(54) Title: CARBON DIOXIDE RECOVERY

(57) Abstract: Disclosed herein is a method and system for separating carbon dioxide (CO_2) from a C02 containing gas stream containing water vapor and additional impurities, for example, nitrogen, oxygen, sulfur oxides, nitrogen oxides, and mercury. The C02 is captured by subjecting the CO_2 gas feed stream to a temperature swing adsorption step. The temperature swing adsorption step comprises an adsorption step for producing a substantially dry carbon dioxide-depleted stream, and an adsorbent regeneration step comprising heating the adsorbent bed to produce a substantially water vapor-free carbon dioxide stream. Moisture from the gas stream containing CO_2 is optionally removed by pressure swing adsorption, temperature swing adsorption, membrane separation, or absorption prior to CO2 capture.

CARBON DIOXIDE RECOVERY

CROSS REFERENCE TO RELATED APPLICATIONS

              61/123,259 titled "Process For Carbon Dioxide Recovery", filed on April 07,
              2008 in the United States Patent and Trademark Office.

           2. The following patent application is incorporated herein in its entirety: Non-
10   provisional patent application number 12/419,513 titled "Carbon Dioxide
              Recovery", filed on 07 April, 2009 in the United States Patent and Trademark
              Office.

BACKGROUND
15

          The method and system disclosed herein relates to capturing carbon dioxide
(CO_2) from combustion sources such as flue gas of a power plant and making the CO_2
available for sequestration or other uses.

20   Emissions of greenhouse gases such as CO_2, if left unchecked, may potentially
affect climatic conditions. Conversion of fossil fuels such as coal and natural gas to
energy is a source of greenhouse gas emissions. Emissions of the greenhouse gases can
be reduced by various means such as increase in efficiency of the combustion process and
use of renewable energy such as wind and solar but the reduction in the emission of the
25   greenhouse gases required to stabilize the greenhouse gas levels cannot be achieved
without capturing a substantial part of the greenhouse gases at the source of the
greenhouse gas emissions during either the pre-combustion process or the post-
combustion process. Post-combustion capture of CO_2 from the flue gas of a power plant
or other streams such as the flue gas from a refinery involves use of a solvent, typically
30   an amine, which is regenerated using a part of the steam generated during the combustion
process. Pre-combustion capture of CO_2 involves chemical reaction of the fuel with air or

oxygen and then with steam to produce a mixture of carbon dioxide and hydrogen. The carbon dioxide is removed from this stream through a CO_2 capture process and hydrogen may be used as a fuel for power generation. If oxygen is used for combustion, a flue gas containing mainly carbon dioxide is produced which can be easily separated for

5   sequestration.

The post-combustion capture of CO_2 results in 9%-11% reduction in absolute efficiency for power generation and about 28-30% reduction in relative efficiency for a pulverized coal power plant as discussed by Ciferno (Ciferno, J., "A Feasibility Study of

10   Carbon Dioxide Capture from an Existing Coal-Fired Power Plant," paper presented at the Sixth Annual Conference on Carbon Capture and Sequestration, Pittsburgh, PA, May 2007.). A May 2007 NETL report (Carbon Sequestration Technology Roadmap and Program Plan - 2007, U.S. DOE National Energy Technology Laboratory (NETL), May 2007.) shows a 60-100% increase in cost of power generation for existing power plants

15   taking into account capital and operating costs for CO_2 separation and sequestration. Net power output from the power plant is also decreased by 30% or more. Means to significantly decrease the power and capital penalty associated with the post-combustion CO_2 capture are sought. For the post-combustion capture, the Department Of Energy (DOE) has a goal of less than 35% increase in power cost for 90% CO_2 capture.

20

Most studies dealing with the post-combustion CO_2 capture use amine or ammonia-based absorption processes for the removal of carbon dioxide from the flue gas. The absorption-based processes have drawbacks such as the significant capital requirements. The best amine based absorbents such as the hindered amines and amine

25   blends have an energy requirement in the range of 750-900 Kcal/kg (1,350-1,620 Btu/lb) of the CO_2 captured. Furthermore, amine-based processes require the use of specialty steel equipment and the associated capital investment because of the corrosive nature of amine and ammonia solutions in the presence of acidic gases and oxygen. This equipment represents a significant capital cost.

30

In contrast to the amine-based systems, the heats of adsorption of CO_2 on various

zeolite and carbon based adsorbents range between 140-240 kcal/kg or 252-432 Btu/lb (Valenzuela, D.P. and A.L Myers, "Adsorption Equilibrium Data Handbook," Prentice Hall, Englewood Cliffs, NJ, 1989.) which is about a fifth of the heat of absorption for the amine-based systems. There is an unmet need for practical adsorption systems that can take advantage of low heats of adsorption while providing high carbon dioxide yield and high recovery.

Temperature swing adsorption systems have been used extensively for applications such as air drying, natural gas drying, and water and CO_2 removal prior to cryogenic distillation of air. These systems typically remove less than 2% of impurities and the regeneration outlet stream containing the impurities is not of high purity. Also the typical temperature swing adsorption processes have adsorption times of the order of 4-12 hours. For feed CO_2 concentrations between 10-12% in the flue gas, these adsorption times would require extremely large adsorption beds. For example, assuming a working capacity of 12 weight% (difference in capacity between the adsorption and the regeneration steps), an adsorbent density of about 660 kgs/m^3 and an adsorption time of 4 hours, a plant processing 1000 tons/day of CO_2 in the feed would require about 8,000 m^3 (5.3 million kilograms) of the adsorbent, a size that makes the systems not practical for capturing carbon dioxide from combustion sources.

The method and system disclosed herein provides a solution for the efficient capture of CO_2 using a process based on a temperature and pressure swing adsorption cycles.

SUMMARY OF THE INVENTION

This summary is provided to introduce a selection of concepts in a simplified form that are further described in the detailed description of the invention. This summary is not intended to identify key or essential inventive concepts of the claimed subject matter, nor is it intended for determining the scope of the claimed subject matter.

The method and system disclosed herein addresses the above stated need for separating carbon dioxide (CO_2) from a gas stream containing water vapor and additional impurities. The method and system disclosed herein captures CO_2 using a process based on a temperature and pressure swing adsorption cycles. The gas is a flue gas from a coal-

5   fired power plant, a natural gas fired power plant, or a refinery.

High purity CO_2, i.e., CO_2 containing no more than about 10 percent by volume of impurities, is produced by subjecting a CO_2 gas stream to a temperature swing adsorption step. The temperature swing adsorption step comprises an adsorption step for

10   producing a substantially dry CO_2-depleted stream, and an adsorbent regeneration step comprising heating the adsorbent bed to produce a substantially water vapor-free CO_2 stream. Temperature in the temperature swing adsorption step during the adsorbent regeneration step is increased to about 80°C to 300°C. Duration of the temperature swing adsorption step is in a range of about 2 minutes to 60 minutes.

15

The adsorption is generally carried out in the gaseous phase at temperatures between 10°C and 80°C and at pressures in the range of about 1.07 to 40.0 bar absolute. The CO_2 concentration is in a range of about 3% to 60% by volume.

20   The impurities that are preferably removed from the CO_2 containing gas stream are selected from the group comprising, for example, nitrogen, oxygen, hydrocarbons, nitrogen oxides, sulfur oxides, mercury, and argon. The adsorption is conducted in a bed comprising an adsorbent material, which preferentially adsorbs or reacts with CO_2 in the gas stream.

25

In an embodiment, the impurities comprising, for example, moisture, hydrocarbons, nitrogen oxides, sulfur oxides, and mercury are removed prior to CO_2 adsorption. The moisture removal is performed using, for example, pressure swing adsorption, temperature swing adsorption, membrane separation, and absorption.

30   Duration of the pressure swing adsorption process is in a range of about 4 minutes to about 60 minutes and duration of the temperature swing adsorption process is in a range

of about 1 hour to 12.0 hours. The moisture content in the moisture removal step is reduced to a dew point of -40°C or below. Adsorbents, for example, activated carbon, carbon molecular sieves, zeolites such as 4A, 5A, 13X, NaY and CaX, metallorganic framework compounds, natural zeolites, modified natural and synthetic zeolites, modified

5   activated carbon, pillared clays, etc. are used for CO_2 adsorption. The CO_2-depleted stream from the CO_2 adsorption section is used for the regeneration of the moisture adsorption system.

In another embodiment, the feed containing moisture is sent directly to the CO_2
10   adsorption system wherein CO_2 from the feed is removed by activated carbon or by chemical reaction with sodium and potassium carbonates, amines or ionic liquids supported on a microporous support.

In both embodiments, the material containing CO_2 is regenerated by direct or
15   indirect heat transfer to produce a high purity CO_2 stream. Further CO_2 removal is performed by bed evacuation after heating. The CO_2 produced is further purified by a membrane process, a distillation process, an adsorption process, or a getter process to remove impurities comprising, for example, nitrogen, oxygen, argon, nitrogen oxides, sulfur oxides, and moisture. Part of the purified CO_2 can be used as a rinse in the CO_2
20   separation system. The method and system disclosed is effective for the removal of about 80% or higher amounts by volume of impurities from the CO_2 stream.

BRIEF DESCRIPTION OF THE DRAWINGS

25   The foregoing summary, as well as the following detailed description of the invention, is better understood when read in conjunction with the appended drawings. For the purpose of illustrating the invention, exemplary constructions of the invention are shown in the drawings. However, the invention is not limited to the specific methods and instrumentalities disclosed herein.

30

FIG. **1** illustrates an overall schematic of the carbon dioxide (CO₂) separation system for recovering high purity CO_2 from a feed stream containing CO_2.

FIGS. **2A-2D** exemplarily illustrate various configurations of the CO_2 separation system wherein moisture is optionally removed in a first separation unit followed by the capture of CO_2 by chemical reaction or adsorption in a second separation unit.

FIG. **3** exemplarily illustrates the configuration of a moisture adsorption system wherein the moisture and additional impurities, for example, hydrocarbons, sulfur oxides or nitrogen oxides, and mercury are removed by a combination of pressure and temperature swing adsorption.

FIG. **4** exemplarily illustrates the configuration of the CO_2 separation system wherein CO_2 is removed from the feed stream by adsorption or chemical reaction and is recovered by heating directly or indirectly by steam, hot water or a dry stream recovered from the CO_2 separation system.

DETAILED DESCRIPTION OF THE INVENTION

FIG. **1** illustrates an overall schematic of the carbon dioxide (CO₂) separation system **80** for recovering high purity CO_2 from a feed stream containing CO_2. The CO_2 is generated in a process **5** which could be a combustion process or another process that generates CO_2. If process **5** is a combustion process, an oxygen-enriched stream **10** can be optionally used during the combustion to improve combustion efficiency and to increase the concentration of CO_2 resulting from combustion. Using the heat-generated in process **5**, steam can be generated as stream **15**. A part of stream **15** can be taken as stream **20** and used in the CO_2 separation system **80** described later. The remaining part of stream **15** is taken off as stream **25** and can be used for other purposes, for example, for power generation or for the production of synthesis gas in unit **30**. Stream **35**, the low pressure stream or hot water in unit **30**, can be used in the CO_2 separation system **80** or can be sent to unit **5** for generating steam. A portion of electrical power generated in unit

30 can be sent to the CO_2 separation system **80** via line **45**. The remaining electrical power can be supplied to the end users such as the industrial and the residential customers through line **50**. The CO_2 containing stream such as the flue gas leaves process **5** as stream **55**.

After removing particulates, the stream **55** can be optionally sent to a feed conditioning unit **60** to remove impurities such as the oxides of nitrogen and sulfur, and mercury. The pressure of stream **55** containing residual sulfur and nitrogen oxides, mercury, nitrogen, oxygen and argon as the main impurities can be raised, if needed, by a fan or a blower **65** after unit **60**. If the CO_2 containing stream is from a chemical plant or a refinery or from a pre-combustion process, the CO_2 containing stream may contain additional impurities, for example, hydrogen, hydrocarbons, and carbon monoxide. For a coal or a natural gas fired power plant, the pressure of the flue gas will typically be raised to about between 1.07 bara to 1.34 bara. For the CO_2 stream generated in chemical or industrial processes, the pressure of the stream may be higher than 1.07-1.34 bara and may not have to be raised. In a gasification process where the fuel is gasified with air or oxygen, the pressure of the stream containing CO_2 may be several atmospheres and would not have to be raised. In the oxy-combustion process the flue gas may be recycled to the combustion system to increase the concentration of CO_2. After the removal of nitrogen oxides, sulfur oxides and mercury, and compression, the CO_2-containing stream is typically cooled to between near ambient temperature and 60°C prior to CO_2 capture. The flue gas cooling unit is not shown in FIG. **1**. Many power plants have systems for the removal of particulates, nitrogen oxides, and sulfur oxides. The systems may include selective catalytic reduction (SCR) for nitrogen oxides, electrostatic precipitators for the particulates, and wet scrubbers for sulfur oxides. Removal of particulates, nitrogen oxides, and sulfur oxides may not be necessary if stream **55** comes from a process such as partial oxidation or reforming.

The stream containing CO_2 leaves unit **65** as stream **70** and enters the CO_2 separation system **80**. The CO_2 separation system **80** contains at least one bed with a material that removes CO_2 from the feed stream by adsorption or chemical reaction. The

pressure of the bed ranges from about 1.07 bar absolute to about 40 bar absolute. Depending on the material used for CO_2 capture, the CO_2 separation system **80** may contain additional units for the removal of other components in the feed stream such as moisture, residual sulfur oxides, nitrogen oxides, and mercury. If a material such as

5   activated carbon, or potassium carbonate, an amine or an ionic liquid on a microporous support is used for CO_2 removal, the moisture in the feed stream **70** may not have to be removed and the CO_2-depleted stream **85** exiting the CO_2 separation system **80** would contain most of the moisture contained in stream **70**. In this case, stream **85** can be vented. However, if a material such as a zeolite is used for CO_2 capture by adsorption, the

10   moisture from the feed stream **70** would have to be removed prior to CO_2 adsorption and the CO_2-depleted stream **85** would be relatively dry. In this case, a part or all of stream **85**, stream **95**, can be used for regenerating the moisture adsorption system **79**.

The CO_2 captured in the CO_2 separation system **80** is recovered by desorbing the

15   CO_2. The energy for CO_2 desorption can be provided by stream **20**, stream **35** or electricity represented by stream **45**. Other external sources of heat and electricity can also be used for regenerating the material in the CO_2 separation system **80**. The adsorbent or reactant can be contacted directly by steam or condensate if the material is able to handle it. The material in the CO_2 separation system **80** can also be regenerated by dry

20   CO_2 depleted stream **85** which is heated with steam, hot water or electricity. If the adsorbent material is not water tolerant, the adsorbent bed would have to be heated indirectly by steam or hot water. Typically, the regeneration of the moisture adsorption material and the CO_2 adsorption material in the CO_2 separation system **80** would be done in parallel to ensure that the CO_2 leaving the CO_2 separation system **80** is dry. In addition

25   to heat, a vacuum pump may be used to remove CO_2 from the CO_2 separation system **80**. The stream used for regeneration is depicted as stream **90** in FIG. **1**. More than 80% of the impurities are typically removed in the CO_2 separation section.

The desorbed CO_2 exits the CO_2 separation system **80** via line **105** and is sent to a

30   CO_2 purification system **125**. An optional vacuum pump **110** may be used to facilitate the recovery of CO_2 from the CO_2 separation system **80**. Part of the CO_2 product enters the

vacuum pump **110** as stream **100** and joins stream **105** after exiting the vacuum pump

110. The stream **105** and the stream exiting the vacuum pump **110** are combined to form

the CO_2 product stream which enters the CO_2 purification system **125** as stream **120**. The

purity of the CO_2 product stream **120** produced during regeneration is dependent on the

5   feed CO_2 concentration but would typically be higher than 90%. This stream **120** can be

optionally compressed to pressures between 1.1 bara and 200 bara prior to purification.

The CO_2 purification system **125** can be, for example, a distillation system, a membrane

system, a pressure or temperature swing adsorption system or a getter system to remove

small amounts of impurities such as nitrogen, oxygen, nitrogen oxides and sulfur oxides

10   from CO_2. Also, if the CO_2 stream exiting the CO_2 separation system **80** is wet, the

moisture is also removed. Purified CO_2 leaves as stream **130** from the CO_2 purification

system **125**. Stream **135**, which is a small part of stream **120**, stream **115**, or stream **130**,

may be used to purge the inerts in the CO_2 separation system **80**. This stream **135** enters

the CO_2 separation system **80** as stream **145**. The purified CO_2 product exits the CO_2

15   purification system **125** as stream **140** and is available for food or beverage applications,

industrial applications, enhanced oil or gas recovery, and sequestration. The CO_2 product

stream **140** may have to be compressed, liquefied or both prior to some of these

applications.

20   FIGS. **2A-2D** exemplarily illustrate various configurations of the CO_2 separation

system **80** wherein moisture is optionally removed in a first separation unit followed by

the capture of CO_2 by chemical reaction or adsorption in a second separation unit.

In FIG. **2A**, a wet CO_2 stream **70** is passed through a bed of material that adsorbs

25   or reacts with CO_2 in the presence of moisture. The adsorption or chemical reaction

system contains at least two beds at least one of which is removing CO_2 from the feed

stream while at least one of which is undergoing regeneration at any given time. As

disclosed later in relation to FIG. **4**, additional beds may be used for other steps such as

cooling, pressurization, rinse, and evacuation. The rinse step can be performed using a

30   relatively pure CO_2 stream **145**. As illustrated in FIG. **1**, the CO_2 product stream exits the

CO_2 separation system **80** as stream **105** and as an additional optional stream **100**.

In FIG. **2B**, wet CO_2 stream **70** is passed through a membrane dryer **71** where the moisture from the feed stream is removed. The dry feed stream **72** is sent to the adsorption or reaction bed **81** wherein the CO_2 from the feed is removed and a dry CO_2-depleted stream **85** exits the CO_2 separation system **80**. While CO_2 is being adsorbed at least one other bed **81** is undergoing regeneration using stream **90**. As in the case of FIG. **2A**, additional beds may be used for other steps such as cooling, pressurization, rinse, and evacuation. Part or all of stream **85** is taken as stream **95** and is used to purge the permeated moisture in the membrane dryer **71**. The moisture laden stream exits the membrane dryer **71** as stream **73**. An optional vacuum pump **74** may be used to increase the driving force across the membrane and to facilitate the moisture removal, and the moisture-laden stream exits the vacuum pump **74** as stream **75**.

In FIG. **2C**, wet CO_2 stream **70** is passed through an absorption system **76** wherein the moisture from the feed stream is removed by an absorbent such as ethylene glycol. The beds used for moisture removal would normally contain dumped or structured packing for mass transfer between the feed and the absorbent phases and streams would typically flow in the countercurrent direction. The dry feed stream **72** exiting the absorption system **76** is sent to CO_2 adsorption beds **81** wherein the CO_2 from feed is removed and a dry CO_2-depleted stream **85** exits the CO_2 separation system **80**. While CO_2 is being adsorbed at least one other bed **81** is undergoing regeneration using stream **90**. Additional beds may be used for other steps such as cooling, pressurization, rinse and evacuation. Part or all of CO_2-depleted stream, stream **85**, is taken as stream **95**, heated in a heat exchanger or heater **96**, and passed through the absorption system **76** as stream **97** to regenerate the moisture loaded solvent stream **77**. The solvent loaded with moisture can also be regenerated by countercurrent heat exchange in a heat exchanger (not shown) with steam. The regenerated solvent stream **78** is sent to the absorption system **76** for moisture removal. The stream **95** can be heated by heat exchange with steam or condensate, or the stream **95** may be heated directly using the electrical energy. The moisture loaded stream exits the absorption system **76** as stream **75**.

In FIG. **2D** wet CO_2 stream **70** is passed through a moisture adsorption system **79** where the moisture from the feed stream is removed by an adsorbent such as activated alumina, silica gel or a molecular sieve. The dry feed stream **72** exiting the moisture adsorption system **79** is sent to the CO_2 adsorption beds **81** where the CO_2 from feed is

5   removed and a dry CO_2-depleted stream **85** exits the CO_2 separation system **80**. While CO_2 is being removed in one or more CO_2 adsorption beds **81**, at least one other CO_2 adsorption bed **81** is undergoing regeneration using stream **90**. Additional beds may be used for other steps such as cooling, pressurization, rinse, and evacuation. Part or all of stream **85** is taken as stream **95**, optionally heated in a heat exchanger or heater **96**, and is

10   used to regenerate the moisture adsorption beds in the moisture adsorption system **79**. If stream **95** is heated prior to regeneration of the moisture adsorption beds, the stream **95** can be heated by heat exchange with steam or hot water. The stream **95** can also be heated directly using electrical energy. The moisture loaded stream exits the moisture adsorption system **79** as stream **73**. An optional vacuum pump **74** can be used to provide

15   additional driving force for the moisture removal and the water loaded stream then exits the vacuum pump **74** as stream **75**.

The moisture adsorption system **79** would typically contain multiple moisture adsorption beds for the removal of moisture as well as other impurities such as the heavy

20   hydrocarbons that can hinder the adsorption of CO_2 in the CO_2 adsorption beds **81**. Moisture adsorption beds in the moisture adsorption system **79** can also be designed to remove some of the sulfur oxides, nitrogen oxides and mercury impurities in the feed. For moisture removal, the moisture adsorption beds in the moisture adsorption system **79** would normally be operated in a pressure swing, temperature swing, or a vacuum swing

25   mode. For pressure or vacuum swing adsorption, the heat of water adsorption would be retained during adsorption and stream **95** at reduced pressure would desorb the moisture. While it is possible to remove moisture by pressure swing adsorption alone, it may be necessary to use the temperature swing adsorption for desorption of other impurities such as the heavy hydrocarbons, sulfur oxides, nitrogen oxides and mercury. This can be done

30   in a cycle comprising three or more beds and is described next.

FIG. **3** exemplarily illustrates the configuration of the moisture adsorption system **79** wherein the moisture and additional impurities, for example, hydrocarbons, sulfur oxides or nitrogen oxides, and mercury are removed by a combination of pressure and temperature swing adsorption. A three-bed pressure and temperature swing adsorption system for the removal of moisture and other impurities is illustrated in FIG. **3**; however, the moisture and trace-impurities removal process is not limited to a three-bed system. If the removal of impurities such as sulfur oxides and hydrocarbons is not needed, two beds operating in pressure swing adsorption (PSA), vacuum swing adsorption (VSA), or temperature swing adsorption (TSA) mode can be used. Also, when the system operates in PSA and TSA or VSA and TSA mode, more than two beds can be used for PSA or VSA operation and more than one bed can be used for the TSA operation. The number of moisture adsorption beds in the moisture adsorption system **79** is not critical to the operation of this process. In the system of FIG. **3**, the wet feed enters the moisture adsorption system **79** as stream **70** through valves **200**, **210** and **220**, respectively. These valves **200**, **210** and **220** control flow of feed gas into vessels **230**, **235** and **240** respectively. Vessels **230**, **235** and **240** each have first adsorbent layers **230a**, **235a** and **240a** respectively which comprise adsorbents such as activated alumina, silica gel or a molecular sieve such as 3A, 4A, 5A and 13X zeolites for moisture removal. Positioned in vessels **230**, **235** and **240** above layers **230a**, **235a** and **240a** are optional layers **230b**, **235b** and **240b**, respectively, which comprise adsorbent(s) selective for hydrocarbons, nitrogen and sulfur oxides, and mercury. Adsorbents such as activated carbon, zeolites such as 13X, and impregnated aluminas can be used for adsorbing these impurities. Modified activated carbons and silicates can be used for the removal of mercury impurities. The adsorbents in vessels **230**, **235** and **240** are chosen to minimize the adsorption of CO_2 so as to maximize the recovery of CO_2 in the CO_2 adsorption beds **81**. The preferred adsorbents for moisture removal are 3A and 4A zeolites, activated alumina, silica gel, and mixtures of activated alumina and zeolites 3A and 4A.

The outlet ends of vessels **230**, **235**, and **240** are connected to discharge lines with valves **245**, **260**, and **275**, respectively. Depending on the bed undergoing adsorption, dry CO_2-containing stream exits the moisture adsorption system **79** through one of these

valves **245** as stream **72** and is sent to the CO_2 separation system **80**. The purge stream **95** from the CO_2 separation system **80** is used to regenerate the moisture adsorption beds. For the PSA or VSA mode of regeneration, the purge gas **95** enters through valve **290** and then one of the valves **250, 265,** and **280** and exits the moisture adsorption system **79**

5   via corresponding valves **205, 215,** and **225** as stream **73**. If an optional vacuum pump **74** is used then the purge gas **95** exits the moisture adsorption system **79** as stream **75**. For the TSA mode of regeneration, the purge gas **95** is heated in the heater or heat exchanger **96** and enters the vessels **230, 235** and **240** through one of the open valves **255, 270,** and **285** and exits the moisture adsorption system **79** via corresponding valves **205, 215,** and

10   **225**. If a vacuum pump **74** is not used the purge gas **95** exits the moisture adsorption system **79** as stream **73**. If a vacuum pump **74** is used the purge gas **95** exits the moisture adsorption system **79** as stream **75**. In normal operation, regeneration of one of the vessels by PSA or VSA and another vessel by TSA is contemplated.

15   The various layers are preferably contained in single vessels, as shown in the drawing, although each layer may be contained in separate vessels, if desired. The duration of each complete cycle of the PSA stage is, at most, several minutes (mins) typically 4-60 minutes, while the duration of the thermal regeneration is generally about 1-12 hours; accordingly, during any single phase of the process, the two vessels in the

20   PSA or VSA mode will undergo many PSA or VSA cycles while the third vessel undergoes a single thermal regeneration step. For purposes of illustration, it will be assumed that the PSA or VSA process is carried out with pressurization to super atmospheric pressure during the adsorption step and reduction of pressure to atmospheric pressure or below during the bed regeneration step. The pressure in the vessel undergoing

25   thermal regeneration is at or near atmospheric pressure.

        The process described below comprises three phases; a first phase, in which vessels **230** and **235** are initially operating in an alternating PSA or VSA cycle and the adsorbent in vessel **240** is undergoing thermal regeneration; a second phase, in which

30   vessels **235** and **240** are operating in an alternating PSA or VSA cycle while the adsorbent in vessel **230** undergoes thermal regeneration; and a third phase, in which

13

vessels **230** and **240** are operating in an alternating PSA or VSA cycle, while the adsorbent in vessel **235** undergoes thermal regeneration.

5   At the start of stage 1 of the first phase of the process, one of the vessels **230** or **235**, for example vessel **230** is in the adsorption mode and the other vessel is in the regeneration mode. With vessel **230** starting in the adsorption mode, wet feed **70** enters the bed through open valve **200** and exits the bed through open valve **245**. Prior to start of adsorption, vessel **230** is pressurized to the adsorption pressure through valve **200**. As the feed **70** passes through vessel **230** substantially all of water vapor, hydrocarbons, sulfur

10   oxides, and mercury and some of the nitrogen oxides are removed. The dew point of the gas stream exiting the moisture adsorption system **79** would normally be below -40°C and more preferably below -60°C. For regeneration of bed **235**, part of the purge gas **95** enters through open valves **290** and **265** and picks up moisture from the adsorbent bed **235** and exits through valve **215**. Although not necessary, the purge gas may be heated

15   prior to its use in the PSA or VSA process. The remainder of the purge gas entering the moisture adsorption system **79** is heated in heater or heat exchanger **96** and then flows through the layers **240a** and **240b** in vessel **240**. As the heated purge gas passes through the layers **240a** and **240b** in vessel **240**, the purge gas desorbs the residual moisture, hydrocarbons, nitrogen and sulfur oxides, and mercury from different layers that have

20   gradually built up in this vessel **240** over the previous PSA or VSA stages carried out in this vessel. The regeneration gas, together with the desorbed impurities leaves vessel **240** through open valve **225**. After a certain time based on the moisture concentration in stream **72** and the retention of the heat front in the bed, typically 4 to 60 minutes, vessel **230** starts undergoing regeneration while vessel **235** starts removing moisture and other

25   impurities. Vessels **230** and **235** continue under PSA or VSA operation for a period of several hours or days, typically 8 to 96 hours, while vessel **240** is thermally regenerated during part of this time. The temperatures for thermal regeneration typically range between 100°C and 300°C but can be higher or lower depending on the material. The impurities such as nitrogen and sulfur oxides removed during the thermal regeneration

30   may be sent to the existing nitrogen and sulfur removal systems for further reduction of these impurities.

As the PSA or VSA cycle proceeds in vessels **230** and **235**, various impurities such as sulfur oxides and mercury which are more strongly adsorbed that water vapor accumulate in these vessels as they are not removed during the purge step of the pressure swing or the vacuum swing adsorption. When the buildup of these components in one or more layers reaches the point where it threatens to adversely affect the efficiency of the gas purification process, the first phase of the process is terminated and the second phase is started.

During the second phase of the process vessels **235** and **240** are in alternating PSA or VSA service and the adsorbents in vessel **230** undergo thermal regeneration. At the start of stage 1 of this phase of the process, one of the vessels **235** or **240**, for example vessel **235** is in the adsorption mode and the other vessel is in the regeneration mode. With vessel **235** starting in the adsorption mode, wet feed **70** enters the bed through open valve **210** and exits the bed through open valve **260** and is purified in the process. Prior to start of adsorption, vessel **235** is pressurized to the adsorption pressure through valve **210**. For regeneration of bed **240**, part of the purge gas **95** enters through open valves **290**, and **280**, picks up moisture from the adsorbent bed **240** and exits through open valve **225**. The remainder of the purge gas entering the moisture adsorption system **79** is heated in a heater or heat exchanger **96** and then flows through the layers **230a** and **230b** in vessel **230** and desorbs the residual moisture, hydrocarbons, nitrogen and sulfur oxides and mercury from different layers that have gradually built up in this vessel **230** over the previous PSA or VSA stages carried out in this vessel **230**. The regeneration gas, together with the desorbed impurities leaves vessel **230** through open valve **205**. After a certain time based on moisture concentration in stream **72** and retention of the heat front in the vessel, vessel **235** starts undergoing regeneration while vessel **240** starts removing moisture and other impurities. Vessels **235** and **240** continue under alternating PSA or VSA operation for a period of several hours or days while vessel **230** is thermally regenerated during part of this time.

As the PSA or VSA cycle proceeds in vessels **235** and **240**, various impurities

which are more strongly adsorbed than water vapor buildup in vessels **235**, and **240**.
When the buildup of these components in one or more layers reaches the point where it
threatens to adversely affect the efficiency of the gas purification process, the second
phase of the process is terminated and the third phase is started.

5

During the third phase of the process vessels **230** and **240** are in PSA or VSA
service and the adsorbent in vessel **235** undergoes thermal regeneration. Operation of the
third phase is similar to the operation of the first and the second phases. After all the three
phases are completed the process starts again with phase one and all three phases are

10   repeated in a cyclic manner.

Like the PSA or VSA beds, the CO_2 adsorption or reaction beds (beds A to E in
FIG. **4**) also undergo a cyclic process to provide continuous operation and also to
maximize CO_2 recovery. These beds contain one or more materials that have a significant

15   selectivity for CO_2 over other major components of the flue gas, namely oxygen, nitrogen
and argon. Some of the materials that can be used to capture CO_2 from the flue gas
comprise, for example, activated carbon, carbon molecular sieves, zeolites such as 4A,
5A, 13X, NaY and CaX, metallorganic framework compounds, natural zeolites, modified
natural and synthetic zeolites, modified activated carbon, pillared clays and reactive

20   sorbents such as sodium and potassium carbonates, amines or ionic liquids supported on a
microporous support.

Various beds in the CO_2 capture section illustrated in FIG. **4** would typically
undergo the steps of adsorption, equalization, rinse with CO_2 product, heating, heating

25   with evacuation, cooling and re-pressurization. Depending on the material and the
process conditions different combinations of the steps can be used to maximize the CO_2
recovery. Also in some of the cycles some of the steps such as bed cooling can be
eliminated. During the operation of the CO_2 adsorption beds **81**, any sulfur oxide
impurities in the feed to the CO_2 capture section are likely to be removed as most

30   adsorbents have a higher affinity for sulfur oxides than CO_2. Since most adsorbents have
a higher affinity for CO_2 over nitrogen oxides, most of the nitrogen oxide impurities in

the feed to this section would pass through into the CO_2-depleted stream **85** leaving the CO_2 separation system **80**. For CO_2 removal by the chemical reaction, such as with supported carbonates or amines, some of the nitrogen and sulfur oxides may also be removed by chemical reaction.

5

FIG. **4** exemplarily illustrates the configuration of the CO_2 separation system **80** wherein CO_2 is removed from the feed stream by adsorption or chemical reaction and is recovered by heating directly or indirectly by steam, hot water or a dry stream recovered from the CO_2 separation system **80**. A five-bed CO_2 capture process is illustrated

10   schematically in FIG. **4**. The CO_2 feed step and the CO_2 production steps are continuous in this cycle. While the CO_2 capture is illustrated using a five-bed process the CO_2 capture process is not limited to five beds. The process can use less than five beds or more than five beds though a minimum of two beds are required to carry out CO_2 capture and production at the same time. As illustrated in FIG. **4** at any given time, one bed is

15   removing CO_2 from feed using adsorption or reaction, another bed is undergoing equalization and pressurization steps, a third bed is producing CO_2 while being heated, a fourth bed is producing CO_2 during heating and evacuation steps and the fifth bed is undergoing the steps of CO_2 rinse and equalization. Other cycles similar to this can be used omitting the steps such as the CO_2 rinse and adding steps such as bed cooling after

20   the heating steps. The equalization can be done from the bottom, from the top or from both top and the bottom. Pressurization can also be done from the bottom using the feed or from the top using the CO_2-depleted stream.

Each individual step of the CO_2 capture process is likely to be of the order of 2-60

25   minutes to maximize the productivity of the process. A typical cycle using the five-bed configuration of FIG. **4** is given in Table I.

The feed to adsorbers A to E is typically at a temperature between about 10 and 80°C and at pressures between about 1.07 bara and 40 bara, and at a temperature in the

30   range of about 20°C and 60°C. For the CO_2 capture from the flue gas of a power plant or a refinery, the pressures will be in the range of about 1.07 and 1.34 bara. The

regeneration temperatures are in the range of about 80°C and 300°C and more typically in the range of about 80°C-150°C. The concentration of CO_2 in the feed gas is about 3% for a natural gas fired power plant, about 12% for a coal-fired power plant and up to 60% of CO_2 for various chemical processes. Prior to the initial start of CO_2 separation, the

5   beds in adsorbers A to E may be heated to temperatures higher than 300°C to remove any residual moisture contained therein. High temperature regeneration may also be performed to remove impurities built up during normal operation.

      The operation of various valves is illustrated using steps 1 and 2 of Table I. In

10   both steps 1 and 2 for bed A, feed gas **72** enters the bed through open valve **302**, CO_2 is captured in the bed and the CO_2-depleted stream exits the bed as stream **85** through the open valve **312**. During step 1, beds B and E undergo pressure equalization through open valves **340** and **430**. During step 2, bed B is pressurized using bed A through open valves **320** and **350**. During both steps 1 and 2, bed C is regenerated by heating under vacuum

15   and valves **366** is open. The high purity CO_2 product leaves as stream **100** prior to entering the vacuum pump **110**. During both steps 1 and 2, bed D is regenerated by heating, valves **398** and **408** are open and product CO_2 leaves as stream **105**. During step 2, bed E is rinsed with product CO_2 stream **145** which enters the bed through open valve **424** and exits through open valve **434**. Operation of various valves during steps 3 to 10 is

20   similar to operation during steps 1 and 2. Once all the steps are completed, the cycle is repeated continuously starting at step 1.

TABLE I

Typical Cycle Sequence for the CO_2 Capture Process

Step	Bed A	Bed B	Bed C	Bed D	Bed E	Time, mins
1	Adsorption/ reaction	Equalization with Bed E	Heating with evacuation	Heating	Equalization with Bed B	2.0
2	Adsorption/ reaction	Pressurization	Heating with evacuation	Heating	CO₂ rinse	2.0
3	Equalization with Bed C	Adsorption/ reaction	Equalization with Bed A	Heating with evacuation	Heating	2.0
4	CO₂ rinse	Adsorption/ reaction	Pressurization	Heating with evacuation	Heating	2.0
5	Heating	Equalization with Bed D	Adsorption/ reaction	Equalization with Bed B	Heating with evacuation	2.0
6	Heating	CO₂ rinse	Adsorption/ reaction	Pressurization	Heating with evacuation	2.0
7	Heating with evacuation	Heating	Equalization with Bed E	Adsorption/ reaction	Equalization with Bed C	2.0
8	Heating with evacuation	Heating	CO₂ rinse	Adsorption/ reaction	Pressurization	2.0
9	Equalization with Bed D	Heating with evacuation	Heating	Equalization with Bed A	Adsorption/ reaction	2.0
10	Pressurization	Heating with evacuation	Heating	CO₂ rinse	Adsorption/ reaction	2.0

Total   20.0 minutes

19

As shown in Table I, various steps in the CO_2 capture and regeneration process are significantly faster than in a typical temperature swing adsorption process where these steps are of the order of hours. For adsorbents and reactants that are moisture tolerant, fast heating can be accomplished by directly heating the beds with steam though this will

5   have to be followed by a purge to remove steam, and then the beds will have to be cooled. For adsorbents or reactants that are not moisture-tolerant such as zeolites, direct heating with steam is not an option and heating with a dry gas will be too slow. For these cases, the beds may have to be heated indirectly. One such configuration is the shell and tube configuration wherein the adsorbents or reactants are contained in small diameter

10   tubes and the heating medium flows on the shell side during the regeneration part of the cycle. Regeneration temperatures of about 80°C -300°C can be obtained using steam or hot water as the heating medium. A heated liquid or vapor stream utilizing the electricity generated in the power plant can also be used for regeneration. An alternative configuration includes the adsorbent material on the shell side and the heating or the

15   cooling fluid on the tube side. Another configuration that allows indirect heating is a plate and frame configuration wherein adsorbents are contained in alternate parallel passages and the heated fluid flows in alternate parallel passages. Steam or a heated fluid may be used as the heating medium. For the shell and tube configuration and the plate and frame configurations, cold fluid can be used during the CO_2 removal step to remove

20   the heat of adsorption or chemical reaction. Cold fluid can also be used for the bed cooling steps. For retrofit applications it might be easier to use the hot water or low pressure steam as the regeneration medium as this minimizes the disruption to the steam cycle of the power plant and would be easy to retrofit. In addition to the vertical beds both the horizontal and the radial beds can be used for carrying out the cycle. Also, if

25   needed, either the shell and tube configuration or the plate and frame configuration can be used for heat exchange with horizontal or the radial beds.

The CO_2 generated during the heating and the evacuation parts of the cycle would typically have a purity of higher than 90%. This stream is compressed and sent to a CO_2

30   purification plant as discussed earlier. If a membrane is used for CO_2 purification, a small portion of the CO_2 stream is allowed to permeate the membrane to produce a higher

purity CO_2 stream which is used as the rinse stream in the CO_2 separation system **80**. The rest of the stream may be further compressed and used for enhanced oil recovery, industrial applications or for CO_2 sequestration. If a getter process is used for CO_2 purification impurities such as oxygen and sulfur dioxide are removed by reaction with

5   the getter and the purified CO_2 stream may be further compressed and used in various applications. If a distillation process is used for CO_2 purification, CO_2 is produced as the bottoms product and the non-condensibles are removed as the overheads of the distillation column. Part of the CO_2 produced by distillation may be used to provide the purge in the CO_2 capture section; the rest is pumped to a higher pressure and used for

10   various applications such as enhanced oil recovery or sequestration. The non-condensibles stream may be further purified by a membrane or an adsorption process to recover additional amounts of CO_2.

     Example 1:

15

          Commercially available 5A zeolite of 8x12 mesh size (about 1.5 mm) was obtained from Aldrich Corporation and loaded in two 18 mm diameter adsorbent beds. The total weight of adsorbent was about 500 grams (gms). A feed stream containing about 12.5% CO_2 with the balance being nitrogen, to simulate flue gas from a coal-fired

20   power plant, was passed through these beds at a flow rate of 11 standard liters/min and at a pressure of 1.34 bara. The standard conditions refer to 21.1°C and 1 bara. The adsorbing bed was cooled with a jacket containing a water/glycol mixture at 30°C. The regenerating bed was heated with a jacket containing water / glycol mixture at 100°C. The concentrations in the CO_2-depleted stream and in the CO_2 product were analyzed

25   using an infrared CO_2 analyzer. The cycle for this process is shown in Table II. After heating, the beds were evacuated to a pressure of about 0.25 bara during the evacuation steps. For these process conditions, an average CO_2 purity of 99.8% and an average CO_2 recovery of 85.8% were obtained.

30   Table II. Two Bed CO_2 Capture Process Cycle

                                            21

Step #	Bed A	Bed B	Step Time
			Mins
1	Adsorption	Heating with evacuation	8.0
2	Equalization	Equalization	1.0
3	Rinse	Idle	1.0
4	Heating	Idle	7.0
5	Heating	Pressurization	1.0
6	Heating with evacuation	Adsorption	8.0
7	Equalization	Equalization	1.0
8	Idle	Rinse	1.0
9	Idle	Heating	7.0
10	Pressurization	Heating	1.0

Example 2:

The process of Example 1 was run at different adsorption temperatures. Other process conditions, namely the feed pressure, feed CO_2 concentration, and the adsorbent material were the same as in Example 1. Again, the concentrations in the CO_2-depleted stream and in the CO_2 product stream were analyzed using an infrared CO_2 analyzer. The process cycle of Table II was used. For a feed temperature of 20°C, an average CO_2 purity of 99.0% and an average CO_2 recovery of 88% were obtained. For a feed temperature of 40°C, an average CO_2 purity of 99.2% and an average CO_2 recovery of 84% were obtained.

Example 3:

The process of Example 1 was run with a commercially available 13X zeolite of 8x12 mesh size (1.5 mm) obtained from the Aldrich Corporation. The feed pressure, and the feed CO_2 concentration were the same as in Example 1 and the process cycle of Table II was used. Again, the concentrations in the CO_2-depleted stream and in the CO_2 product stream were analyzed using an infrared CO_2 analyzer. For a feed temperature of 20°C, an average CO_2 purity of 98.5% and an average CO_2 recovery of 87% were obtained. For a feed temperature of 30°C, an average CO_2 purity of 98.5% and an average CO_2 recovery of 78% were obtained.

Example 4:

The beds containing 5A as in Example 1 were used (total weight of about 500 gms) with a feed stream containing about 3.4% CO_2 with the balance being nitrogen, to simulate the flue gas from a natural gas fired power plant. The feed was passed through these beds at a total flow rate of 17 standard liters/min. The adsorbing bed was cooled with a jacket containing a water/glycol mixture at 20°C. The process cycle in Table II was used. The regenerating bed was heated with a jacket containing water/glycol mixture at 100°C. The concentrations in the CO_2-depleted stream and in the CO_2 product were analyzed using an infrared CO_2 analyzer. For these process conditions, an average CO_2 purity of 91% and an average CO_2 recovery of 86% were obtained. The results of this example indicate that the process of this invention can provide reasonable purities and recoveries for streams containing very low levels of carbon dioxide such as that from a natural gas fired power plant.

Comparative Example 1:

The 5A zeolite of Example 1 was used to obtain the results for a vacuum swing adsorption process without any thermal regeneration. The feed comprised 12.8% CO_2 at 1.34 bara and 30°C. The beds were evacuated to a pressure of 0.25 bara during the regeneration step. Both the adsorption and the regeneration steps were carried out at 30°C. The process cycle comprised adsorption, equalization, rinse with pure CO_2, evacuation, equalization and pressurization steps.

For a feed flow of 5.5 standard liters per min and an adsorption time of 4 minutes, an equalization time of 0.5 minutes, a rinse time of 1.0 minutes, an evacuation time of 4.0 minutes, and a pressurization time of 0.5 minutes, an average CO_2 purity of 81.6% and an average CO_2 recovery of 25.4% were obtained. The reduction of feed flow to 2.2 standard liters per minutes decreased the average purity to 53% and the average recovery to 26%. For a feed flow of 5.5 standard liters per minute and a faster cycle (2 minute

adsorption, 0.25 minute equalization, 0.5 minute rinse, 2 minute evacuation and 0.25 minute pressurization) an average purity of 59.4% and an average recovery of 43.9% were obtained.

5   Comparison of the results of this example with Example 1 indicates that the performance both in terms of CO_2 recovery and CO_2 purity is significantly worse without thermal regeneration of the beds.

         Example 5:

10

         Commercially available F-200 activated alumina from Alcoa (1.5 mm size) was loaded in the beds of Example 1. The total weight of the adsorbent was about 300 gms. A feed stream saturated with water at 25°C and containing about 12.5% CO_2 with the balance being nitrogen was passed through these beds at a total flow rate of 10 standard

15   liters/min and at a pressure of 1.34 bara. The cycle comprised an adsorption time of 5 minutes, a purge time of 4.5 minutes, and a pressurization and depressurization time of 0.25 minutes each and was designed to retain most of the heat of water adsorption in the beds. The dry product exiting the adsorbing bed was used for purge after reducing the pressure to about atmospheric. The dew point of the product stream exiting the beds was

20   monitored continuously and the product moisture concentration remained below 1 parts per million (ppm) during a period of five days.

         This example illustrates that under certain conditions the feed stream to the CO_2 separation can be dried to very low moisture levels to improve the CO_2 recovery in the

25   CO_2 separation section. The purge gas in a process wherein the moisture is removed prior to CO_2 adsorption would be the CO_2-depleted stream from the CO_2 adsorption section.

         The results of these Examples suggest that the process disclosed herein can be used for recovering CO_2 from various process streams at high purity and recovery.

30   Estimates of the energy consumption for this process indicate that the energy required to capture CO_2 for this process is about half the energy required for the amine-based CO_2

capture process.

The method and system disclosed herein for the capture of CO_2 offers a number of advantages. The process can be used both for retrofit applications as well as for the new plants. Modifications required to the power plant for retrofit applications are significantly smaller than those needed for amine-based CO_2 capture. The process is applicable to both coal-fired and natural-gas fired power plants. The process is also applicable to other streams such as the refinery and chemical process streams containing carbon dioxide. Unlike absorption processes where nitrogen and sulfur oxides (NO_X and SO_X) in the feed can react with the solvent irreversibly and require removal to below about 10 ppm levels, the NO_X and SO_X in the feed do not affect the adsorbent adversely. Oxygen in the feed has no effect on the adsorbents unlike absorption-based processes where oxygen degrades the amine solvent. The process provides dry CO_2 product eliminating the drying step prior to CO_2 compression and liquefaction, and the power and capital costs associated with it.

Although the system and methods herein are described with reference to specific examples, the scope of the invention is not limited thereto. For example, the feed gas containing CO_2 can come from other processes such as a natural gas fired power plant or from a coal gasification plant.

The foregoing examples have been provided merely for the purpose of explanation and are in no way to be construed as limiting of the present method and system disclosed herein. While the invention has been described with reference to various embodiments, it is understood that the words, which have been used herein, are words of description and illustration, rather than words of limitation. Further, although the invention has been described herein with reference to particular means, materials and embodiments, the invention is not intended to be limited to the particulars disclosed herein; rather, the invention extends to all functionally equivalent structures, methods and uses, such as are within the scope of the appended claims. Those skilled in the art, having the benefit of the teachings of this specification, may effect numerous modifications

thereto and changes may be made without departing from the scope and spirit of the invention in its aspects.

1   CLAIMS

2

3   I claim:

4

5   1.   A method for separating carbon dioxide from a gas stream containing water vapor

6   and additional impurities comprising performing the following steps one or more

7   times:

8

9   subjecting said gas stream to a first moisture removal step, wherein substantially

10   all of the moisture from gas in the gas stream is removed using a process selected

11   from a group comprising pressure swing adsorption, temperature swing

12   adsorption, membrane separation, and absorption; and

13

14   subjecting the substantially water vapor-free gas to a second temperature swing

15   adsorption step, wherein said second temperature swing adsorption step is

16   conducted in a bed comprising an adsorbent, wherein the second temperature

17   swing adsorption step comprises an adsorption step for producing a substantially

18   dry carbon dioxide-depleted stream, and an adsorbent regeneration step

19   comprising heating said adsorbent bed to produce a substantially water vapor-free

20   carbon dioxide stream.

21

22   2.   The method of claim 1, wherein pressure of the gas stream is in a range of about 1.07

23   to about 40 bar absolute, the carbon dioxide concentration is in a range of about 3%

24   to 60% by volume, and gas temperature is in a range of about 10°C to 80°C.

25

26   3.   The method of claim 1, wherein duration of said pressure swing adsorption process in

27   said first moisture removal step is in a range of about 4 minutes to about 60 minutes

28   and duration of said temperature swing adsorption process during the first moisture

29   removal step is in a range of about 1 hour to 12.0 hours.

30

31   4.   The method of claim 1, wherein temperature in the second temperature swing

1   adsorption step during said adsorbent regeneration step is increased to about 80°C to

2   300°C.

3

4   5. The method of claim 1, wherein duration of the second temperature swing adsorption

5   step is in a range of about 2 minutes to 60 minutes.

6

7   6. The method of claim 1, wherein said gas is a flue gas from one of a coal-fired power

8   plant, a natural gas fired power plant, and a refinery.

9

10   7. The method of claim 1, wherein adsorbent used in said first moisture removal step is

11   selected from a group comprising activated alumina, silica gel, and a molecular sieve

12   comprising 3A, 4A, 5A and 13X zeolites.

13

14   8. The method of claim 1, wherein moisture content in said first moisture removal step

15   is reduced to a dew point of -40°C or below.

16

17   9. The method of claim 1, wherein said adsorbent used in the second temperature swing

18   adsorption step is selected from activated carbon, carbon molecular sieves, 4A, 5A,

19   13X, NaY and CaX zeolites, metallorganic framework compounds, natural zeolites,

20   modified natural and synthetic zeolites, modified activated carbon, and pillared clays.

21

22   10. The method of claim 1, wherein purity of said substantially water vapor-free carbon

23   dioxide stream produced in the second temperature swing adsorption step is 90% or

24   higher.

25

26   11. The method of claim 1, wherein the substantially dry carbon dioxide-depleted stream

27   from the second temperature swing adsorption step is used for one of regenerating the

28   adsorbents or absorbents in said first moisture removal step, and for providing a

29   driving force for a membrane drying step.

30

31   12. The method of claim 1, wherein said adsorbent regeneration step comprises heating

1   the adsorbent bed directly with a gas stream or indirectly using steam or a hot fluid in

2   a heat exchanger configuration.

3

4   13. The method of claim 12, further comprising bed evacuation after bed heating to

5   recover additional amounts of carbon dioxide.

6

7   14. The method of claim 1, wherein the second temperature swing adsorption step further

8   comprises the steps of bed equalization, bed pressurization, bed depressurization, and

9   bed cooling.

10

11   15. The method of claim 1, wherein impurities in the feed to the second temperature

12   swing adsorption step comprise hydrocarbons, oxygen, nitrogen, argon, and nitrogen

13   oxides.

14

15   16. The method of claim 1, wherein said additional impurities selected from the group

16   comprising hydrocarbons, nitrogen oxides, sulfur oxides, and mercury are removed

17   from the gas stream in said first moisture removal step.

18

19   17. The method of claim 1, wherein adsorbents used for removal of hydrocarbons,

20   nitrogen oxides, sulfur oxides, and mercury are selected from activated carbon, 13X

21   zeolites, impregnated aluminas, modified activated carbons, and silicates.

22

23   18. The method of claim 1, wherein said moisture and additional impurities removal

24   process comprises a system comprising a first adsorption section, a second adsorption

25   section, and a third adsorption section arranged in parallel, each of said first

26   adsorption section, said second adsorption section, and said third adsorption section

27   comprising a first zone containing a moisture removal adsorbent and a second zone

28   containing one or more adsorbents for the removal of impurities selected from

29   hydrocarbons, nitrogen oxides, sulfur oxides, and mercury, comprising performing

30   the following steps one or more times:

31

1   subjecting said gas to a cyclic pressure swing adsorption process comprising

2   alternating adsorption steps and adsorbent regeneration steps in the first

3   adsorption section and the second adsorption section, thereby removing

4   substantially all of the water vapor from the gas, while desorbing water vapor and

5   other impurities from said adsorbents in said first zone and said second zone of

6   said third adsorption section by heating the adsorbents;

7

8   subjecting said gas to a cyclic pressure swing adsorption process comprising

9   alternating adsorption steps and adsorbent regeneration steps in the first

10   adsorption section and the third adsorption section, thereby removing

11   substantially all of the water vapor from the gas, while desorbing water vapor and

12   other impurities from the adsorbents in the first zone and the second zone of the

13   second adsorption section by heating the adsorbents; and

14

15   subjecting said gas to a cyclic pressure swing adsorption process comprising

16   alternating adsorption steps and adsorbent regeneration steps in the second

17   adsorption section and the third adsorption section, thereby removing

18   substantially all of the water vapor from said gas, while desorbing water vapor

19   and other impurities from the adsorbents in the first zone and the second zone of

20   the first adsorption section by heating the adsorbents.

21

22 19. The method of claim 18, wherein the adsorbent heating step is carried out at a

23   temperature in a range of about 80°C-300°C.

24

25 20. The method of claim 1, wherein the gas stream containing water vapor and additional

26   impurities is sent directly to the second temperature swing adsorption step without

27   first removing the moisture and additional impurities, wherein the second temperature

28   swing adsorption step comprises an adsorption step to produce a carbon dioxide-

29   depleted stream, and an adsorbent regeneration step comprising heating the adsorbent

30   bed to produce a substantially pure carbon dioxide stream.

31

1   21. The method of claim 20, wherein the adsorbent for the second temperature swing

2   adsorption step is selected from activated carbon, or a carbonate, an amine or an ionic

3   liquid on a microporous support.

4

5   22. The method of claim 1, wherein the carbon dioxide stream is further purified by one

6   of a membrane process, a distillation process, an adsorption process, and a getter

7   process to remove impurities comprising nitrogen, oxygen, argon, nitrogen oxides,

8   sulfur oxides, and moisture.

9

10   23. The method of claim 22, wherein said purified carbon dioxide is used for providing

11   high purity rinse in a carbon dioxide separation system.
