ABSTRACT
A method estimates parameters for a self-energized brake mechanism having a moving part, a brake pad, a brake disc, a caliper, and a wedge profile. The method includes the following acts: applying the same actuator force to the brake mechanism and simultaneously to a dynamical model of the brake mechanism; calculating deviations based on measured state variables of the brake mechanism and simulated state variables of the dynamical model; and producing the estimated parameters by online minimization. A device is provided for executing the method.

PARAMETER ESTIMATION METHOD FOR SELF-ENERGIZED BRAKE MECHANISM

CROSS-REFERENCE TO RELATED APPLICATIONS

BACKGROUND AND SUMMARY OF THE INVENTION

The present invention relates to a parameter estimation method for a self-energized brake mechanism, and a device for executing such a method.

With conventional disc brake mechanisms the frictional brake force has no feedback to the actuator force or the clamping force. This means that the mechanism is not capable of determining any relation between the clamping force and the friction force. However, in case of self-amplified wedge brakes, where one part of the actuation energy is generated from the friction force, the friction coefficient can be reconstructed because the friction force has a direct feedback to the actuator movement.

In conventional commercial vehicle brake systems, the control feedback is the pressure which has a good relation to the clamping force. In this case, the value of an air gap between a brake pad and a brake disc influences the relation only marginally, so it is taken into consideration via threshold pressure. In self-amplifying brake mechanisms, the air gap between the brake pad and the brake disc has a more significant influence so its value is also useful information for a brake controller.

With self energized wedge brakes, considering the cost optimal realization, the friction force cannot be measured effectively in direct ways, moreover, the clamping force, being the analogous signal to the brake pressure of current brakes, is also not always measured by sensors. However, the friction coefficient is one of the most important parameters (a disturbance signal) of the system since it determines the magnitude of the self-amplification as well as being a further factor between the clamping force and the friction force. Thus the friction coefficient needs to be reconstructed from the other measured signals.

In the case of the electro-mechanical brake systems, the actuator position can be easily measured (e.g. as a motor position), which has a certain correlation with the clamping force. However, this correlation contains a new uncertainty, namely the air gap between a brake pad and a brake disc. This disturbance signal should also be reconstructed in order to adjust low brake force levels accurately if there is no direct clamping force measurement.

WO 2007/073927 A1 describes a method for determining the friction value of a disc brake, in particular of self-energizing disc brakes. The determination of the friction value is carried out mathematically on the basis of the following variables: motor current for the application and retraction directions; idle current; wedge angle; transmission constant and clamping force.

WO 2005/036121 A1 shows a self-energizing electromechanical disc brake comprising a rotatable brake disc and an electric actuator that generates an actuating force acting on a friction lining via a wedge system against the brake disc. Also provided is a device for detecting the moment of friction, which comprises first means for measuring the friction force and second means for detecting the force perpendicular to the brake disc, or first means for detecting the force of the actuator and second means for detecting the force perpendicular to the brake disc.

These solutions for friction coefficient estimation calculate the estimate based on static relations and on the assumption that the static load of the actuator can be separated from the dynamic load in practice as well.

Methods for estimating a torque/force exerted by a load against an actuator driven by an electric motor against the load are described in US 2007/0085414 A1. A first method includes measuring motor current of the electric motor and measuring a position/angular speed of the actuator and includes calculating the torque/force exerted by the load against the actuator using at least a difference between a calculated motor torque/force and a calculated actuator-experienced torque/force. The effect of the load is a “Disturbance Torque” calculated as an “Observed Disturbance Torque” and can be mathematically converted and then used as an “Observed Disturbance Force” by a controller to compute an “Input Voltage” to the electric motor to control the brake. A second method includes measuring input voltage of the electric motor instead of measuring motor current, and a third method includes measuring both motor current and input voltage. The actuator is an automotive electromechanical brake caliper. The methods use mathematical models of the actuator. The mathematical models are mathematical models of the mechanical aspects of the electromechanical actuator. Estimating the actuator load can be a disadvantage due to time consuming calculation time.

In view of the above, it is an object of the present invention to provide an improved parameter estimation method for a self-energized brake mechanism. Another object of the present invention is to provide an improved device for executing such a method.

According to the present invention, this object is achieved with a method for estimating parameters for a self-energized brake mechanism having a moving part, a brake pad, a brake disc, a caliper, and a wedge profile, the method including the following steps: applying the same actuator force to the brake mechanism and simultaneously to a dynamical model of the brake mechanism; calculating deviations based on measured state variables of the brake mechanism and simulated state variables of the dynamical model; and producing the estimated parameters by online minimization.

According to the present invention, this object is achieved with a device for parameter estimation for a self-energized brake mechanism having a moving part, a brake pad, a brake disc, a caliper, and a wedge profile, the device including: a brake mechanism with measuring device for state variables; a dynamical model for calculating simulated state variables; a deviation unit for comparing the measured state variables and the simulated state variables; and a minimization unit for providing estimated parameter values, wherein inputs of the brake mechanism and the dynamical model are connected in parallel and outputs of the minimization unit are connected with the dynamical model for feedback.

The estimation of the parameters of a self-amplifying brake system uses the properties of the self-energized brake system and does not contain any intermediate step for estimating the actuator load. Therefore, the method of the present invention is capable of covering any stationary or transient situation and saves calculation time.

The method is based on the dynamical model of the system. The same actuator force input to the dynamical model as to
the real brake mechanism is applied simultaneously. Therefore, only one input value is needed.

At least the position of the moving part is measured, and optionally the speed thereof; otherwise the actuator speed is reconstructed from the measured position. A calculation of deviation norms based on the measured and simulated state variables is executed.

The parameters of the model, to which the system is sensitive like friction coefficient and air gap, are adjusted, which provides the main output of the estimated parameters in order to minimize the deviation norm. The estimated parameters are fed back to the dynamical model in order to obtain an optimized output.

It is a parameter identification method which can be executed in the brake controller online in real-time. Furthermore, the method can be applied for non self-amplifying brakes as well as for estimation of the air gap only.

Other objects, advantages and novel features of the present invention will become apparent from the following detailed description of one or more preferred embodiments when considered in conjunction with the accompanying drawings.

**BRIEF DESCRIPTION OF THE DRAWINGS**

FIG. 1 shows a first exemplary schematic embodiment of a device for executing a parameter estimation method for a self-energized brake mechanism according to the invention;

FIG. 2 illustrates an exemplary simplified dynamic model of a wedge brake mechanism; and

FIG. 3 shows a second exemplary schematic embodiment of the device for executing the parameter estimation method according to the present invention.

**DETAILED DESCRIPTION OF THE DRAWINGS**

FIG. 1 shows a first exemplary schematic embodiment of a device 10 for executing a parameter estimation method for a self-energized brake mechanism. The device 10 includes, a brake mechanism 6, a dynamical model 7 of the brake mechanism 6, a deviation unit 8 and an online minimization unit 9. An input 6in of the brake mechanism 6 and an input 7in of the dynamical model 7 are connected in parallel and receive the same actuator force $F_x$ (or torque). An output 6out of the brake mechanism 6 and an output 7out of the dynamical model 7 are connected to the inputs of the deviation unit 8. An output of the deviation unit 8 is connected to an input 9 in of the minimization unit 9. An output 9out1 and another output 9out2 of the minimization unit 9 are connected to the dynamical model 7.

The dynamical model 7 of the brake mechanism 6 is calculated in parallel with the operation of the actual device; i.e., the brake mechanism 6. The dynamical model 7 receives the same actuator force $F_x$ (or torque) that is applied to the input 6in of the brake mechanism 6. So, the dynamical model 7 should produce the same (simulated) state variable values 12 on its output 7out as measured on the real brake mechanism 6.

The measured state variables 11 are available at the output 6out of the brake mechanism 6.

The measured state variables 11 and the simulated state variables 12 are fed to the deviation unit 8. The deviation unit 8 calculates a deviation between the simulated state variables 12 and the measured state variables 11. The deviation is caused by the uncertain parameters of the model, which are the friction coefficient $\mu$ and the air gap $\delta$ in this case. This means that the amount of the error has a relationship with the uncertain parameters which can be readjusted based on the magnitude and the behavior of the error. This error deviation is fed to the input 9in of the minimization unit 9. The online minimization unit 9 realizes this functionality and determines the parameter setting of the dynamical model 7 for the next execution step based on the deviation in the current execution step.

As an exemplified model of a wedge brake mechanism, the dynamical model 6 has to use a simplified dynamic model that can be evaluated in real-time. This dynamic model is shown in FIG. 2 together with a coordinate system $x, y$, wherein the $x$-direction is parallel to the moving direction of a moving element 1 with a brake pad 5 and the $y$-direction is perpendicular to the $x$-direction.

An actuator force $F_x$ acts on the moving element 1 of the system. The moving element 1 represents the actuator path together with the brake pad 5. The moving element 1 is connected to a caliper 3 through a wedge profile 4. The moving element 1 includes the brake pad 5, which acts on a brake disc 2. This example shows the brake disc 2 rotating in $x$-direction with a speed $V_x$. The brake force is produced between the moving element 1 and the brake disc 2 after an air gap $\delta$ has been reduced and eliminated by a movement $\Delta y$ of the moving element 1 created by the actuator force $F_x$. The necessary variables to be measured are the actuator position and the actuator force as an input (based on the currents of the actuator).

In this system two significant parameters can be defined to which the model is sensitive and which are uncertain and not measurable. These parameters are the friction coefficient $\mu$ and the air gap $\delta$ between the disc 2 and the brake pad 5.

The dynamical model 7 (see FIG. 1) can be described by the following state equation:

$$\begin{bmatrix}
x
\end{bmatrix} = \begin{bmatrix}
f_1(x)
n_2(x, d)
\end{bmatrix} + \begin{bmatrix}
g_1
\end{bmatrix} \mu$$

where the state and input coordinate functions are as follows:

$$f_1(x) = v_x,$$

$$f_2(x, d) = \frac{(k_0 x \tan \theta + k_0 x_x \tan \theta_x - \delta) \mu \cos \phi - \sin \phi}{m},$$

$$g_1 = 0,$$

$$g_2 = \frac{1}{m \cos \phi}.$$  

The state vector includes the position and the speed of the moving element 1:

$$x = \begin{bmatrix}
x_0
v_x
\end{bmatrix}$$

The input vector includes the actuating force only:

$$u = [F_x].$$

The disturbance vector comprises the two uncertain time dependent parameters, namely the friction coefficient $\mu$ and the air gap $\delta$. 

Finally, the rest of the variables in the coordinate equations are the parameters of the model as follows: damping coefficient $k_0$, of the caliper $3$, reduced stiffness $s_0$ of the caliper $3$, wedge angle $\Phi_a$, actuator force angle of attack $\Phi_{a_{act}}$, and the mass $m$ of the moving element $1$.

The simulated state variables $X_{s_m}$, $V_{s_m}$ are then compared to the measured ones and a relative deviation is formed as follows:

$$e_{v_m} = \frac{v_{s_m} - v_{m}}{v_{m}},$$

$$e_{x_m} = \frac{x_{s_m} - x_{m}}{x_{m}}.$$

In the example, the speed of the moving element $1$ is not measured, just the position. Then, the speed can be reconstructed from it (e.g., by derivation, by a PLL filter, etc.). Of course, if the speed is available from measurement, then it can/has to be used in the above deviation norms.

Finally, a summed weighted deviation is calculated:

$$e_{\text{sum}} = w_{v_m} e_{v_m} + w_{x_m} e_{x_m}.$$

Based on the sum deviation there are many possibilities for the online minimization step to produce estimations for the disturbance signals, namely the friction coefficient $\mu$ and the air gap $\delta$. Some examples are the gradient method or the simplex method. Another simple example where these estimates are changed by a proportional and an integral portion of the sum deviation is as follows:

$$v_{\text{out}} = -(P_{v_m} e_{v_m} + I_{v_m} \int e_{v_m} dt) + v_{m},$$

$$\delta_{\text{out}} = -(P_{\delta_m} e_{\delta_m} + I_{\delta_m} \int e_{\delta_m} dt) + \delta_{m}.$$

In this case $P$ and $I$ are the minimization parameters which can influence the estimation performance. However, the simultaneous adjustment of these two parameters cannot always provide optimal performance.

A solution for this problem can be if the two parameters are adjusted alternately in time, which means that one of the two uncertain parameters is constant during the estimation of the other one. The alternation can be time based or conditional based. If it is time based, the estimation is switched in each time step from the first parameter to the second.

The conditional switching means that the actual parameter to be estimated can be selected based on its effect in the actual condition. For example, if the brake disc $2$ is stopped, the friction force is zero and it does not affect the actuation. So in this case only the air gap $\delta$ should be estimated. But if the brake disc $2$ rotates, the air gap $\delta$ parameter could be constant and the friction coefficient $\mu$ can be adjusted based on the error.

A second solution can use the dependency of the friction coefficient $\mu$ on the air gap $\delta$. It means that in the air gap $\delta$ the estimated friction coefficient $\mu$ will be zero because there is no contact between the brake pad $5$ and the brake disc $2$. In this way, the air gap $\delta$ can be calculated from the actuator position value when the estimated friction value jumps up from zero (see FIG. 3).

FIG. 3 shows a second exemplary schematic embodiment of the device $10$ for executing the parameter estimation method according to the present invention. The input $6in_1$ of the brake mechanism $6$ and the input $7in_1$ of the dynamical model are connected in parallel similar to the first embodiment shown in FIG. 1. The inputs $6in_1$ and $7in_1$ receive the actuator force $F_a$ (or the torque) simultaneously.

Output $7out_1$ provides the simulated state variable $X_{s_m_{sim}}$ to an input $9in_1$ of the minimization unit $9$. Output $7out_2$ provides the simulated state variable $V_{s_m_{sim}}$ to an input $9in_1$ of the minimization unit $9$. The output $6out_1$ transmits the measured state variable $X_{s_m}$ to the deviation unit $8$ and to an input $9in_4$ of the minimization unit $9$. The deviation unit $8$ provides the measured state variable $V_{s_m_{meas}}$ and feeds it to an input $9in_3$ of the minimization unit $9$.

In this example, the minimization unit $9$ is shown by way of example only and not to be limiting.

The measured and simulated variables are processed in various functional units as mentioned above.

An estimated value of the air gap $\delta$ is provided at an output $9out_1$ and an estimated value of the friction coefficient $\mu$ is provided at another output $9out_2$. Both are fed back to the dynamical model $7$.

In a special case, when the system is not self-energized, i.e. the wedge angle $\Phi_a$ equals $90^\circ$, then the air gap $\delta$ can only be estimated.

The main characteristics of the present invention are as follows:

An estimation of the parameters of self-energizing brake systems:

- based on the dynamical model of the system, providing the same actuator force input to the dynamical model as to the real brake mechanism, measuring at least the position of the moving part, and optionally the speed thereof; otherwise the actuator speed is reconstructed from the measured position, calculation of deviation norms based on the measured and simulated state variables, adjusting the parameters of the model, to which the system is sensitive like friction coefficient and air gap, which provides the main output of the estimated parameters in order to minimize the deviation norm, feeding back the estimated parameters to the dynamical model:

- The method is capable to cover any stationary or transient situation

It is a parameter identification method which can be executed in the brake controller online in real-time. The method can be applied for non self-energizing brakes as well as for estimation of the air gap only.

The foregoing disclosure has been set forth merely to illustrate the invention and is not intended to be limiting. Since modifications of the disclosed embodiments incorporating the spirit and substance of the invention may occur to persons skilled in the art, the invention should be construed to include everything within the scope of the appended claims and equivalents thereof.

What is claimed is:

1. A method for estimating parameters for a self-energized brake mechanism having a moving part, a brake pad, a brake disc, a caliper, and a wedge profile, the method comprising the acts of:
   applying a same actuator force to the brake mechanism and simultaneously to a dynamical model of the brake mechanism;
   calculating deviations based on measured state variables of the brake mechanism and simulated state variables of the dynamical model; and
   producing the estimated parameters by online minimization,
   wherein
   the parameters are a friction coefficient and an air gap of the brake pad and the brake disc,
   the act of calculating deviations comprises the acts of:
       calculating relative deviations:
   \[
   e_u = \frac{v_{max} - v_{sim}}{v_{max}},
   \]
   \[
   e_x = \frac{x_{max} - x_{sim}}{x_{max}},
   \]
   and calculating a summed weighted deviation:
   \[
   e = (w_x e_x + w_u e_u),
   \]
   the dynamical model is:
   \[
   \begin{bmatrix}
   x_0 \\
   \dot{x}_0
   \end{bmatrix} = \begin{bmatrix}
   f_1(x) \\
   f_2(x, d)
   \end{bmatrix} + \begin{bmatrix}
   g_1 \\
   g_2
   \end{bmatrix} u
   \]
   where state and input coordinate functions are as follows:
   \[
   f_1(x) = v_u,
   \]
   \[
   f_2(x, d) = \frac{(k_d v_u \sin \psi + s_d (x_u \tan \psi - \delta))(\mu \cos \psi - \sin \psi)}{m_1},
   \]
   \[
   g_1 = 0,
   \]
   \[
   g_2 = \frac{1}{m_1 \cos \psi}
   \]
   a deviation unit for comparing the one or more measured state variables and the one or more simulated state variables, wherein calculated relative deviations are determined in accordance with the equations:
   \[
   e_u = \frac{v_{max} - v_{sim}}{v_{max}},
   \]
   \[
   e_x = \frac{x_{max} - x_{sim}}{x_{max}},
   \]
   and a summed weighted deviation is calculated in accordance with the equation:
   \[
   e = (w_x e_x + w_u e_u); \text{ and}
   \]
   a minimization unit for providing estimated parameter values, wherein minimization is provided by a proportional and integral portion of the sum deviation:
   \[
   u_{new} = (P e_x + I e_u),
   \]
   \[
   \delta_{new} = -(P \delta_x + I \delta_u),
   \]
   wherein inputs of the brake mechanism and the dynamical model are connected in parallel and outputs of the minimization unit are connected with the dynamical model for feedback,
   wherein the parameters are a friction coefficient and an air gap of the brake pad and the brake disc.

2. The method according to claim 1, wherein one of: (a) a speed of the moving part is measured, and (b) a position of the moving part is measured and the speed is reconstructed from the measured position.

3. The method according to claim 1, wherein the online minimization is provided by at least one of a gradient method and a simplex method.

4. The method according to claim 1, wherein the estimated parameters are fed back to the dynamical model.

5. A device for parameter estimation for a self-energized brake mechanism having a moving part, a brake pad, a brake disc, a caliper, and a wedge profile, the device comprising:
   a brake mechanism with one or more measuring devices for state variables;
   a dynamical model for calculating one or more simulated state variables, wherein the dynamical model is based on the equations:
   \[
   \begin{bmatrix}
   x_0 \\
   \dot{x}_0
   \end{bmatrix} = \begin{bmatrix}
   f_1(x) \\
   f_2(x, d)
   \end{bmatrix} + \begin{bmatrix}
   g_1 \\
   g_2
   \end{bmatrix} u
   \]
   where state and input coordinate functions are as follows:
   \[
   f_1(x) = v_u,
   \]
   \[
   f_2(x, d) = \frac{(k_d v_u \sin \psi + s_d (x_u \tan \psi - \delta))(\mu \cos \psi - \sin \psi)}{m_1},
   \]
   \[
   g_1 = 0,
   \]
   \[
   g_2 = \frac{1}{m_1 \cos \psi}
   \]
   a deviation unit for comparing the one or more measured state variables and the one or more simulated state variables, wherein calculated relative deviations are determined in accordance with the equations:
   \[
   e_u = \frac{v_{max} - v_{sim}}{v_{max}},
   \]
   \[
   e_x = \frac{x_{max} - x_{sim}}{x_{max}},
   \]
   and a summed weighted deviation is calculated in accordance with the equation:
   \[
   e = (w_x e_x + w_u e_u); \text{ and}
   \]
   a minimization unit for providing estimated parameter values, wherein minimization is provided by a proportional and integral portion of the sum deviation:
   \[
   u_{new} = (P e_x + I e_u),
   \]
   \[
   \delta_{new} = -(P \delta_x + I \delta_u),
   \]
   wherein inputs of the brake mechanism and the dynamical model are connected in parallel and outputs of the minimization unit are connected with the dynamical model for feedback,
   wherein the parameters are a friction coefficient and an air gap of the brake pad and the brake disc.
6. The device according to claim 5, wherein the brake mechanism comprises a reconstruction unit for reconstructing speed values from measured position values.

7. The device according to claim 6, wherein the reconstruction unit comprise one of a derivation unit and PLL-filters.

8. The device according to claim 5, wherein the device is part of a brake controller.
