relative humidity sensor 124 coupled to the DSP 123. The second set of modules 120 may further include a memory or data bank 128 and a radio frequency data communication link 129 also coupled to the digital signal processor 123 for communicating with the platform P and/or other beacons using radio frequency signals.

The analog signal conditioning circuit 112 or 122 converts digital signal into analog signals and conditions the resulting analog signal for transmission by the ultrasonic array 111 or 121, respectively. The analog signal conditioning circuit 112 or 122 also conditions and converts analog signals received from the ultrasonic array 111 or 121, respectively, into digital signals for processing by the DSP 113 or 123, respectively.

Figure 1C is a block diagram illustrating the ultrasonic array 111 or 121 (of the mobile system 110 or a beacon 120) according to one embodiment of the present invention. The ultrasonic array 111 or 121 consists of one or more ultrasonic transducers. There may be separate transducers for transmission and reception, or the transducers can be operated as transceivers. In Figure 1C, the ultrasonic array 111 or 121 includes four transceivers or transducer pairs, 1A, 1B, 2A and 2B, where 1A and 1B are placed back-to-back with each other, and 2A and 2B are placed back-to-back with each other and orthogonal to 1A and 1B, so that the four transducer pairs are

facing four different horizontal directions. Figure 1C only shows one of many possible configurations for the ultrasonic array 111 and 121, as the ultrasonic array 111 and 121 may include more or less transceivers or transducers that may be configured differently for different applications.

5 In many cases, an originator of an ultrasonic signal, which can be the platform or a beacon, does not possess knowledge of the relative direction of an intended recipient for the ultrasonic signal, and therefore does not know which transceiver or transducer to use to send the ultrasonic signal. One way of making sure that the ultrasonic signal will be received by the intended recipient is to broadcast out of all
10 of the transducer pairs in the array 111 or 121. When transmitting from multiple transducers in an array simultaneously, care needs to be taken to ensure that sufficient transducer beam separation exists to avoid signal-cancellation effects. As a result, often more than one measurement cycles are required. In a preferred embodiment of the present invention, the ultrasonic signal is broadcast from transceiver pair 1A and
15 1B at one time, and then broadcast from transceiver 2A and 2B at a later time.

 In some applications, the originator of the ultrasonic signal has rough knowledge about its location relative to the intended recipient array and thus will have knowledge of the optimal transducer(s) to transmit from in order to ensure successful link closure.

20 The transducers in the array 111 or 121 are coupled with the digital signal processor 113 or 123, through the analog signal conditioning circuits 112 or 122, respectively. The analog signal conditioning circuits 122 includes an analog to digital converter (ADC) 126 that converts any received signal to digital form for use by the digital signal processor 123. Circuits 122 also includes a digital to analog converter
25 127 for converting digital signals into analog signals to be sent to the transducer pairs in the ultrasonic array 121. Circuits 112 is configured similarly. The digital signal processor 113 or 123 is capable of controlling signal transmission and reception, including calculating signal arrival times and a figure-of-merit on the quality of each received signal. The digital signal processor 113 is further coupled to a CPU 114 that
30 implements a positioning/navigation algorithm as described below.

Figure 2 illustrates a 2-way time-of-flight measurement cycle 200 between an initiator and a respondent, according to one embodiment of the present invention. For ease of discussion, the initiator is assumed to be the platform P and the respondent is assumed to be one of the beacons, such as B_0 . However, only slight modification of the following discussion is needed if the initiator is one of the beacons and the respondent is the platform P or another beacon. In the 2-way time-of flight measurement cycle 200, as shown in Figure 2, the platform P transmits at least one initiating ultrasonic signal 210 having a signal duration T_s at time 0. Commensurate with the transmission of the ultrasonic signal 210, the platform P starts a timer at time $T_{start} = T_s$. Assuming the beacon B_0 successfully receives the ultrasonic signal 210 at time $T_{p,or}$, the beacon B_0 will, after a short fixed time delay T_d , respond back to the platform P by transmitting at least one responding ultrasonic signal 220 toward the platform P. The responding ultrasonic signal 220 may have the same or a different signal duration as the initiating ultrasonic signal 210. When multiple distinguishable ultrasonic signals are received by the same beacon at approximately the same time, the beacon internally computes a figure-of-merit for each received signal, determines which received signal has the largest figure of merit, and responds only to the received signal with the largest internally calculated figure-of-merit. Determining a figure-of-merit is discussed in more detail below. In one embodiment of the present invention, the ultrasonic array 121 on the beacon B_0 include multiple transceiver or transducer pairs, and one transceiver or transducer on the beacon will detect a signal before the others. The beacon B_0 will respond back to only the first arrival of an initiating ultrasonic signal, to mitigate effects of signal multipath. A signal multipath is caused by the ultrasonic signal hitting another object(s) and being reflected from that object(s) to the beacon B_0 .

Assuming that the responding ultrasonic signal 220 is successfully detected at the platform P, the timer reading (T_{STOP}) at the signal time-of-arrival is noted. The two-way time-of-flight can be calculated by subtracting from T_{STOP} the fixed time delay, the signal duration(s) and other (known in advance) processing delays. The two-way time-of-flight measurements are converted to a distance between the platform and the beacon B_0 by halving the two-way time-of-flight and multiplying the

resulting time-of-flight by the speed of sound in air. Typically, the above process repeats, whereby the platform P will, in turn, communicate with each of the other beacons in-view. In a further embodiment of this invention, the platform may at times signal to multiple beacons, as explained in more detail below. In this case, special
 5 care is taken to ensure that the initiating or responding ultrasonic signals do not cause excessive self-interference (which would prevent successful signal receptions), either at any beacons $B_0, B_1, \dots,$ and B_{N-1} or at the platform P.

The one-way time-of-flight measurement between the platform P and one of the beacons, such as B_0 , located respectively at (x_o, y_o, z_o) and (x_r, y_r, z_r) , is given by:

$$10 \quad \text{tof}_{or} = \frac{d_{or}}{c_{or}} = \frac{1}{c_{or}} \sqrt{(x_o - x_r)^2 + (y_o - y_r)^2 + (z_o - z_r)^2}$$

where c_{or} represents the average speed of sound along the path from the platform P to the beacon B_0 and d_{or} is the distance from the platform P to the beacon B_0 . The above expression assumes a three-dimensional application. In cases where the platform and all of the beacons are located in the same plane or approximately the same plane, the
 15 third coordinate z can be disregarded. Similarly, the one-way time-of-flight measurement from the beacon B_0 to the platform P is given by:

$$\text{tof}_{ro} = \frac{d_{ro}}{c_{ro}}$$

where $d_{ro} = d_{or}$ if the platform P is stationary or slow-moving, i.e., its speed is much smaller than the speed of sound in air. In the above expression, c_{ro} represents the
 20 average speed of sound along the path from the beacon B_0 to the platform P. The speed of sound in air can be calculated based readings from environmental sensors and known analytic expressions, or determined from the 2-way time-of-flight measurements among beacons or between the platform and beacons, or a combination of both.

25 Wind effects on the speed of sound are made less significant by using the two-way ultrasonic positioning/navigation system 100, as explained below. The speed of sound in air to a first-order approximation is given by the following expression:

$$c = c_0 \sqrt{1 + \frac{T}{273} + \vec{e}^T \cdot \vec{w}}$$

as stated in the literature by H. Wehn and P. Belanger, "Ultrasound-Based Robot Position Estimation," IEEE Transactions on Robotics and Estimation, Vol. 13, No. 5, October 1997. In the above equation, c is the speed of sound in the direction \vec{e} (which is a unit vector), T is the atmospheric temperature in Celsius, \vec{w} is a wind velocity vector, and c_0 is the speed of sound at temperature 0°C (which is approximately 331.45 m/s). If $v = |\vec{e}^T \cdot \vec{w}|$ is the magnitude of the wind velocity along

\vec{e} , and $\hat{c} = c_0 \sqrt{1 + \frac{T}{273}}$ is the nominal speed of sound, then the speed of sound in

the two opposite directions along \vec{e} are given by $\hat{c} + v$ and $\hat{c} - v$, as illustrated in Figure 3. The two respective one-way measurements should produce,

$$tof_+ = \frac{d}{\hat{c} + v} = \frac{d}{\hat{c}} \left(\frac{1}{1 + v/\hat{c}} \right) = \frac{d}{\hat{c}} + O((v/\hat{c}))$$

, and

$$tof_- = \frac{d}{\hat{c} - v} = \frac{d}{\hat{c}} \left(\frac{1}{1 - v/\hat{c}} \right) = \frac{d}{\hat{c}} + O((v/\hat{c}))$$

Thus, the timing error due to wind effects in a one-way system is proportional to v/\hat{c} , with the two one-way time-of-flight measurements in the system

$$\begin{aligned} 15 \quad tof_{+-} &= \frac{1}{2} \left(\frac{d}{\hat{c} + v} + \frac{d}{\hat{c} - v} \right) = \frac{d}{2} \left(\frac{2\hat{c}}{\hat{c}^2 - v^2} \right) \\ &= \frac{d}{\hat{c}} \left(\frac{\hat{c}^2}{\hat{c}^2 - v^2} \right) = \frac{d}{\hat{c}} \left(\frac{1}{1 - (v/\hat{c})^2} \right) = \frac{d}{\hat{c}} + O((v/\hat{c})^2) \end{aligned}$$

where the term $O((v/\hat{c})^2)$ represents the timing error resulting from the wind effects and it signifies that the error is proportional to $(v/\hat{c})^2$. Thus, the timing error in the two-way system 100 is proportional to $(v/\hat{c})^2$. Because, under normal conditions, $v \ll \hat{c}$, the two-way paradigm, represents a significant improvement in positioning accuracy and hence provide the foundation for an improved ranging and positioning system. n example illustrating this advantage is as follows:

$\hat{c} = 331.45$ m/s (nominal sound speed, neglecting wind)

$v = 10$ m/s (magnitude of wind velocity along path)

$d = 20$ m (actual distance)

$$10 \quad d_{\pm} = \hat{c} \times \text{tof}_{\pm} = 331.45 \times \frac{1}{2} \left(\frac{20}{331.45 + 10} + \frac{20}{331.45 - 10} \right) = 20.0182m$$

$$d_{+} = \hat{c} \times \text{tof}_{+} = 331.45 \times \left(\frac{20}{331.45 + 10} \right) = 19.4143m$$

$$d_{-} = \hat{c} \times \text{tof}_{-} = 331.45 \times \left(\frac{20}{331.45 - 10} \right) = 20.622m$$

Clearly, the two-way measured distance d_{\pm} is more accurate than either the one-way measured distance d_{+} along the blow of the wind or one-way measured distance d_{-} against the blow of the wind. This example assumes that the platform P remains stationary or is slow moving during the two-way measurement cycle, so that the geometry between the beacon and the platform remains roughly constant over a fraction of a second in practical applications to make this approach effective. For faster moving mobil platforms, the movement during the measurement cycle needs to be modeled as part of the navigation algorithm.

In one embodiment of the present invention, the system 100 includes multiple beacons, and each ultrasonic signal has only one intended recipient. In order to facilitate this mode of operation, the ultrasonic signals are coded using, for example,

signal modulation. At least one unique code is associated with each beacon and, in some cases, with the platform itself. Well-known modulation techniques include frequency shift keying, phase shift keying or pulse positioning (on-off keying). The ultrasonic transducers/transceivers and associated tuning circuitry are configured to provide adequate bandwidth to support the signal design. In a preferred embodiment, the ultrasonic signal is coded with information using binary phase shift keying (BPSK). In particular, two basis functions are defined as:

$$s_1(t) = \cos(\omega t) \quad 0 \leq t \leq T_c$$

$$s_2(t) = \cos(\omega t + \pi) = -s_1(t)$$

10

Because of the antipodal relationship between these two functions, only a single basis function is necessary in practice. The form of the transmitted signal is:

$$s(t) = \sum_{p=0}^{N-1} g_p s_1(t - pT_c) U(t - pT_c) \quad 0 \leq t \leq NT_c$$

$$U(\tau) = \begin{cases} 1 & 0 \leq \tau \leq T_c \\ 0 & \text{otherwise} \end{cases}$$

Thus, the total pulse duration is the product NT_c , where N is the length of the binary sequence $\{g_p\}$ and T_c is the duration of each chip (i.e., each item in the binary sequence). In the above expression, the sequence $\{g_p\}$ is chosen to provide good signal correlation properties as is well known to those skilled in the art of signal processing. As an example, Gold Codes of length 127 have been utilized for this purpose. These codes provide good autocorrelation properties for time-of-flight detection as well as low cross-correlations among different signal sequences, and facilitate unique identification of signal recipients. A sampled matched filter has been implemented in the analog signal conditioning circuits 112/122 for the purposes of real-time signal detection. The output value of the matched filter is compared to a threshold to detect signal arrival and the precise time-of-arrival is computed by finding a local maximum value of the matched filter output over a short interval following the initial threshold crossing. Also, the maximum value of the

25

corresponding matched filter can be used as a signal detection figure-of-merit for discriminating between simultaneous arrivals (in different array faces) and/or computing an expected measurement error. Mathematically, the resulting signal from the sampled matched filter is:

$$5 \quad z[m] = \sum_{p=0}^{N-1} g_p \sum_{k=0}^{N_c-1} c[k] r[m + (p - N)N_c + k + 1]$$

where,

$$m = 1, 2, 3, \dots$$

$$\Delta t = \text{sample time interval}$$

$$N_c = \# \text{ samples per chip} = T_c / \Delta t$$

$$10 \quad r[m] = \text{sampled received signal} = r((m-1)\Delta t), r(t)=0 \text{ for } t < 0$$

$$c[k] = \cos(\omega(k-1)\Delta t)$$

$$z[m] = \text{sampled matched filter output at } t = (m-1)\Delta t.$$

A block diagram illustrating a correlator circuit for detecting an input signal is shown in Figure 4. If no gain control is utilized in the analog/digital converter 112/122 or the signal is not hard-limited, the amplitude of the matched filter output may scale with the amplitude of the received signal. To mitigate this effect, the algorithm can be slightly modified to normalize the matched filter output by the autocorrelations of the received and ideal signals,

20

$$z[m] = \frac{\sum_{p=0}^{N-1} g_p \sum_{k=0}^{N_c-1} c[k] r[m + (p - N)N_c + k + 1]}{\left(N \sum_{j=0}^{N_c-1} c[j]^2 \right)^{1/2} \left(\sum_{j=0}^{NN_c-1} r[m - j]^2 \right)^{1/2}}$$

25 The number of identification codes assigned to each ultrasonic array 111 or 121 depends on the number and orientation of the transducers in the array, and more generally on the array architecture and how the transducers are used. In one embodiment, each array 111 or 121 includes four faces each having a transducer pair (see Figure 1C). Transmitted ultrasonic beam patterns from neighboring faces 30 overlap, and two distinct device identification codes are associated with each

ultrasonic array (beacon or the platform). Each transmitted signal specifies via the code the intended recipient so that each ultrasonic array listens for only those codes unique to itself. When responding to a detected signal, the array will in turn respond back with a corresponding code, also unique to itself. The use of unique codes helps
5 avoid false detections. In another embodiment of this invention, the intended recipient of a transmitted signal are communicated using a RF signal accompanying the ultrasonic signal.

Because the transmitted ultrasonic beam patterns of neighboring transducers overlap, simultaneous transmission from adjacent transducers is not preferred due to
10 possible signal cancellation effects resulting from differences in signal phases. Thus, only transducers on opposing faces of the ultrasonic array (or a "transmitting pair") are allowed to transmit simultaneously. Each pair of opposing transducers in a ultrasonic array is assigned a distinct code, and at least two distinct codes are assigned to each
15 ultrasonic array to allow for the identification of each of the two transducer pairs of the array. At the initiator of a measurement cycle, typically no information is available to the initiator concerning which face (or face-pair) is optimally aligned with a desired recipient, and therefore the initiator transmits a sequence of signals from each transmitting pair of the initiator's ultrasonic array. Furthermore, each signal in the sequence of transmitted signals is encoded with a different one of the
20 identification codes associated with the intended recipient. In some cases, each signal may also include the code associated with the transmitting pair that transmits the signal. The intended recipient responds only to a first reception of a coded signal that is above the detection threshold to minimize the effect of multipath transmission of the transmitted signals, because in many cases it is possible for a multipath signal to
25 possess larger signal energy than the direct path signal. By processing only the first coded signal to be received that is above the detection threshold, the system ignores (and thus effectively filters out) multipath signals that travel by indirect paths from the transmitting device to the recipient device.

At the recipient, receive channels from different array faces are processed
30 independently but in parallel. When multiple signals arrive closely in time, the device

responds to the signal received from the face having the best reception (e.g., the face with the largest correlation value or figure of merit).

In one embodiment of the present invention, the platform P polls the beacons $B_0, B_1, \dots,$ and B_N in turn to determine its position with respect to the beacons $B_0, B_1,$
5 $\dots,$ and B_{N-1} . A polling scheme involving a platform P and three beacons $B_0, B_1,$ and B_2 according to one embodiment of the present invention is illustrated in Figure 5. In this polling scheme, each beacon is signaled twice in succession from the two transmitting pairs in the array 111 positioned on the platform P. As shown in figure 5, the platform P transmits ("TX: C_0 "), from transmitting pair 1A, 1B, an initiating
10 ultrasonic signal with signal code C_0 identifying beacon B_0 . This signal is received and recognized ("RX: C_0 ") by beacon B_0 , and in response, beacon B_0 transmits a responding ultrasonic signal coded with signal code C_2 after a predetermined time delay from receiving the signal C_0 , as illustrated in Figure 2. The responding ultrasonic signal C_2 is preferably transmitted from the same transceiver of the array
15 121 that received the signal C_0 . This signal is received and recognized by the platform P ("RX: C_2 "). Shortly thereafter, the platform P transmits, from transmitting pair 2A, 2B, another initiating ultrasonic signal with signal code C_1 also identifying beacon B_0 . The signal C_1 is also received and recognized by the beacon B_0 , and in response, beacon B_0 transmits another responding ultrasonic signal coded C_3 after the
20 predetermined time delay from receiving the signal C_1 , as illustrated in Figure 2. The responding signal C_3 is preferably transmitted from the same transceiver or transducer pair of the array 121 that received the signal C_1 . This signal is received and recognized by the platform P ("RX: C_3 ").

The platform P continues to poll the other beacons using the same process.
25 Some signals may not be received by the intended recipient. For example, as shown in Figure 5, the platform P transmits an initiating ultrasonic signal with signal code C_4 identifying beacon B_1 . This signal, which is transmitted by transmitting pair 1A, 1B, is not received by beacon B_1 . The platform P then transmits another initiating ultrasonic signal with signal code C_5 also identifying beacon B_1 , this time from
30 transmitting pairs 2A and 2B. The signal C_5 is received and recognized by the beacon B_1 ("RX: C_5 "), and in response, beacon B_1 transmits a responding ultrasonic signal

coded C_7 after the predetermined time delay from receiving the signal C_5 , as illustrated in Figure 2. The responding signal C_7 is preferably transmitted from the same transceiver or transducer pair of the array 121 that received the signal C_5 . This signal is received and recognized by the platform P ("RX: C_7 ").

5 Still referring to Figure 5, the platform P continues to transmit an initiating ultrasonic signal with signal code C_8 identifying beacon B_2 . The ultrasonic signal with signal code C_8 is transmitted by platform P from transmitting pair 1A, 1B. This signal is received and recognized ("RX: C_8 ") by beacon B_2 , and in response, beacon B_2 transmits a responding ultrasonic signal coded with signal code C_{10} after a
10 predetermined time delay from receiving the signal C_8 , as illustrated in Figure 2. The responding signal C_{10} is preferably transmitted from the same transceiver or transducer pair of the array 121 that received the signal C_8 . This signal is received and recognized by the platform P ("RX: C_{10} "). Shortly thereafter, the platform P transmits from transmitting pair 2A, 2B another initiating ultrasonic signal with signal code C_9 ,
15 also identifying beacon B_2 . The signal C_9 is also received and recognized by the beacon B_2 , and in response, beacon B_2 transmits another responding ultrasonic signal coded C_{11} after the predetermined time delay from receiving the signal C_9 , as illustrated in Figure 2. The responding signal C_{11} is preferably transmitted from the same transceiver of the array 121 that received the signal C_9 . In the example shown in
20 Figure 5, this signal is not received by the platform P. There are many reasons why a signal may not be received by the intended recipient, including insufficient transmission amplitude, insufficient signal sensitivity at the recipient, multipath or noise.

 In an alternative embodiment of the present invention, the system 100 includes
25 radio frequency (RF) devices establishing an RF data communication link 119/129 between the platform and each beacon and/or among the beacons. The RF link provides an independent data communication channel between the platform and beacons (and/or beacon-to-beacon). The identification of a recipient for an ultrasonic signal can be communicated using the radio frequency data communication link
30 119/129 rather than by the encoding of the ultrasonic signal itself. One way of using the RF link to identify a recipient of a transmitted ultrasonic signal is to transmit an

RF trigger signal identifying the recipient together with the ultrasonic signal. The recipient, upon receiving the ultrasonic signal, also transmits an RF acknowledge signal to indicate that the ultrasonic signal is successfully received. Because the RF signals travel at the speed of light (roughly 3 orders of magnitude faster than the speed of sound in air), they arrive at the recipient essentially instantaneously relative to the accompanying ultrasonic signals.

Figures 6A and 6B illustrate a polling scheme using the RF link 119/129 for a system 100 having one platform P and four beacons B_0 , B_1 , B_2 , and B_4 . In this example, it is assumed that the initiator does not possess knowledge of what transducer face in its array 111/121 is most optimal for transmission, so that each recipient is signaled twice in succession, as in the previous scheme with the RF link unavailable. As shown in Figures 6A and 6B, the platform P transmits (“TX”) an initiating ultrasonic signal C_0 from transmitting pair 1A and 1B of the array 111. At approximately the same time, the platform P also transmits through the RF link 119 either one RF trigger signal (“RFT”) identifying both beacon B_0 and beacon B_2 as the recipients for the ultrasonic signal C_0 , or two RF trigger signals, one identifying beacon B_0 and another identifying beacon B_2 . The RFT identifying beacon B_2 is received at beacon B_2 , triggering B_2 to accept the ultrasonic signal C_0 that arrives shortly after. After a predetermined delay, the beacon B_2 transmits a responding ultrasonic signal C_6 from the same transceiver in the array 121 that received the ultrasonic signal C_0 . At approximately the same time, the beacon B_2 also transmits through the RF link 129 an RF acknowledge signal (“RFA”) identifying the beacon B_2 as the initiator and the platform P as the recipient for the ultrasonic signal C_6 .

The RFT identifying B_0 is received at the beacon B_0 , triggering B_0 to accept the ultrasonic signal C_0 that arrives shortly after the RFT. After a predetermined delay, the beacon B_0 transmits a responding ultrasonic signal C_2 from the same transceiver in the array 121 positioned on the beacon B_0 that received the ultrasonic signal C_0 . At approximately the same time, the beacon B_0 also transmits through the RF link 129 an RF acknowledge signal (“RFA”) identifying the beacon B_0 as the initiator and the platform P as the recipient for the ultrasonic signal C_2 . The responding ultrasonic signal arrives at the platform P shortly after the corresponding

RFA arrives at the platform. Since the RFA from B_2 is received before the RFA from B_0 is received, the platform knows that the signal C_6 is from B_2 and the signal C_2 is from B_0 because C_6 is received before C_0 .

As illustrated in Figures 6A and 6B, this process is repeated again for beacons B_0 and B_2 , except that this time, the initiating ultrasonic signal C_1 is transmitted from the transmitting pair 2A and 2B. Next, the platform goes ahead to poll the other two beacons also twice, once by transmitting the initiating ultrasonic signals from transmitting pairs 1A and 1B, and once from transmitting pairs 2A and 2B. In the example shown in Figure 6A, some of these signals are not received at the intended recipients (e.g., because of the direction of transmission or signal strength of the transmitted signals).

In addition to providing identification of the initiator and/or the recipient(s) for a respective transmission, the trigger message may also provide information regarding additional fixed turn-around delays that are unique to each recipient. In some implementations, the “fixed” turn-around delay of each distinct beacon is adjustable or programmable, enabling the system to adjust the turn-around delays so as to minimize the probability of overlapping signal returns. Overlapping signal returns are highly undesirable because they result in increased receiver noise and may also prohibit successful signal detection back at the initiator. Simultaneous (or nearly simultaneous) signaling to multiple recipients is feasible in cases where a priori knowledge of expected time-of-flight is available, which is often the case shortly after system startup, when the positioning or navigation system 100 has reached steady state performance, and the approximate relative positions of the platform and the beacons have already been determined.

Another use of the RF link is to add a power-saving feature to the system 100, whereby the beacons can be remotely switched to a low-power sleep mode when the system 100 is not operational.

Although some signals are not received by their intended recipients, in many cases (with or without the RF link), both polling trials targeted at the same beacon result in signal detection at the beacon(s) and the platform. Frequently, when both attempts to signal a particular intended recipient are successful, one of the two

resulting distance measurements between the platform and beacon is possibly erroneous due to signal multipath. Normally, the erroneous measurement corresponds to a longer path and hence a longer time-of-flight and is therefore easy to recognize. The positioning or navigation algorithm in the system 100 detects and ignores these
5 erroneous measurements. More specifically, the system is configured to use only the shorter of the two measurements in cases where both two-way measurements are successful. This procedure can be optimized when the optimal face to transmit from is known. Depending on the array design and accuracy requirements, it may also be necessary to take into consideration the geometric difference between the transducer
10 face centers and the reference position of the respective beacon (typically the center of the array head).

In a further embodiment of this invention, the CPU 114 may be distributed between the system 100 and a remote station, where data is communicated between the platform and the remote station using radio frequency devices. In one version of
15 this embodiment, the initializing ultrasonic signals are sent from the beacons, with the platform responding to the beacons by sending a responding ultrasonic signal for each received initializing ultrasonic signal. The beacons transmit the resulting distance measurements to the remote station, which in turn computes the location of the platform. The resulting location information is then sent to the platform for use in
20 navigation of the platform.

In one embodiment of the present invention, the coordinate frame for the platform P is a local coordinate system tied to the beacon locations, rather than an absolute coordinate frame tied to an external reference (such as absolute latitude and longitude). Algorithms for trilateration or tracking (e.g. Kalman Filtering) well
25 known to those in the art are used to solve for the position of the platform. The equations to be solved are inherently nonlinear. One algorithm for positioning of a static platform can be found in an article by Figueroa, F. and Mahajan, A., "A Robust Navigation System for Autonomous Vehicles using Ultrasonics," *Control Engineering Practice*, Vol. 2, No. 1, pp. 49-54, February, 1992. This algorithm
30 includes the speed of sound as an unknown to be solved for by using the time-of-flight measurements. In matrix form,

$$5 \quad \begin{bmatrix} (\text{tof}_0/2)^2 \\ (\text{tof}_1/2)^2 \\ \vdots \\ (\text{tof}_{N-1}/2)^2 \end{bmatrix} = \begin{bmatrix} 1 & r_0^2 & 2x_0 & 2y_0 & 2z_0 \\ 1 & r_1^2 & 2x_1 & 2y_1 & 2z_1 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & r_{N-1}^2 & 2x_{N-1} & 2y_{N-1} & 2z_{N-1} \end{bmatrix} \begin{bmatrix} p^2/c^2 \\ 1/c^2 \\ -u/c^2 \\ -v/c^2 \\ -w/c^2 \end{bmatrix} \quad (1)$$

where:

tof_i = two-way time-of-flight to i th beacon, where $i = 0, 1, \dots, N-1$;

(x_i, y_i, z_i) = coordinates of the i th beacon;

$$10 \quad r_i = x_i^2 + y_i^2 + z_i^2;$$

(u, v, w) = coordinates of the platform P;

c = speed of sound; and

$$p = u^2 + v^2 + w^2.$$

The above formulation is sub-optimal due to the fact that it contains a
 15 redundant unknown (p), but is nonetheless simple, which is easily solved as long as at
 least 5 measurements from five different beacons are available and geometric
 singularity conditions, such as all beacons lying in a same plane for 3D
 implementation or on a same line for 2D implementation, are avoided. This model
 assumes that the measurements are taken while the platform is stationary or slow
 20 moving, the average speed of sound is constant amongst the various lines-of-sight,
 and measurement biases (e.g., the fixed time delays at the recipient devices) have been
 removed from the time-of-flight values.

Alternatively, a common approach to positioning a static or slow-moving
 platform involves an iterative least-squares adjustment resulting from linearizing a
 25 nonlinear set of equations, as in the following

$$30 \quad \begin{bmatrix} \text{tof}_0/2 \\ \text{tof}_1/2 \\ \vdots \\ \text{tof}_{N-1}/2 \end{bmatrix} = \begin{bmatrix} \sqrt{(u-x_0)^2 + (v-y_0)^2 + (w-z_0)^2} \\ \sqrt{(u-x_1)^2 + (v-y_1)^2 + (w-z_1)^2} \\ \vdots \\ \sqrt{(u-x_{N-1})^2 + (v-y_{N-1})^2 + (w-z_{N-1})^2} \end{bmatrix}$$

where an initial approximate position (u, v, w) of the platform P is assumed to be known. The idea is to successively compute improved estimates of the platform position (u+Δu,v+Δv,w+Δw) and the speed of sound c + Δc, using the following set of equations:

5
$$\Delta \vec{m} = A \Delta \vec{x}$$

or,

10
$$\begin{bmatrix} \Delta m_0 \\ \Delta m_1 \\ \vdots \\ \vdots \\ \Delta m_{n-1} \end{bmatrix} = \begin{bmatrix} s \frac{(u-x_0)}{d_0} & s \frac{(v-y_0)}{d_0} & s \frac{(w-z_0)}{d_0} & -\frac{d_0}{c} \\ s \frac{(u-x_1)}{d_1} & s \frac{(v-y_1)}{d_1} & s \frac{(w-z_1)}{d_1} & -\frac{d_1}{c} \\ \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots \\ s \frac{(u-x_{n-1})}{d_{n-1}} & s \frac{(v-y_{n-1})}{d_{n-1}} & s \frac{(w-z_{n-1})}{d_{n-1}} & -\frac{d_{n-1}}{c} \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta v \\ \Delta w \\ \Delta c \end{bmatrix} \quad (2)$$

15 where:

$$\Delta m_i = c \left(\frac{tof_i}{2} \right) - d_i$$

is the ith measurement residual, i = 0, 1, ..., n-1, where c is the current approximate speed of sound estimate, which can be calculated initially based on current temperature and possible relative humidity readings, and n is the number of beacons for which measurements are available;

20

$\Delta \vec{m} = (\Delta m_0 \quad \Delta m_1 \quad \dots \quad \Delta m_{n-1})^T$ is a vector of measurement residuals;

$(u, v, w)^T$ is the current platform position estimate;

$(\Delta u, \Delta v, \Delta w)^T$ is the platform position differential correction;

Δc is the speed of sound differential correction;

25 $\Delta \vec{x} = (\Delta u \quad \Delta v \quad \Delta w \quad \Delta c)^T$ is a vector of the unknowns; and

$$5 \quad A = \begin{bmatrix} s \frac{(u-x_0)}{d_0} & s \frac{(v-y_0)}{d_0} & s \frac{(w-z_0)}{d_0} & -\frac{d_0}{c} \\ s \frac{(u-x_1)}{d_1} & s \frac{(v-y_1)}{d_1} & s \frac{(w-z_1)}{d_1} & -\frac{d_1}{c} \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ s \frac{(u-x_{n-1})}{d_{n-1}} & s \frac{(v-y_{n-1})}{d_{n-1}} & s \frac{(w-z_{n-1})}{d_{n-1}} & -\frac{d_{n-1}}{c} \end{bmatrix}$$

10 is a matrix of measurement partial derivatives.

A weighted least-squares solution to the above Equation (2) is given by

$$\Delta \bar{x} = (A^T W A)^{-1} A^T W \bar{r}$$

where $\bar{r} = (\bar{r}_1 \quad \bar{r}_2 \quad \dots \quad \bar{r}_n)$, and W is a weighting matrix having diagonal
 15 elements $\sigma_0^2 \quad \sigma_1^2 \quad \dots \quad \sigma_{n-1}^2$ with all other elements being zero, where

σ_i^2 is an error variance for the *i*th measurement. The error variance represents the
 uncertainty of the measurement and is assumed known in advance. In cases where the
 measurement variance is not known, W may be taken to identity (i.e. all σ_i^2 equal to
 one), resulting in an unweighted solution. The improved estimates of platform
 20 position and speed of sound scaling factor are computed as described and provides the
 maximum likelihood estimate of these parameters. The procedure can be iterated
 (i.e., take the improved estimate of $(u+\Delta u, v+\Delta v, w+\Delta w)$ as the new approximate
 position and repeat) until sufficient convergence (or divergence in a pathological case)
 is detected. An advantage of the iterative techniques using equation (2) over the
 25 former linear method of equation (1) is that the iterative method tends to provide more
 accurate position and speed of sound estimates. However, this iterative approach
 requires an approximate initial position and speed of sound for convergence. In some

cases, such estimates may be unavailable and Equation (1) can be solved first to provide this initial estimate for subsequent iteration using Equation (2).

In an alternative embodiment of the invention, the speed of sound is assumed known. For example, the speed of sound may be computed from environmental
 5 readings or from inter-beacon measurements. In this case, the unknowns are only the platform position coordinates (u, v, w) . Accordingly, the row dimension of Equations (1) or (2) is reduced by one.

In order to accurately utilize ultrasonic time-of-flight measurements when the platform is mobile, it is necessary that the platform either moves very slowly, so that
 10 movement during each measurement epoch can be ignored, [See C.-C. Tsai, "A Localization System of a Mobile Robot by Fusing Dead-Reckoning and Ultrasonic Measurements", IEEE Transactions on Instrumentation and Measurement, Vol. 47, No. 5, October 1998], or the movement of the platform during each measurement epoch is accurately modeled. The "movement modeling" requirement relates to the
 15 fact that the speed of sound in air is slow enough that in some situations platform movement during the time the signal travels from the beacon to the platform (and/or platform to beacon) can be significant. Therefore, system 100, when used in navigation applications involving wheeled mobile platforms, further includes a vehicle odometry control/feedback sensor 117a, and a field programmable gate array
 20 (or DSP) 118 coupled between the sensor 117a and the CPU 114. The system 100 may further include additional navigation sensors for improved accuracy, such as gyroscope(s) and accelerometer(s) 117b. These components provide a measure (or permits estimation) of translation and rotation of the platform P during the measurement cycle. The measurement model within the tracking algorithm is then
 25 augmented appropriately, such as,

$$\begin{aligned} \frac{tof_i}{2} = \frac{1}{c} & \left(\sqrt{(u_{TX} - x_i)^2 + (v_{TX} - y_i)^2 + (w_{TX} - z_i)^2} \right. \\ & \left. + \sqrt{(u_{RX} - x_i)^2 + (v_{RX} - y_i)^2 + (w_{RX} - z_i)^2} \right) \end{aligned}$$

where $(u_{TX}, v_{TX}, w_{TX})^T$ and $(u_{RX}, v_{RX}, w_{RX})^T$ are the positions of the platform at the time of transmission to the *i*th beacon and the time of reception from the *i*th beacon, respectively. The platform positions $(u_{TX}, v_{TX}, w_{TX})^T$ and

$(u_{RX}, v_{RX}, w_{RX})^T$ may be related to the platform position at the time the

5 measurement is incorporated using either measurements or estimates of vehicle orientation and velocity. Care must be taken to ensure that adequate computational consistency of coordinate frames (body frame, earth-referenced inertial frame and beacon-relative frame, etc.) is maintained when integrating sensors in a local navigation system.

10 Figure 8 is a navigation data flow diagram for a navigation system using the two-way ultrasonic positioning techniques of the present invention. Navigation algorithms for tracking mobile platforms are well known. See for example L. Kleeman, "Optimal estimation of position and heading for mobile robots using ultrasonic beacons and dead-reckoning", IEEE International Conference on Robotics and Automation, Nice, France, pp 2582-2587, May 10-15 1992 and J. J. Leonard and
15 H. F. Durrant-Whyte. Mobile robot localization by tracking geometric beacons. IEEE Trans. Robotics and Automation, 7(3): 376-382, June 1991.

The positioning and navigation algorithms discussed above assume that the ultrasonic array on the platform array is located at a position reference point
20 corresponding to the platform coordinates. If this is not the case, the measurement equations should be modified to include the body frame transformation from the ultrasonic array to the positioning reference point (e.g. from an array antenna on the top of a wheeled mobile robot to the center of its axle). This transformation requires knowledge of vehicle orientation, and the navigation-tracking algorithm includes
25 estimation of the necessary parameters (e.g. vehicle heading in a 2D application).

Furthermore, it is understood that in practice erroneous measurements are likely to occur, such as those due to hardware anomalies and multipath. As a result, successful implementation of the described positioning and navigation algorithms should include some form of statistical outlier testing to detect and eliminate these

erroneous measurements. Such tests are well known to those in the art and include externally Studentized residual tests and Kalman Filter innovations tests.

In a further embodiment of the present invention, inter-platform measurements and/or environmental readings such as temperature and possibly relative humidity readings are used to further enhance the speed of sound calculation. In the case that the speed of sound is not expected to vary spatially, (i.e. no large temperature gradients along the signal path), its average value can be modeled as a time-varying random constant. So at any given instant in time, the speed of sound in air is assumed constant throughout the service volume, but is expected to vary (slowly) in time. The variation can be computed from temperature/environmental readings or estimated based on, for example, platform-beacon or inter-beacon measurements. For the case that the system is self-calibrating, as explained in more detail below, the speed of sound during calibration is fixed using temperature and possibly relative humidity readings, but is solved for during subsequent operation. In one embodiment, the beacons are configured to periodically signal each other to measure the time-of-flight between the various beacon pairs. This information is then used to compute the current speed of sound. Since the inter-beacon distances are fixed, speed of sound computations based on inter-beacon time-of-flight measurements are typically very accurate.

In another embodiment, temperature and/or humidity sensors are incorporated into the platform and/or each of the beacons. The CPU in the platform or in a remote device receives the temperature information from all the beacons and the platform, and uses the temperature information to construct a spatially varying sound speed-scaling map. One approach is to compute a temperature dependent factor at each

device (platform and beacon), $f(T_k) = \sqrt{1 + \frac{T_k}{273}}$, where T_k is the temperature in

Celsius at the k^{th} device. A modified measurement model is then used to compensate for spacial sound speed changes,

$$tof_{or} = \frac{2}{(f(T_o) + f(T_r)) \times c} \sqrt{(x_o - x_r)^2 + (y_o - y_r)^2 + (z_o - z_r)^2}$$

where c represents an (overall) average sound speed value. The above model assumes that temperature changes linearly along the path, which is likely violated in any real environment. However, the error in making this approximation is small enough in many operating environments.

5 To eliminate the need for manual survey equipment for determining the positions of the beacons, the system can be self-calibrating. Typically self-calibration is only done once at initial installation, before training and using the system 100, unless the system 100 is later reconfigured. The self-calibration procedure determines the location of the beacons in a single local coordinate system. The self-calibration
10 procedure of a local navigation system is simplified when all beacons are capable of ranging to each other. One approach to the self-calibration problem (for a two-dimensional case) can be found in E. LeMaster and S. Rock, Self-Calibration of Pseudolite Arrays Using Self-Differencing Transceivers, Institute of Navigation GPS-99 Conference, Nashville, Tennessee, September 1999, which discusses a radio-
15 frequency based ranging system using GPS-like signals.

In one embodiment of the present invention, inter-beacon measurements are used collectively to construct a relative coordinate system for subsequent positioning or navigation. First, all possible inter-beacon measurements are taken. Successful inter-beacon measurements require that the two beacons participating in a
20 measurement cycle 200 possess line-of-sight visibility and are within range of one-another. Improved accuracy is expected incorporates platform-beacon measurements from various locations in the service volume are incorporated. Note that the self-calibration discussion that follows assumes a 2D implementation. Extensions to 3D require only slight modification of these procedures. Also, the discussion assumes that
25 the measurements are in terms of distance rather than time-of-flight, so that the conversion of signal time-of-flight to distance has already been completed.

Given only the distances between the beacons, the solution for the locations or coordinates of the beacons in a coordinate frame is not unique unless the arrangement of the beacons is constrained in some way. In one embodiment of the present
30 invention, the N beacons B_0, B_1, \dots, B_{N-1} are first placed at various fixed locations throughout the service volume subject to the following constraints:

The first 3 beacons B_0 , B_1 , and B_2 installed should be capable of measuring to each other and be in an arrangement that is not close to collinear (i.e. the first three beacons are within range and possess line-of-sight of each other, and not lying on or near a single line). Moreover, the arrangement of B_0 - B_1 - B_2 should be
 5 counterclockwise (i.e., if one is standing at beacon B_0 and looking toward B_1 , B_2 should lie on the left).

- (1) Additional beacons B_3, B_4, \dots, B_{N-1} are installed such that any beacon B_k has visibility to at least 3 other beacons of the set B_0, B_1, \dots, B_{k-1} that are themselves not close to a collinear arrangement.
- 10 (2) Enough beacons are installed to provide adequate solution geometry throughout the service volume, preferably with redundancy for system robustness. In one embodiment of the present invention, the number of beacons is at least 4.

Figure 9 illustrate a self-calibration procedure 900, according to one
 15 embodiment of the present invention. The self-calibration procedure 900 involves an iterative adjustment, requiring an initial condition that is subsequently improved with iteration. In one embodiment of the present invention, after the beacons are placed subject to the above constraint (step 910) and the inter-beacon measurements are done to determine a set of inter-beacon distances (step 920), B_0 is initially fixed as the
 20 origin of a coordinate frame for the system 100 (step 930), or B_0 has coordinates (0,0) in a 2D implementation. The direction from B_0 to B_1 initially defines the x-axis of the coordinate system (step 940). Therefore, B_1 initially has coordinates $(d_{01}, 0)$, where d_{01} is the distance between beacons B_0 and B_1 , as determined by the inter-beacon measurements between the two beacons. The initial location of beacon B_2 is then
 25 determined by the law of cosines (step 950), i.e., $B_2 = (x_2, y_2)$,

$$\text{where } x_2 = \frac{d_{01}^2 + d_{02}^2 - d_{12}^2}{2d_{01}} \text{ and } y_2 = \sqrt{d_{02}^2 - x_2^2}, \text{ with } d_{02} \text{ and } d_{12} \text{ being the}$$

measured distances between B_2 and, respectively, B_0 and B_1 . The y-coordinate of beacon B_2 is assumed positive due to the restriction that the beacon arrangement B_0 - B_1 - B_2 are counterclockwise. The coordinates of all other beacons are determined

likewise (step 960). For example, the coordinates of beacon B_k is determined after the locations of the beacons B_0, B_1, \dots, B_{k-1} are known.

Having determined the initial locations of the beacons, the exact locations of the beacons are iteratively improved (step 970). In one embodiment of the present invention, the Moore-Penrose pseudo-inverse method is used in the iteration process as described below. Each individual distance measurement d_{ij} represents the distance between two beacons B_i and B_j , such that

$$d_{ij} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} .$$

The available measurements M are collected and arranged in vector form. The beacon coordinates are also arranged in a state vector having $2N$ elements:

$$\vec{x} = (x_0, y_0, x_1, y_1, \dots, x_{N-1}, y_{N-1})^T ,$$

and the correction to the beacon coordinates are arranged in a state correction vector

$$\Delta \vec{x} = (\Delta x_0, \Delta y_0, \Delta x_1, \Delta y_1, \dots, \Delta x_{N-1}, \Delta y_{N-1})^T .$$

The matrix equation for the coordinates correction is

$$\Delta \vec{d} = A \Delta \vec{x} ,$$

where $\Delta \vec{d}$ is a vector of M measurement residuals,

$$\Delta d_k = d_{ij} - \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} ,$$

and the k th row of the M by $2N$ matrix A has only four non-zero elements,

$$A_{k,2i} = (x_i - x_j) / d_{ij}$$

$$A_{k,2i+1} = (y_i - y_j) / d_{ij}$$

$$A_{k,2j} = -(x_i - x_j) / d_{ij} = -A_{k,2i}$$

$$A_{k,2j+1} = -(y_i - y_j) / d_{ij} = -A_{k,2i+1}$$

So the matrix A has a rank of at most $2N-3$ and is sparse, with relatively few non-zero elements. The state correction $\Delta \vec{x}$ is calculated as

$$\Delta \vec{x} = A^+ \Delta \vec{d},$$

where A^+ is the Moore-Penrose pseudo-inverse of A . Efficient methods of computing the Moore-Penrose pseudo-inverse of a sparse matrix are well known to those in the art of numerical analysis. The iteration can be continued until sufficient convergence is detected (e.g., by monitoring the norm of the state correction $\|\Delta \vec{x}\|$), or until divergence is detected in the pathological case (e.g. too many iterations as a result of not enough valid measurements). The method automatically compensates for the fact that the matrix equation is rank-deficient.

In an alternative embodiment of the present invention, platform-beacon measurements are taken at various locations throughout the service volume for improved accuracy. In this case, the vector of unknowns expands to include the coordinates of the platform at each of these locations where the measurements are taken. In yet other embodiments of the present invention, geometrical and/or statistical tests are included to help eliminate erroneous measurements expected in practice.

Overall, the self-calibration procedure as discussed above is relatively straightforward, except that special care must be taken to resolve ambiguities and geometrical singularities (or poor conditioning) that can arise in practice. Also, convergence difficulties can arise if a poor initial condition is chosen, due to the nonlinear nature of the problem. The accuracy with which the beacon coordinates are known or calculated limits the overall positioning accuracy of the platform during operation of the system. A self-calibrating system is inherently less accurate than a system in which the beacon locations are accurately surveyed. Two factors that limit the accuracy of the self-calibration, and which can result in "dilution of precision" of platform position measurements, are the relative geometry of the beacons and the accuracy of the ranging measurements. It is the responsibility of the system installer (e.g., the user) to ensure that the system enjoys "good geometry," by placing sufficiently many beacons in the environment at favorable locations. For instance, the

beacons should be placed at locations so that the mobile platform not only has a direct signaling path to at least four beacons at all positions within the allowed range of platform positions, but also the directions of the signal paths between the platform and the four beacons must be separated by at least a specified minimum angle (e.g., 20
5 degrees) at all possible platform locations. If it is not possible to meet these requirements using only four beacons, then the system should include one or more additional beacons so that there are always four beacons among the set of beacons in the system that meet these requirements for all possible positions of the mobile platform.

10 Other important factors affecting the resulting positioning or navigation accuracy include unknown platform characteristics and unknown local temperature and possibly relative humidity conditions, which result in uncertainty in the measurement model, including uncertainty in determining the local speed of sound and uncalibrated body frame biases. Signal processing errors and uncertainties
15 concerning signal propagation time through the circuitry in the platform and beacons also reduce the accuracy of the self-calibration process and determination of the platform position. To the extent that the accuracy of the positioning system depends on the use of augmenting sensors, such as gyroscopes, accelerometers and wheel sensors, for determining the direction and speed of movement of the mobile platform,
20 the accuracy of such sensors may limit the accuracy of the positioning system. Wheel slippage on the mobile platform, due to environmental conditions, may also reduce positioning accuracy.

WHAT IS CLAIMED IS:

- 1 1. A method of operating a positioning system having a plurality of objects each
2 configured to transmit and receive ultrasonic signals, comprising
3 transmitting an initiating ultrasonic signal from a first one of the plurality of
4 objects, the initiating ultrasonic signal including a code identifying a second one of
5 the plurality of objects for responding to the initiating ultrasonic signal;
6 transmitting a responding ultrasonic signal from the second one of the plurality
7 of objects;
8 receiving the responding ultrasonic signal at the first one of the plurality of
9 objects; and
10 determining a distance between the first one and the second one of the
11 plurality of objects based on a time period starting at the transmission of the initiating
12 ultrasonic signal and ending at the reception of the responding ultrasonic signal.
- 1 2. The method of claim 1 wherein the responding ultrasonic signal is transmitted
2 after a predetermined time delay from a reception of the initiating ultrasonic signal at
3 the second one of the plurality of objects.
- 1 3. The method of claim 2 wherein the responding ultrasonic signal is transmitted
2 in a direction from which the initiating ultrasonic signal is received.
- 1 4. The method of claim 1 wherein the initiating ultrasonic signal is received
2 among a plurality of ultrasonic signals and is selected out of the plurality of ultrasonic
3 signals based on a calculated figure-of-merit for each of the plurality of ultrasonic
4 signals.
- 1 5. The method of claim 1 wherein the responding ultrasonic signal is encoded to
2 identify the object from which the responding ultrasonic signal is sent.

1 6. A method of operating a positioning system having a plurality of objects each
2 configured to transmit and receive ultrasonic signals, comprising
3 transmitting an initiating ultrasonic signal from a first one of the plurality of
4 objects, the initiating ultrasonic signal being accompanied by a radio frequency signal
5 identifying a second one of the plurality of objects intended for receiving the initiating
6 ultrasonic signal;
7 transmitting a responding ultrasonic signal from the second one of the plurality
8 of object;
9 receiving the responding ultrasonic signal at first one of the plurality of object;
10 and
11 determining a distance between the first one and the second one of the
12 plurality of objects based on a time period starting at the transmission of said
13 initiating ultrasonic signal and ending at the reception of said responding ultrasonic
14 signal.

1 7. The method of claim 6 wherein the second one of the plurality of objects
2 transmits the responding ultrasonic signal after a time delay from receiving the
3 initiating ultrasonic signal that follows the radio frequency signal identifying the
4 second one of the plurality of objects.

1 8. The method of claim 7, wherein the radio frequency signal accompanying the
2 ultrasonic signal further include information for the time delay.

1 9. The method of claim 6 wherein the responding ultrasonic signal is transmitted
2 in a direction from which the initiating ultrasonic signal is received.

1 10. The method of claim 6 wherein the responding ultrasonic signal is
2 accompanied by a radio frequency signal identifying object from which the
3 responding ultrasonic signal is sent.

1 11. An ultrasonic positioning system, comprising:
2 a plurality of objects each configured to transmit and receive ultrasonic
3 signals, a number of the plurality of objects being greater than 2;
4 a first ultrasonic array positioned on a first one of the plurality of objects and
5 configured to transmit initiating ultrasonic signals, each initiating ultrasonic signals
6 including a code that identifies another one of the plurality of objects for responding
7 to the initiating ultrasonic signal;
8 a second ultrasonic array positioned on a second one of the plurality of objects
9 and configured to respond to the initiating ultrasonic signal coded to identify the
10 second one of the plurality of objects by transmitting a responding ultrasonic signal;
11 and
12 wherein the first ultrasonic array is configured to receive the responding
13 ultrasonic signal, and is coupled to a timer that records a time period between the
14 transmission of the initiating ultrasonic signal and reception of the responding
15 ultrasonic signal.

1 12. The system of claim 11, wherein the second ultrasonic array include a plurality
2 of ultrasonic transceivers facing different directions, and the responding ultrasonic
3 signal is transmitted from a ultrasonic transceiver that received the initiating
4 ultrasonic signal.

1 13. The system of claim 11, wherein the responding ultrasonic signal is encoded
2 to identify the object from which the responding ultrasonic signal is sent.

1 14. The system of claim 11, wherein said second ultrasonic array positioned is
2 programed to respond to the initiating ultrasonic signal identifying the second one of
3 the plurality of objects by transmitting a responding ultrasonic signal after a
4 predetermined time delay from receiving the initiating ultrasonic signal identifying the
5 second one of the plurality of objects.

1 15. The system of claim 11, further comprising:
2 a processor positioned on the first one of the plurality of objects, and
3 configured to calculate a distance between the first one and the second one of the
4 plurality of objects based on the time period recorded by the timer and the speed of
5 sound.

1 16. The system of claim 15, further comprising:
2 temperature and humidity sensors coupled to the processor.

1 17. The system of claim 15 wherein the first one of the plurality of objects is a
2 mobile platform to be positioned and the second one of the plurality of objects is one
3 of a plurality of beacons at fixed locations.

1 18. The system of claim 17 wherein the speed of sound is determined by inter-
2 beacon ultrasonic measurements

1 19. An ultrasonic positioning system, comprising:
2 a plurality of objects each configured to transmit and receive ultrasonic
3 signals;
4 a first ultrasonic array positioned on a first one of the plurality of objects and
5 configured to transmit initiating ultrasonic signals;
6 a radio transmitter positioned on the first one of the plurality of objects and
7 configured to transmit a radio frequency signal with each initiating ultrasonic signal to
8 identify another one of the plurality of objects intended for responding to the initiating
9 ultrasonic signal;
10 a radio receiver positioned each of the plurality of objects;
11 a second ultrasonic array positioned on a second one of the plurality of objects
12 and configured to respond to the initiating ultrasonic signal following a received radio
13 frequency signal identifying the second one of the plurality of objects; and
14 wherein the first ultrasonic array is configured to receive the responding
15 ultrasonic signal, and is coupled to a timer that records a time period between the

1 transmission of the initiating ultrasonic signal and the reception of the responding
2 ultrasonic signal.

1 20. The system of claim 19, further comprising a radio transmitter positioned the
2 second one of the plurality of objects, and configured to transmit a radio frequency
3 signal identifying the second object with the responding ultrasonic signal.

1 21. The system of claim 19 wherein the ultrasonic array on the second one of the
2 plurality of objects transmits a responding ultrasonic signal after a time delay from
3 receiving the initiating ultrasonic signal following a radio frequency signal identifying
4 the second one of the plurality of objects.

1 22. The system of claim 21 wherein the radio frequency signal further includes
2 information of the time delay.

1 23. The system of claim 19, wherein the first one of the plurality of objects is a
2 mobile platform to be positioned and the second one of the plurality of objects is one
3 of a plurality of beacons at fixed locations.

1 24. A method for calibrating a positioning system having a plurality of beacons,
2 comprising
3 placing the beacons in or around a service volume according to a set of
4 predetermined constraints;
5 determining a set of inter-beacon distances using inter-beacon 2-way
6 ultrasonic measurements;
7 setting the origin of a coordinate frame at a first beacon;
8 setting one axis of the coordinate frame along the direction from the first
9 beacon and a second beacon;
10 determining initial coordinates of the second beacon based on the distance
11 between the first beacon and the second beacon;

1 determining initial coordinates of a third beacon based on the distances
2 between the first beacon and the second beacon, between the second beacon and the
3 third beacon, and between the third beacon and the first beacon, and based on the
4 predetermined constraints.

1 25. The method of claim 18, further comprising:
2 iteratively improving the initial coordinates to obtain final coordinates for the
3 beacons.
